Preface

The AIEE *Transactions* for 1960 (volume 79) is published in three parts: Part I. Communication and Electronics; Part II. Applications and Industry; and Part III. Power Apparatus and Systems. The papers in each of the three parts are classified according to subject matter as follows:

Part I. Communication and Electronics

Aero-Space Instrumentation
Basic Sciences
Broadcasting
Communication Switching Systems
Communication Theory
Computing Devices
Data Communication
Electrical Insulation
Electrical Techniques in Medicine and Biology
Electronic and High-Frequency Instruments
Electronics
Fundamental Electrical Standards
Indicating and Integrating Instruments
Magnetic Amplifiers
Nuclear Instrumentation
Nucleonics
Radio Communication Systems
Recording and Controlling Instrumentation
Semiconductor Rectifiers
Solid State Devices
Space Communications
Special Instruments and Auxiliary Apparatus
Telegraph Systems
Telemetering
Wire Communication Systems

Part II. Applications and Industry

Aero-Space Transportation
Chemical Industry
Domestic and Commercial Applications
Electric Heating
Electric Welding
Feedback Control Systems
General Industry Applications
Industrial and Commercial Power Systems
Industrial Control
Industrial Power Rectifiers
Land Transportation
Marine Transportation
Machine Tools Industry
Metal Industry
Mining Industry
Petroleum Industry
Production and Application of Light
Rubber and Plastic Industries
Textile Industry

Part III. Power Apparatus and Systems

Insulated Conductors
Power Generation
Power System Communications
Protective Devices
Relays
Rotating Machinery
Substations
Switchgear
System Engineering
Transformers
Transmission and Distribution

New Technical Activities
Research
Safety
Standards

Each part has been indexed separately in the back of that particular part. The three parts are not cross-referenced; hence the user should determine first whether the subject matter of the paper desired is in the field of communication and electronics, applications and industry, or power apparatus and systems. Papers are listed in the subject index under several key words in the titles. The original numbers assigned to the papers are given in the author index. Volume 79 contains the technical papers and related discussions presented at these meetings:

1. Winter General Meeting, New York, N. Y., January 31–February 5, 1960.
2. Southwest District Meeting, Houston, Tex., April 4–6, 1960.
3. Great Lakes District Meeting, Milwaukee, Wis., April 27–29, 1960.
4. Northeastern District Meeting, Providence, R. I., May 2–4, 1960.
5. Summer General Meeting, Atlantic City, N. J., June 19–24, 1960.
6. Pacific General Meeting, San Diego, Calif., August 8–12, 1960.
7. Fall General Meeting, Chicago, Ill., October 9–14, 1960.

Statements and opinions given in the papers and discussions published in *Transactions* are the expressions of the contributors for which the American Institute of Electrical Engineers assumes no responsibility.

Communication and Electronics Index for 1960

1. Technical Subject Index

A-C Powered Cranes, D-C Magnetic Crane Hoist Control for. Myles, Davies, Srnka........207–11
Accurate Voltage Measurements to 30 Megacycles Per Second, Thermal Voltage Converters for. Hermach, Williams................200–05; disc. 205
Air-Borne Ice and Snow Measurement, Proposed Monocycle-Pulse Very-High-Frequency Radar for. Cook........................588–93; disc. 593
Air-Borne Real-Time Control, The Relative Merits of Incremental and Conventional Digital Computers in. Shackell, Tryon....................393–400
Air-Cooled Nuclear Reactors, A Digital Start-up Control for. Lehr, Mathis...............369–75
Air Ions on the Trachea, Experiments with. Beckett, Krueger.................................695–9
Air, The Effects of Nuclear Radiation on the Electrical Strength of. Duncan, Fraser, Valachovic...19–26
Aircraft Nuclear Reactor, Magnetic Automatic Power-Range Control for an. Russell, Hemmenway, Scharf, Sharr...........................379–84
Airlines Reservations, Teletypewriter Selective Calling Applied to Automatic. Bratschi, Pennington, Whitman..............................579–83
All-Transistorized Trunk Carrier System, An. Gardner 212–16
Amplidyne Circuit Analysis. Bills.............711–15
Amplifier, A High-Speed Microcurrent. Dever, Sickles 375–9
Amplifiers, Stable Transistor Wide-Band D-C. Okada 26–33
Analog-Digital Simulation, A 2-Channel Data Link for Combined. Greenstein........................40–4
Analog of a Magnetic Circuit Established by the Basic Laws Defining Magnetostatics, The Existence of an Electric. Koenig....................400–03
Analog Solution of Some Functional Analysis Problems, The. Graupe..................793–7; disc. 798
Analog with Spiral Search Coils, The Magnetic. Moore ....256–63; disc. 263
Analysis, Amplidyne Circuit. Bills............711–15
Analysis and Optimization of the Bridge Magnetic Servoamplifier with True Motor Load. Walsh, Meiksin..................................413–20
Analysis of a Polarized Electromagnetic Drive System and of Vibrator Drive Systems, An. Nunn..346–52
Analysis of Self-Saturating Magnetic Amplifiers, Rectifier Unblocking from a Generalized. Bourne, Nitzan...................................99–105
Analysis of the Operation of the Magnetic Second-Harmonic Modulator, An. Jalbert.......268–72
Analysis of Transcendental Nonlinear Systems. Wolf 449–51
Analyzer and General Purpose Equipment in Guidance Systems, A Comparison of Digital Differential. Dickinson..............................706–08
Antenna Array Excited Parasitically by a Central Driven Element, An Omnidirectional Circular. Neff, Tillman..................................190–2
Applications, A New Ceramic Triode for VHF. Campbell.....................................404–08
Approach to Dynamic Optimizing Control of the Continuous Process, An. Sandelien........291–9
Arc Extinction, Voltage Transients Due to. Steiner, Strecker...................................139–44
Arsenal Closed-Circuit Educational Television System, Redstone. Argo, Howell.................185–90
Assessment, Tubes or Transistors: A Realistic. Moe. 81–5
Assignment of Carry Variables in Iterative Networks. McCluskey..............................772–8
Audio Frequencies, A Transistor Automatic Gain Control System for. Shirman.............664–9
Audio Frequencies with 1-Microsecond Precision, A Test Set for Measurement of Envelope Delay Distortion at. Codd.......................241–5
Automatic Airlines Reservations, Teletypewriter Selective Calling Applied to. Bratschi, Pennington, Whitman..............................579–83
Automatic Gain Control System for Audio Frequencies, A Transistor. Shirman..................664–9
Automatic Power-Range Control for an Aircraft Nuclear Reactor, Magnetic. Russell, Hemmenway, Scharf, Sharr.......................379–84
Automation in Switching Equipment Engineering. Hacker, Davis...........................545–52
Automation of Computer Panel Wiring. Altman, DeCampo, Warburton...................118–25
Automation of Telephone Switching Equipment Engineering. Blumer, Reifenstuhl, List.........560–4

B

Back-Transient Diode Logic. Wolff..............4–9
Barium Titanate, Quantitative Study of Low-Frequency Hysteresis Loops of Polarized Polycrystalline. Marks, Hanna.........................799–808
Basic Concepts for Magnet Coil Design, Some. Gauster 822–8
Basic Laws Defining Magnetostatics, The Existence of an Electric Analog of a Magnetic Circuit Established by the. Koenig.........................400–03
(Basic Sciences) A Method for the Design of Holding Electromagnets. Ludwig..................300–10
(Basic Sciences) An Analysis of a Polarized Electromagnetic Drive System and of Vibrator Drive Systems. Nunn.........................346–52
(Basic Sciences) Analysis of Transcendental Nonlinear Systems. Wolf.........................449–51
(Basic Sciences) Difference Equations and Their Applications. Pipes.............333–9; disc. 339
(Basic Sciences) Generalized Brillouin Flow. Kent... 144–8
(Basic Sciences) Inductors Biased with Permanent Magnets. Ludwig:
  Part I.....................................273–8
  Part II....................................278–91
(Basic Sciences) On the Response of Linear Systems to Periodic Excitations. LePage, McFee.......... ....746–8; disc. 749
(Basic Sciences) Quantitative Study of Low-Frequency Hysteresis Loops of Polarized Polycrystalline Barium Titanate. Marks, Hanna........799–808
(Basic Sciences) The Properties of Pole and Zero Locations for Nondecreasing Step Responses. Zemanian................................421–6
(Basic Sciences) The Synthesis of Linear Filters with Real or Imaginary Transfer Functions. Gilbert, Otterman................................323–30
Binary Operations, Switching Function Canonical Forms Based on Commutative and Associative. Calingaert...............................808–14
Biphase Rectifiers, Saturable-Reactor Control of Full-Wave and. Thomas, Drenning.............36–9
Bistable Transistor Pulse Circuits, Fundamental Considerations of Power Dissipation Limits in Some. Raillard..................................53–5
Bistatic Radar at 3,000 Mc, Moon Reflection Studies with. Straiton, Tolbert........436–9; disc. 439
Brake for a Sodium-Cooled Nuclear Power Reactor, Design of an Eddy-Current. Baker.........330–3
Breakdown Phenomenon in Selenium Rectifiers, A Nondestructive. English, Tobin.............9–14
Bridge Magnetic Amplifier, Theory of 3-Phase. Storm, Flairty:
  Part II....................................451–8
  (Part I—1959)
Bridge Magnetic Servoamplifier with True Motor Load, Analysis and Optimization of the. Walsh, Meiksin 413–20
Brillouin Flow, Generalized. Kent.............144–8
(Broadcasting) An Omnidirectional Circular Antenna Array Excited Parasitically by a Central Driven Element. Neff, Tillman..................190–2
(Broadcasting) Dial-Selected Industrial Television for Ticket Reservation Facilities. Alinsky......174–7
(Broadcasting) New Television Network Switching Facilities. Bachelet, Collins, Taylor.......625–34
(Broadcasting) Production Design Considerations in Television Chassis Sweep Interference Reduction. Carson...................................557–60
(Broadcasting) Redstone Arsenal Closed-Circuit Educational Television System. Argo, Howell...185–90

C

Cable Carrier Repeater, A Transistorized. Griffith.. 675–80
Calling Applied to Automatic Airlines Reservations, Teletypewriter Selective. Bratschi, Pennington, Whitman...................................579–83
Canonical Forms Based on Commutative and Associative Binary Operations, Switching Function. Calingaert...............................808–14
Carrier Communications on the Union Pacific Railroad, Wire Line and. Jett......................520–5
Carrier Repeater, A Transistorized Cable. Griffith.. 675–80
Carrier System, An All-Transistorized Trunk. Gardner 212–16
Carrier Systems, Two-Wire Operation of N. Dean, Karkar....................................594–7
Carry Variables in Iterative Networks, Assignment of. McCluskey..............................772–8
Centers, Voice Immunity of Tone Operating Switching. Guenther, Shirman...........................553–7
Central Driven Element, An Omnidirectional Circular Antenna Array Excited Parasitically by a. Neff, Tillman.................................190–2
Centralized Testing of a Very-High-Frequency Mobile Radio System. MacDonald................641–5
Ceramic Triode for VHF Applications, A New. Campbell.....................................404–08
Channel Reactor Protection System for Nuclear Power Plants, A Dual-. Bartu...................358–62
Channels for Doubling TD-2 Radio System Capacity, Interstitial. Curtis, Collins, Jamison......646–54
Character-Metered Transatlantic Switching System, A. Coggeshall, Holcomb............56–64; disc. 64
Characteristics of a High-Speed Wide-Chart Recorder, Design and Performance. Garrigus.......163–70
Charge-Limited Currents with Application to Electrical Precipitation, A Theory for Space-. Cooperman. 47–50
Charges on the Inception Voltage Between Dielectric and Metal Dielectric Surfaces, The Measurement and Influence of Surface. Reynolds.......310–14
Chemical Processing Model for the Investigation of Computer Control, A Generalized. Williams, Otto.....................................458–73
Chemical Reactor, Dynamic Optimization and Control of a Stirred-Tank. Gould, Kipiniak.......... ....734–43; disc. 743
Circuit Analysis, Amplidyne. Bills............711–15
Circuit Established by the Basic Laws Defining Magnetostatics, The Existence of an Electric Analog of a Magnetic. Koenig.......................400–03
Circuits, Fundamental Considerations of Power Dissipation Limits in Some Bistable Transistor Pulse. Raillard...................................53–5
Circuits, Symmetrical Frequency Multiplier. Dick.. 125–34
Circular Antenna Array Excited Parasitically by a Central Driven Element, An Omnidirectional. Neff, Tillman..............................190–2
Closed-Circuit Educational Television System, Redstone Arsenal. Argo, Howell.................185–90
Codes for Correcting Bursts of Errors, Error-Correcting. Meggitt.............................708–11
Coil Design, Some Basic Concepts for Magnet. Gauster 822–8
Coils, The Magnetic Analog with Spiral Search. Moore ....256–63; disc. 263
Combi-System—A Proposal for New Concepts in Digital Data Processing, The. Schwab............193–7
(Committee Report) Proposed Symbology for Digital Systems. (60–1224)............787–93; disc. 793
(Communication Switching Systems) A 240-Line Fully Electronic Telephone Switchboard. Goudet..... 232–41
(Communication Switching Systems) Automation in Switching Equipment Engineering. Hacker, Davis 545–52
(Communication Switching Systems) Automation of Telephone Switching Equipment Engineering. Blumer, Reifenstuhl, List..................560–4
(Communication Switching Systems) Radio-Frequency Interference Considerations in the TD-2 Radio Relay System. Curtis.....................64–70
(Communication Switching Systems) Reflections on the Traffic Usage Recorder with Emphasis on Traffic Engineering. Bauerfeld...................566–70
(Communication Switching Systems) Synthesis of a Resonant Transfer Filter as Applied to a Time Division Multiplex System. May, Stump..615–20
(Communication Switching Systems) The New Nation-Wide Telephone Numbering Plan. Myers..673–5
(Communication Switching Systems) Voice Immunity of Tone Operated Switching Centers. Guenther, Shirman...................................553–7
(Communication Theory) On the Transmission of Information by Orthogonal Time Functions. Harmuth...................................248–55
Communication with Orthogonal Time Functions, Radio. Harmuth.........................221–8

Vol.
Pt. 1

FM and PM Systems, Intermodulation Effects in. Love......245–8
Feeding the Field of an Electric Machine, Instabilities of Push-Pull Magnetic Amplifiers. Storm....33–6
Field Telephone Incorporating an Electronic Signalling System, A Military 4-Wire. Faherty, Howell......177–83
57A Microwave Path Protection System, The. Hesselgrave, Kebby......654–9
Filter as Applied to a Time Division Multiplex System, Synthesis of a Resonant Transfer. May, Stump......615–20
Filters with Real or Imaginary Transfer Functions, The Synthesis of Linear. Gilbert, Otterman....323–30
Flow, Generalized Brillouin. Kent......144–8
Focused Cyclotrons, Sector-. Blosser......814–22
Forms Based on Commutative and Associative Binary Operations, Switching Function Canonical. Calingaert......808–14
450-Mc Vehicular Radio System in the Los Angeles Basin, Establishment of a. Applegarth....597–606
Four-Layer Diodes, An Investigation of the Dynamic Switching Properties of. McDuffie, Chadwell......50–3
Four-Wire Field Telephone Incorporating an Electronic Signalling System, A Military. Faherty, Howell......177–83
Frequencies, A Transistor Automatic Gain Control System for Audio. Shirman......664–9
Frequency Interference Considerations in the TD-2 Radio Relay System, Radio-. Curtis......64–70
Frequency Multiplier Circuits, Symmetrical. Dick......125–34
Frequency Transmission Line Engineering, Radio-. Lewis......634–41
Full-Wave and Biphase Rectifiers, Saturable-Reactor Control of. Thomas, Drenning......36–9
Function Generator, A New. Eggers, Sze......756–62
Functional Analysis Problems, The Analog Solution of Some. Graupe......793–7; disc. 798
Fundamental Considerations of Power Dissipation Limits in Some Bistable Transistor Pulse Circuits. Raillard......53–5
Fusion Power from Magnetically Confined Plasma. Mills......833–6

G

Gain Control System for Audio Frequencies, A Transistor Automatic. Shirman......664–9
Gates, Current-Operated Diode Logic. Reinecke......762–72
Generalized Brillouin Flow. Kent......144–8
Generalized Chemical Processing Model for the Investigation of Computer Control, A. Williams, Otto......458–73
Generalizing Communications Systems, Data Processing as a Tool for. Luebbert......431–6
Generation Using Semiconductors and Magnetic Cores, High-Power Pulse. Lassiter, Johannessen, Spencer......511–17
Generator, A New Function. Eggers, Sze......756–62
Generator Performance, The Effect of Source and Sink Thermal Resistance on Thermoelectric. Gray......15–19
Global Communications, Use of Moon or Satellite Relays for. Yeh......607–15
Guidance Systems, A Comparison of Digital Differential Analyzer and General Purpose Equipment in. Dickinson......706–08

H

Harmonic Modulator, An Analysis of the Operation of the Magnetic Second-. Jalbert......268–72
High-Power Pulse Generation Using Semiconductors and Magnetic Cores. Lassiter, Johannessen, Spencer......511–17
High-Speed Microcurrent Amplifier, A. Dever, Sickles......375–9
High-Speed Wide-Chart Recorder, Design and Performance Characteristics of a. Garrigus...163–70
High-Temperature Operation, Pigmented Polyester Magnet Wire for. Sattler, Scala......503–05
High-Voltage Static Eliminators for Teletypewriters. Jonas, Hanscom......576–8
Hoist Control for A-C Powered Cranes, D-C Magnetic Crane. Myles, Davies, Srnka......207–11
Honeywell H-290, Logical Organization of the. Eachus......715–19
Horizons in Electric Power, Education for Expanding. Brown......149–53; disc. 153
Hybrid Computers for Process Control. Birkel......726–34; disc. 734
Hysteresis Loops of Polarized Polycrystalline Barium Titanate, Quantitative Study of Low-Frequency. Marks, Hanna......799–808

I

Ice and Snow Measurement, Proposed Monocycle-Pulse Very-High-Frequency Radar for Air-Borne. Cook......588–93; disc. 593
Impedance of Semiconductor Devices, Transient Thermal. Diebold, Luft......719–26
Impulse Metering System, A New. Snyder, Booker......159–63
Incremental and Conventional Digital Computers in Air-Borne Real-Time Control, The Relative Merits of. Shackell, Tryon......393–400
(Indicating and Integrating Instruments) A New Impulse Metering System. Snyder, Booker......159–63
(Indicating and Integrating Instruments) Thermal Voltage Converters for Accurate Voltage Measurements to 30 Megacycles Per Second. Hermach, Williams......200–05; disc. 206
Indicator, Portable Dynamic Electronic Speed-Torque. Weed......388–92
Inductors Biased with Permanent Magnets. Ludwig:
  Part I......273–8
  Part II......278–91
(Industrial Control) D-C Magnetic Crane Hoist Control for A-C Powered Cranes. Myles, Davies, Srnka......207–11
Industrial Television for Ticket Reservation Facilities, Dial-Selected. Alinsky......174–7
Information by Orthogonal Time Functions, On the Transmission of. Harmuth......248–55
Ink Recorders, Miniaturized Current Transformers for Multirange Operation of Milliammeter. Geyger......681–9
Instabilities of Push-Pull Magnetic Amplifiers Feeding the Field of an Electric Machine. Storm....33–6
Instrumentation for Experimental Reactor Kinetic Studies. Gardner......384–8
Instruments, Protection for Underwater. Edgerton, Hoadley......689–94
Interference Considerations in the TD-2 Radio Relay System, Radio-Frequency. Curtis......64–70
Interference Reduction, Production Design Considerations in Television Chassis Sweep. Carson..557–60
Intermodulation Effects in FM and PM Systems. Love......245–8
Interstitial Channels for Doubling TD-2 Radio System Capacity. Curtis, Collins, Jamison......646–54
Investigation of the Dynamic Switching Properties of 4-Layer Diodes, An. McDuffie, Chadwell...50–3
Ions on the Trachea, Experiments with Air. Beckett, Krueger......695–9
Iterative Networks, Assignment of Carry Variables in. McCluskey......772–8

K

Kilocycle Range, The Empretron, a Mercury Pool Arc Tube Allowing Operation at Repetition Rates in the. Hernqvist, Norman......85–91
Kinetic Studies, Instrumentation for Experimental Reactor. Gardner......384–8

L

LN 3000 Computer Control System, The. Harple, Lex......408–13
Laws Defining Magnetostatics, The Existence of an Electric Analog of a Magnetic Circuit Established by the Basic. Koenig......400–03
Limit Switch for Indicating and Recording Instruments, A Transistor-Oscillator. Wintermute, Hayter......518–19
Linear Filters with Real or Imaginary Transfer Functions, The Synthesis of. Gilbert, Otterman.323–30
Linear Reactor Simulator, A Multidecade. Schwartzenberg, Finan, Underkoffler, Brey......353–8
Linear Systems to Periodic Excitations, On the Response of. LePage, McFee......746–8; disc. 749
Load, Analysis and Optimization of the Bridge Magnetic Servoamplifier with True Motor, Walsh, Meiksin......413–20
Loads, Power Semiconductor Ratings Under Transient and Intermittent. Gutzwiller, Sylvan......699–705; disc. 705
Locking Range of an Oscillator for Different Nonlinearities. Nag......134–6
Logarithmic Count-Rate and Period Meters, Transients in. Barrow, Maitland......362–9
Logic, Back-Transient Diode. Wolff......4–9
Logic Gates, Current-Operated Diode. Reinecke......762–72
Logical Organization of the Honeywell H-290. Eachus......715–19
Los Angeles Basin, Establishment of a 450-Mc Vehicular Radio System in the. Applegarth......597–606
Low-Frequency Hysteresis Loops of Polarized Polycrystalline Barium Titanate, Quantitative Study of. Marks, Hanna......799–808

M

Magnet Coil Design, Some Basic Concepts for. Gauster......822–8
Magnet Wire for High-Temperature Operation, Pigmented Polyester. Sattler, Scala......503–05
Magnetic Amplifier, Theory of 3-Phase Bridge. Storm, Flarity:
  Part II......451–8
  (Part I—1959)
Magnetic Amplifiers Feeding the Field of an Electric Machine, Instabilities of Push-Pull. Storm...33–6
Magnetic Amplifiers, Rectifier Unblocking from a Generalized Analysis of Self-Saturating. Bourne, Nitzan......99–105
(Magnetic Amplifiers) Static Control for a Mechanically Regulated D-C Supply. Abrams, Brubaker......426–30
(Magnetic Amplifiers) Symmetrical Frequency Multiplier Circuits. Dick......125–34
Magnetic Amplifiers, Time Response Constant and Transfer Function of. Manteuffel......473–82; disc. 482
Magnetic Analog with Spiral Search Coils, The. Moore......256–63; disc. 263
Magnetic Automatic Power-Range Control for an Aircraft Nuclear Reactor. Russell, Hemmenway, Scharf, Sharr......379–84

Magnetic Circuit Established by the Basic Laws Defining Magnetostatics, The Existence of an Electric Analog of a. Koenig........400–03
Magnetic Cores, High-Power Pulse Generation Using Semiconductors and. Lassiter, Johannessen, Spencer........511–17
Magnetic-Coupled Multivibrators, Recent Developments on. Geyger........106–12
Magnetic Crane Hoist Control for A-C Powered Cranes, D-C. Myles, Davies, Srnka........207–11
Magnetic Memory Drum Design. Carne........749–56
Magnetic Modulator, Theory and Operation of a Cross-Field. Boensel........505–10; disc. 510
Magnetic Recorder, A Step-Driven Digital. Hansen........564–5
Magnetic Second-Harmonic Modulator, An Analysis of the Operation of the. Jalbert........268–72
Magnetic Servoamplifier with True Motor Load, Analysis and Optimization of the Bridge. Walsh, Meiksin........413–20
Magnetic-Tape-to-Paper-Tape Converter, A. Ringer, Mintzer........339–46
Magnetically Confined Plasma, Fusion Power from. Mills........833–6
Magnetization in Tape-Wound Cores. Barker........482–501; disc. 501
Magnetostatics, The Existence of an Electric Analog of a Magnetic Circuit Established by the Basic Laws Defining. Koenig........400–03
Magnets, Inductor Biased with Permanent. Ludwig:
  Part I........273–8
  Part II........278–91
Matrix Logic VI, Universal Modulus. Schubert........778–81
Measurement and Influence of Surface Charges on the Inception Voltage Between Dielectric and Metal Dielectric Surfaces, The. Reynolds........310–14
Measurement, Telephone Influence Factor (TIF) and Its. Ball, Poarch........659–64
Mechanically Regulated D-C Supply, Static Control for a. Abrams, Brubaker........426–30
Megacycle Telephone Service to North Carolina's Ocracoke Island, Providing 150-. McMillan........542–5
Megacycles Per Second, Thermal Voltage Converters for Accurate Voltage Measurements to 30. Hermach, Williams........200–05; disc. 205
Memory Drum Design, Magnetic. Carne........749–56
Memory Translator with Shared Access, A Wired-. Pace, Ostendorf........216–20
Mercury Pool Arc Tube Allowing Operation at Repetition Rates in the Kilocycle Range, The Empretron. Hernqvist, Norman........85–91
Metered Transatlantic Switching System, A Character-. Coggeshall, Holcomb........56–54; disc. 64
Metering System, A New Impulse. Snyder, Booker........159–63
Meters, Transients in Logarithmic Count-Rate and Period. Barrow, Maitland........362–9
Method for the Design of Holding Electromagnets, A. Ludwig........300–10
Microcurrent Amplifier, A High-Speed. Dever, Sickles........375–9
Microsecond Precision, A Test Set for Measurement of Envelope Delay Distortion at Audio Frequencies with One-. Codd........241–5
Microwave Path Protection System, The 57A. Hesselgrave, Kebby........654–9
Military 4-Wire Field Telephone Incorporating an Electronic Signalling System, A. Faherty, Howell........177–83
Milliammeter Ink Recorders, Miniaturized Current Transformers for Multirange Operation of. Geyger........681–9
Miniaturized Current Transformers for Multirange Operation of Milliammeter Ink Recorders. Geyger........681–9
Mobile Radio System, Centralized Testing of a Very-High-Frequency. MacDonald........641–5
Mobile Telephone Service, A New Control Terminal for. Getgen, McGibbon........583–8
Modulator, An Analysis of the Operation of the Magnetic Second-. Jalbert........268–72
Modulator, Theory and Operation of a Cross-Field Magnetic. Boensel........505–10; disc. 510
Modulus, Universal—Matrix Logic VI. Schubert........778–81
Monocycle-Pulse Very-High-Frequency Radar for Air-Borne Ice and Snow Measurement, Proposed. Cook........588–93; disc. 593
Moon or Satellite Relays for Global Communications, Use of. Yeh........607–15
Moon Reflection Studies with Bistatic Radar at 3,000 Mc. Straiton, Tolbert........436–9; disc. 439
Motor Load, Analysis and Optimization of the Bridge Magnetic Servoamplifier with True. Walsh, Meiksin........413–20
Multidecade Linear Reactor Simulator, A. Schwartzenberg, Finan, Underkoffler, Brey........353–8
Multiplex System, Synthesis of a Reasonant Transfer Filter as Applied to a Time Division. May, Stump........615–20
Multiplexing Telemetering Equipment for Data Transmission on an Electric Power System, Development and Application of Time-Division. Almon, Donelson........155–9
Multiplier Circuits, Symmetrical Frequency. Dick........125–34
Multirange Operation of Milliammeter Ink Recorders, Miniaturized Current Transformers for. Geyger........681–9
Multivibrators, Recent Developments on Magnetic-Coupled. Geyger........106–12

N

N Carrier Systems, Two-Wire Operation of. Dean, Karkar........594–7
Nation-Wide Telephone Numbering Plan, The New. Myers........673–5
Negative Pulsed Corona, Current-Voltage Relationships in. Thomas, Williams........136–9
Network Switching Facilities, New Television. Bachelet, Collins, Taylor........625–34
Networks, Assignment of Carry Variables in Iterative. McCluskey........772–8
New Impulse Metering System, A. Snyder, Booker........159–63
Nondestructive Breakdown Phenomenon in Selenium Rectifiers, A. English, Tobin........9–14
Nonlinear Systems, Analysis of Transcendental. Wolf........449–51
Nonlinearities, Locking Range of an Oscillator for Different. Nag........134–67
North Carolina's Ocracoke Island, Providing 150 Megacycle Telephone Service to. McMillan........542–5
Nuclear Power Plants, A Dual-Channel Reactor Protection System for. Bartu........358–62
Nuclear Power Reactor, Design of an Eddy-Current Brake for a Sodium-Cooled. Baker........330–3
Nuclear Radiation on the Electrical Strength of Air, The Effects of. Duncan, Fraser, Valachovic........19–26
Nuclear Reactor, Magnetic Automatic Power-Range Control for an Aircraft. Russell, Hemmenway, Scharf, Sharr........379–84
Nuclear Reactors, A Digital Start-up Control for Air-Cooled. Lehr, Mathis........369–75
(Nucleonic and Radiation Instrumentation) A High-Speed Microcurrent Amplifier. Dever, Sickles........375–9
(Nucleonic and Radiation Instrumentation) A Multidecade Linear Reactor Simulator. Schwartzenberg, Finan, Underkoffler, Brey........353–8
(Nucleonic and Radiation Instrumentation) Instrumentation for Experimental Reactor Kinetic Studies. Gardner........384–8
(Nucleonic and Radiation Instrumentation) Transients in Logarithmic Count-Rate and Period Meters. Barrow, Maitland........362–9
(Nucleonics) Fusion Power from Magnetically Confined Plasma. Mills........833–6
(Nucleonics) Sector-Focused Cyclotrons. Blosser........814–22
(Nucleonics) Some Basic Concepts for Magnet Coil Design. Gauster........822–8
Numbering Plan, The New Nation-Wide Telephone. Myers........673–5

O

Ocracoke Island, Providing 150-Megacycle Telephone Service to North Carolina's. McMillan........542–5
Omnidirectional Circular Antenna Array Excited Parasitically by a Central Driven Element, An. Neff, Tillman........190–2
Optimization and Control of a Stirred-Tank Chemical Reactor, Dynamic. Gould, Kipiniak........734–43; disc. 743
Optimization of the Bridge Magnetic Servoamplifier with True Motor Load, Analysis and. Walsh, Meiksin........413–20
Optimizing Control of the Continuous Process, An Approach to Dynamic. Sandelien........291–9
Optimum Design Considerations for Radio Relays Utilizing the Tropospheric Scatter Mode of Propagation. Parry........71–80
Orthogonal Time Functions, On the Transmission of Information by. Harmuth........248–55
Orthogonal Time Functions, Radio Communication with. Harmuth........221–8
Oscillator for Different Nonlinearities, Locking Range of an. Nag........134–6
Oscillator Limit Switch for Indicating and Recording Instruments, A Transistor-. Wintermute, Hayter........518–19

P

PM Systems, Intermodulation Effects in FM and. Love........245–8
Panel Wiring, Automation of Computer. Altman, DeCampo, Warburton........118–25
Paper-Tape Converter, A Magnetic-Tape-to-. Ringer, Mintzer........339–46
Parasitically by a Central Driven Element, An Omnidirectional Circular Antenna Array Excited. Neff, Tillman........190–2
Path Protection System, The 57A Microwave. Hesselgrave, Kebby........654–9
Performance Characteristics of a High-Speed Wide-Chart Recorder, Design and. Garrigus........163–70
Period Meters, Transients in Logarithmic Count-Rate and. Barrow, Maitland........362–9
Periodic Excitations, On the Response of Linear Systems to. LePage, McFee........746–8; disc. 749
Permanent Magnets, Inductors Biased with. Ludwig:
  Part I........273–8
  Part II........278–91
Phenomenon in Selenium Rectifiers, A Nondestructive Breakdown. English, Tobin........9–14
Pigmented Polyester Magnet Wire for High-Temperature Operation. Sattler, Scala........503–05
Plan, The New Nation-Wide Telephone Numbering. Myers........673–5
Plasma, Fusion Power from Magnetically Confined. Mills........833–6
Polarized Electromagnetic Drive System and of Vibrator Drive Systems, An Analysis of a. Nunn........346–52
Polarized Polycrystalline Barium Titanate, Quantitative Study of Low-Frequency Hysteresis Loops of. Marks, Hanna........799–808
Pole and Zero Locations for Nondecreasing Step Responses, The Properties of. Zemanian........421–6
Polycrystalline Barium Titanate, Quantitative Study of Low-Frequency Hysteresis Loops of Polarized. Marks, Hanna........799–808
Polyester Magnet Wire for High-Temperature Operation, Pigmented. Sattler, Scala........503–05
Pool Arc Tube Allowing Operation at Repetition Rates in the Kilocycle Range, The Empretron, a Mercury. Hernqvist, Norman........85–91
Portable Dynamic Electronic Speed-Torque Indicator. Weed........388–92
Potentials in D-C Corona Fields. Penney, Matick........91–9
Power Dissipation Limits in Some Bistable Transistor Pulse Circuits, Fundamental Considerations of. Raillard........53–5
Power, Education for Expanding Horizons in Electric. Brown........149–53; disc. 153
Power from Magnetically Confined Plasma, Fusion. Mills........833–6
Power-Line Transient Recorder, A. Hoshall........170–3
Power Plants, A Dual-Channel Reactor Protection System for Nuclear. Bartu........358–62
Power-Range Control for an Aircraft Nuclear Reactor, Magnetic Automatic. Russell, Hemmenway, Sharf, Sharr........379–84
Power Relationships and Temperature Dependence in the D-C Corona Field. Thomas, Williams, Suzuki........1–4
Power Semiconductor Ratings Under Transient and Intermittent Loads. Gutzwiller, Sylvan........699–705; disc. 705
Power System, Development and Application of Time-Division Multiplexing Telemetering Equipment for Data Transmission on an Electric. Almon, Donelson........155–9
Precipitation, A Theory for Space-Charge-Limited Currents with Application to Electrical. Cooperman........47–50
Precision, Continuous Voltage Reference for Industrial Recorders, A. Robinson........197–200
Problems, The Analog Solution of Some Functional Analysis. Graupe........793–7; disc. 798
Process Control, Hybrid Computers for. Birkel........726–34; disc. 734
Processing as a Tool for Generalizing Communications Systems, Data. Luebbert........431–6
Processing Model for the Investigation of Computer Control, A Generalized Chemical. Williams, Otto........458–73
Production Design Considerations in Television Chassis Sweep Interference Reduction. Carson........557–60
Propagation, Optimum Design Considerations for Radio Relays Utilizing the Tropospheric Scatter Mode of. Parry........71–80
Properties of Pole and Zero Locations for Nondecreasing Step Responses, The. Zemanian........421–6
Proposal for New Concepts in Digital Data Processing, The Combi-System—A. Schwab........193–7
Proposed Monocycle-Pulse Very-High-Frequency Radar for Air-Borne Ice and Snow Measurement. Cook........588–93; disc. 593
Proposed Symbology for Digital Systems. (Committee Report)........787–93; disc. 793
Protection for Underwater Instruments. Edgerton, Hoadley........689–94
Protection System for Nuclear Power Plants, A Dual-Channel Reactor. Bartu........358–62
Protection System, The 57A Microwave Path. Hesselgrave, Kebby........654–9

Providing 150-Megacycle Telephone Service to North Carolina's Ocracoke Island. McMillan.....542–5
Pulse Circuits, Fundamental Considerations of Power Dissipation Limits in Some Bistable Transistor. Raillard.....53–5
Pulse Generation Using Semiconductors and Magnetic Cores, High-Power. Lassiter, Johannessen, Spencer.....511–17
Pulse Transformer for Computer Use, Specifying a. Blessing.....44–7
Pulse Very-High-Frequency Radar for Air-Borne Ice and Snow Measurement, Proposed Monocycle-. Cook.....588–93; disc. 593
Pulsed Corona, Current-Voltage Relationships in Negative. Thomas, Williams.....136–9
Push-Pull Magnetic Amplifiers Feeding the Field of an Electric Machine, Instabilities of. Storm....33–6

Q

Quantitative Study of Low-Frequency Hysteresis Loops of Polarized Polycrystalline Barium Titanate. Marks, Hanna.....799–808

R

REA-1 Transposition System, The. Chapman, Buscemi, Flanigan.....440–8
Radar at 3,000 Mc, Moon Reflection Studies with Bistatic. Straiton, Tolbert.......436; disc. 439
Radar for Air-Borne Ice and Snow Measurement, Proposed Monocycle-Pulse Very-High-Frequency. Cook.....588–93; disc. 593
Radiation on the Electrical Strength of Air, The Effects of Nuclear. Duncan, Fraser, Valachovic....19–26
(Radio Communication Systems) A New Control Terminal for Mobile Telephone Service. Getgen, McGibbon.....583–8
(Radio Communication Systems) Intermodulation Effects in FM and PM Systems. Love......245–8
(Radio Communication Systems) Moon Reflection Studies with Bistatic Radar at 3,000 Mc. Straiton, Tolbert.....436–9; disc. 439
(Radio Communication Systems) Providing 150-Megacycle Telephone Service to North Carolina's Ocracoke Island. McMillan.....542–5
(Radio Communication Systems) The 57A Microwave Path Protection System. Hesselgrave, Kebby.....654–9
(Radio Communication Systems) Use of Moon or Satellite Relays for Global Communications. Yeh.....507–15
Radio Communication with Orthogonal Time Functions. Harmuth.....221–8
Radio-Frequency Interference Considerations in the TD-2 Radio Relay System. Curtis.....64–70
Radio-Frequency Transmission Line Engineering. Lewis.....634–41
Radio Relays Utilizing the Tropospheric Scatter Mode of Propagation, Optimum Design Considerations for. Parry.....71–80
Radio System Capacity, Interstitial Channels for Doubling TD-2. Curtis, Collins, Jamison..646–54
Radio System, Centralized Testing of a Very-High-Frequency Mobile. MacDonald.....641–5
Radio System in the Los Angeles Basin, Establishment of a 450-Mc Vehicular. Applegarth......597–606
Railroad, Wire Line and Carrier Communications on the Union Pacific. Jett.....520–5
Ratings Under Transient and Intermittent Loads, Power Semiconductor. Gutzwiller, Sylvan.....699–705; disc. 705
Reactor, Design of an Eddy-Current Brake for a Sodium-Cooled Nuclear Power. Baker.....330–3
Reactor Kinetic Studies, Instrumentation for Experimental. Gardner.....384–8
Reactor Protection System for Nuclear Power Plants, A Dual-Channel. Bartu.....358–62
Reactor Simulator, A Multidecade Linear. Schwartzenberg, Finan, Underkoffler, Brey.....353–8
Recent Developments on Magnetic-Coupled Multivibrators. Geyger.....106–12
Recorder, A Power-Line Transient. Hoshall....170–3
Recorder, A Step-Driven Digital Magnetic. Hansen.....564–5
Recorder, Design and Performance Characteristics of a High-Speed Wide-Chart. Garrigus.......163–70
Recorder with Emphasis on Traffic Engineering, Reflections on the Traffic Usage. Bauerfeld.....566–70
Recorders, A Precision, Continuous Voltage Reference for Industrial. Robinson.....197–200
Recorders, Miniaturized Current Transformers for Multirange Operation of Milliammeter Ink. Geyger.....681–9
(Recording and Controlling Instrumentation) The Combi-System—A Proposal for New Concepts in Digital Data Processing. Schwab.....193–7
Recording Instruments, A Transistor-Oscillator Limit Switch for Indicating and. Wintermute, Hayter.....518–19
Rectifier Unblocking from a Generalized Analysis of Self-Saturating Magnetic Amplifiers. Bourne, Nitzan.....99–105
Rectifiers, Saturable-Reactor Control of Full-Wave and Biphase. Thomas, Drenning.....36–9
Redstone Arsenal Closed-Circuit Educational Television System. Argo, Howell.....185–90
Reflection Studies with Bistatic Radar at 3,000 Mc, Moon. Straiton, Tolbert.......436–9; disc. 439
Reflections on the Traffic Usage Recorder with Emphasis on Traffic Engineering. Bauerfeld.......566–70
Regulated D-C Supply, Static Control for a Mechanically. Abrams, Brubaker.....426–30
Relative Merits of Incremental and Conventional Digital Computers in Air-Borne Real-Time Control, The. Shackell, Tryon.........393–400
Relay System, Radio-Frequency Interference Considerations in the TD-2 Radio. Curtis.....64–70
Relays for Global Communications, Use of Moon or Satellite. Yeh.....607–15
Relays Utilizing the Tropospheric Scatter Mode of Propagation, Optimum Design Considerations for Radio. Parry.....71–80
Repeater, A Transistorized Cable Carrier. Griffith.....675–80
Repeater Background, Description, and Theory of Operation, The E6 Telephone. Doyle, Talley, Hochgraf, Pedersen, Smethurst.....525–42
Repetition Rates in the Kilocycle Range, The Empretron, a Mercury Pool Arc Tube Allowing Operation at. Hernqvist, Norman.....85–91
Reservation Facilities, Dial-Selected Industrial Television for Ticket. Alinsky.....174–7
Reservations, Teletypewriter Selective Calling Applied to Automatic Airlines. Bratschi, Pennington, Whitman.....579–83
Resonant Transfer Filter as Applied to a Time Division Multiplex System, Synthesis of a. May, Stump.....615–20
Response of Linear Systems to Periodic Excitations, On the. LePage, McFee..........746–8; disc. 749
Responses, The Properties of Pole and Zero Locations for Nondecreasing Step. Zemanian........421–6

S

S-Band Crestatrons, Experiments on a Series of. Rowe, Konrad, Krage.....828–33
Satellite Relays for Global Communications, Use of Moon or. Yeh.....607–15
Saturable-Reactor Control of Full-Wave and Biphase Rectifiers. Thomas, Drenning.....36–9
Scatter Mode of Propagation, Optimum Design Considerations for Radio Relays Utilizing the Tropospheric. Parry.....71–80
Second-Harmonic Modulator, An Analysis of the Operation of the Magnetic. Jalbert......268–72
Sector-Focused Cyclotrons. Blosser.....814–22
Selective Calling Applied to Automatic Airlines Reservations, Teletypewriter. Bratschi, Pennington, Whitman.....579–83
Selenium Rectifiers, A Nondestructive Breakdown Phenomenon in. English, Tobin.....9–14
Self-Saturating Magnetic Amplifiers, Rectifier Unblocking from a Generalized Analysis of. Bourne, Nitzan.....99–105
Semiconductor Device Be Used?, Shall an Electron Tube or a. Scheneman, Waldorf.....264–8
Semiconductor Devices, Transient Thermal Impedance of. Diebold, Luft.....719–26
(Semiconductor Metallic Rectifiers) An Investigation of the Dynamic Switching Properties of 4-Layer Diodes. McDuffie, Chadwell.....50–3
Semiconductor Ratings Under Transient and Intermittent Loads, Power. Gutzwiller, Sylvan.....699–705; disc. 705
Semiconductors and Magnetic Cores, High-Power Pulse Generation Using. Lassiter, Johannessen, Spencer.....511–17
Series of S-Band Crestatrons, Experiments on a. Rowe, Konrad, Krage.....828–33
Servoamplifier with True Motor Load, Analysis and Optimization of the Bridge Magnetic. Walsh, Meiksin.....413–20
Set Using Swept-Band Techniques, A Voice-Band Transmission-Measuring. Lent.....570–6
Shall an Electron Tube or a Semiconductor Device Be Used? Scheneman, Waldorf.....264–8
Signalling System, A Military 4-Wire Field Telephone Incorporating an Electronic. Faherty, Howell.....177–83
Simulation, A 2-Channel Data Link for Combined Analog-Digital. Greenstein.....40–4
Simulation Set, A Delay Distortion. Dunbar....183–5
Simulator, A Multidecade Linear Reactor. Schwartzenberg, Finan, Underkoffler, Brey.....353–8
Sink Thermal Resistance on Thermoelectric Generator Performance, The Effect of Source and. Gray.....15–19
Snow Measurement, Proposed Monocycle-Pulse Very-High-Frequency Radar for Air-Borne Ice and. Cook.....588–93; disc. 593
Sodium-Cooled Nuclear Power Reactor, Design of an Eddy-Current Brake for a. Baker.....330–3
(Solid State Devices) A Nondestructive Breakdown Phenomenon in Selenium Rectifiers. English, Tobin.....9–14
(Solid State Devices) The Effect of Source and Sink Thermal Resistance on Thermoelectric Generator Performance. Gray.....15–19
Solution of Some Functional Analysis Problems, The Analog. Graupe.....793–7; disc. 798
Space-Charge-Limited Currents with Application to Electrical Precipitation, A Theory for. Cooperman.....47–50
Sparkover as Influenced by Surface Conditions in D-C Corona. Penney, Craig.....112–18
Specifying a Pulse Transformer for Computer Use. Blessing.....44–7
Speed-Torque Indicator, Portable Dynamic Electronic. Weed.....388–92
Spiral Search Coils, The Magnetic Analog with. Moore.....256–63
Stable Transistor Wide-Band D-C Amplifiers. Okada.....26–33
Start-up Control for Air-Cooled Nuclear Reactors, A Digital. Lehr, Mathis.....369–75
Static Control for a Mechanically Regulated D-C Supply. Abrams, Brubaker.....426–30
Static Eliminators for Teletypewriters, High-Voltage. Jonas, Hanscom.....576–8
Step-Driven Digital Magnetic Recorder, A. Hansen.....564–5
Step Responses, The Properties of Pole and Zero Locations for Nondecreasing. Zemanian.....421–6
Stirred-Tank Chemical Reactor, Dynamic Optimization and Control of a. Gould, Kipiniak.....734–43; disc. 743
Studies, Instrumentation for Experimental Reactor Kinetic. Gardner.....384–8
Studies with Bistatic Radar at 3,000 Mc, Moon Reflection. Straiton. Tolbert......436–9; disc. 439
Study of Low-Frequency Hysteresis Loops of Polarized Polycrystalline Barium Titanate, Quantitative. Marks, Hanna.....799–808
Subset, Datacom Unit—An Experimental Data Transmission. Stoffels.....669–73
Surface Conditions in D-C Corona, Sparkover as Influenced by. Penney, Craig.....112–18
Swept-Band Techniques, A Voice-Band Transmission-Measuring Set Using. Lent.....570–6
Switch for Indicating and Recording Instruments, A Transistor-Oscillator Limit. Wintermute, Hayter.....518–19
Switchboard, A 240-Line Fully Electronic Telephone. Goudet.....232–41
Switching Centers, Voice Immunity of Tone Operated. Guenther, Shirman.....553–7
Switching Equipment Engineering, Automation in. Hacker, Davis.....545–52
Switching Equipment Engineering, Automation of Telephone. Blumer, Reifenstuhl, List......560–4
Switching Facilities, New Television Network. Bachelet, Collins, Taylor.....625–34
Switching Function Canonical Forms Based on Commutative and Associative Binary Operations. Calingaert.....808–14
Switching Properties of 4-Layer Diodes, An Investigation of the Dynamic. McDuffie, Chadwell.......50–3
Switching System, A Character-Metered Transatlantic. Coggeshall, Holcomb............56–64; disc. 64
Symbology for Digital Systems, Proposed. (Committee Report).....787–93; disc. 793
Symmetrical Frequency Multiplier Circuits. Dick.....125–34
Synthesis of a Resonant Transfer Filter as Applied to a Time Division Multiplex System. May, Stump.....615–20
Synthesis of Linear Filters with Real or Imaginary Transfer Functions, The. Gilbert, Otterman.....323–30
System, The LN 3000 Computer Control. Harple, Lex.....408–13
System, The REA-1 Transposition. Chapman, Buscemi, Flanigan.....440–8

T

TD-2 Radio Relay System, Radio-Frequency Interference Considerations in the. Curtis.......64–70
TD-2 Radio System Capacity, Interstitial Channels for Doubling. Curtis, Collins, Jamison.......646–54
Tank Chemical Reactor, Dynamic Optimization and Control of a Stirred-. Gould, Kipiniak.....734–43; disc. 743
Tape-to-Paper-Tape Converter, A Magnetic-. Ringer, Mintzer.....339–46
Tape-Wound Cores, Magnetization in. Barker.....482–501; disc. 501
Teaching the Uses of Digital Computers at the Technical University of Denmark. Franksen.....781–7
(Telegraph Systems) A Character-Metered Transatlantic Switching System. Coggeshall, Holcomb.....56–64; disc. 64

(Telegraph Systems) A Step-Driven Digital Magnetic Recorder. Hansen.........564–5
(Telegraph Systems) An Electronic Teleprinter Distributor. Biswas, Rakshit.........620–4
(Telegraph Systems) High-Voltage Static Eliminators for Teletypewriters. Jonas, Hanscom.........576–8
Telemetering Equipment for Data Transmission on an Electric Power System, Development and Application of Time-Division Multiplexing. Almon, Donelson.........155–9
Telephone Incorporating an Electronic Signalling System, A Military 4-Wire Field. Faherty, Howell.........177–83
Telephone Influence Factor (TIF) and Its Measurement. Ball, Poarch.........659–64
Telephone Numbering Plan, The New Nation-Wide. Myers.........673–5
Telephone Repeater Background, Description, and Theory of Operation, The E6. Doyle, Talley, Hochgraf, Pedersen, Smethurst.........525–42
Telephone Service, A New Control Terminal for Mobile Getgen, McGibbon.........583–8
Telephone Service to North Carolina's Ocracoke Island, Providing 150-Megacycle. McMillan.........542–5
Telephone Switchboard, A 240-Line Fully Electronic. Goudet.........232–41
Telephone Switching Equipment Engineering, Automation of. Blumer, Reifenstuhl, List.........560–4
Teleprinter Distributor, An Electronic. Biswas, Rakshit.........620–4
Teletypewriter Selective Calling Applied to Automatic Airlines Reservations. Bratschi, Pennington, Whitman.........579–83
Teletypewriters, High-Voltage Static Eliminators for. Jonas, Hanscom.........576–8
Television Chassis Sweep Interference Reduction, Production Design Considerations in. Carson.........557–60
Television for Ticket Reservation Facilities, Dial-Selected Industrial. Alinsky.........174–7
Television Network Switching Facilities, New. Bachelet, Collins, Taylor.........625–34
Television System, Redstone Arsenal Closed-Circuit Educational. Argo, Howell.........185–90
Temperature Dependence in the D-C Corona Field, Power Relationships and. Thomas, Williams, Suzuki.........1–4
Terminal for Mobile Telephone Service, A New Control. Getgen, McGibbon.........583–8
Test Set for Measurement of Envelope Delay Distortion at Audio Frequencies with 1-Microsecond Precision, A. Codd.........241–5
Testing of a Very-High-Frequency Mobile Radio System, Centralized. MacDonald.........641–5
Theory and Operation of a Cross-Field Magnetic Modulator. Boensel.........505–10; disc. 510
Theory for Space-Charge-Limited Currents with Application to Electrical Precipitation, A. Cooperman.........47–50
Theory of 3-Phase Bridge Magnetic Amplifier. Storm, Flairty:
  Part II.........451–8
  (Part I—1959)
Thermal Resistance on Thermoelectric Generator Performance, The Effect of Source and Sink. Gray.........15–19
Thermal Voltage Converters for Accurate Voltage Measurements to 30 Megacycles Per Second. Hermach, Williams.........200–05; disc. 205
Thermoelectric Generator Performance, The Effect of Source and Sink Thermal Resistance on. Gray.........15–19
30 Megacycles Per Second, Thermal Voltage Converters for Accurate Voltage Measurements to. Hermach, Williams.........200–05; disc. 205
Three-Phase Bridge Magnetic Amplifier, Theory of. Storm, Flairty:
  Part II.........451–8
  (Part I—1959)
3,000 Mc, Moon Reflection Studies with Bistatic Radar at. Straiton, Tolbert.........436–9; disc. 439
Ticket Reservation Facilities, Dial-Selected Industrial Television for. Alinksy.........174–7
Time Division Multiplex System, Synthesis of a Resonant Transfer Filter as Applied to a. May, Stump.........615–20
Time-Division Multiplexing Telemetering Equipment for Data Transmission on an Electric Power System, Development and Application of. Almon, Donelson.........155–9
Time Functions, On the Transmission of Information by Orthogonal. Harmuth.........248–55
Time Functions, Radio Communication with Orthogonal. Harmuth.........221–8
Time Response Constant and Transfer Function of Magnetic Amplifiers. Manteuffel.........473–82; disc. 482
Titanate, Quantitative Study of Low-Frequency Hysteresis Loops of Polarized Polycrystalline Barium. Marks, Hanna.........799–808
Tone Operated Switching Centers, Voice Immunity of. Guenther, Shirman.........553–7
Trachea, Experiments with Air Ions on the. Beckett, Krueger.........695–9
Traffic Usage Recorder with Emphasis on Traffic Engineering. Reflections on the. Bauerfeld.........566–70
Transatlantic Switching System, A Character-Metered. Coggeshall, Holcomb.........56–64; disc. 64
Transcendental Nonlinear Systems, Analysis of. Wolf.........449–51
Transfer Filter as Applied to a Time Division Multiplex System, Synthesis of a Resonant. May, Stump.........615–20
Transfer Function of Magnetic Amplifiers, Time Response Constant and. Manteuffel.........473–82; disc. 482
Transfer Functions, The Synthesis of Linear Filters with Real or Imaginary. Gilbert, Otterman.........323–30
Transformer Design by Digital Computers, Electronic. Deise, Etchison, Lee.........314–22; disc. 322
Transformer for Computer Use, Specifying a Pulse. Blessing.........44–7
Transformers for Multirange Operation of Milliammeter Ink Recorders, Miniaturized Current. Geyger.........681–9
Transient and Intermittent Loads, Power Semiconductor Ratings Under. Gutzwiller, Sylvan.........699–705; disc. 705
Transient Diode Logic, Back-. Wolff.........4–9
Transient Recorder, A Power-Line. Hoshall.........170–3
Transient Thermal Impedance of Semiconductor Devices. Diebold, Luft.........719–26
Transients Due to Arc Extinction, Voltage. Steiner, Strecker.........139–44
Transients in Logarithmic Count-Rate and Period Meters. Barrow, Maitland.........362–9
Transistor Automatic Gain Control System for Audio Frequencies, A. Shirman.........664–9
Transistor-Oscillator Limit Switch for Indicating and Recording Instruments, A. Wintermute, Hayter.........518–19
Transistor Pulse Circuits, Fundamental Considerations of Power Dissipation Limits in Some Bistable. Raillard.........53–5
Transistor Wide-Band D-C Amplifiers, Stable. Okada.........26–33
Transistorized Cable Carrier Repeater, A. Griffith.........675–80
Transistorized Trunk Carrier System, An All-. Gardner.........212–16
Transistors: A Realistic Assessment, Tubes or. Moe.........81–5
Translator with Shared Access, A Wired-Memory. Pace, Ostendorf.........216–20
Transmission Line Engineering, Radio-Frequency. Lewis.........634–41
Transmission-Measuring Set Using Swept-Band Techniques, A Voice-Band. Lent.........570–6
Transmission of Information by Orthogonal Time Functions, On the. Harmuth.........248–55
Transmission Subset, Datacom Unit—An Experimental Data. Stoffels.........669–73
Triode for VHF Applications, A New Ceramic. Campbell.........404–08
Tropospheric Scatter Mode of Propagation, Optimum Design Considerations for Radio Relays Utilizing the. Parry.........71–80
Trunk Carrier System, An All-Transistorized. Gardner.........212–16
Tube Allowing Operation at Repetition Rates in the Kilocycle Range, The Empretron, a Mercury Pool Arc. Hernqvist, Norman.........85–91
Tubes or Transistors: A Realistic Assessment. Moe.........81–5
Two-Channel Data Link for Combined Analog-Digital Simulation, A. Greenstein.........40–4
240-Line Fully Electronic Telephone Switchboard, A. Goudet.........232–41
Two-Wire Operation of N Carrier Systems. Dean, Karkar.........594–7

U

Unblocking from a Generalized Analysis of Self-Saturating Magnetic Amplifiers, Rectifier. Bourne, Nitzan.........99–105
Underwater Instruments, Protection for. Edgerton, Hoadley.........689–94
Union Pacific Railroad, Wire Line and Carrier Communications on the. Jett.........520–5
Universal Modulus—Metrix Logic VI. Schubert.........778–81
Usage Recorder with Emphasis on Traffic Engineering, Reflections on the Traffic. Bauerfeld.........566–70

V

VHF Applications, A New Ceramic Triode for. Campbell.........404–08
Variables in Iterative Networks, Assignment of Carry. McCluskey.........772–8
Vehicular Radio System in the Los Angeles Basin, Establishment of a 450-Mc. Applegarth.........597–606
Very-High-Frequency Mobile Radio System, Centralized Testing of a. MacDonald.........641–5
Vibrator Drive Systems, An Analysis of a Polarized Electromagnetic Drive System and of. Nunn.........364–52
Voice-Band Transmission-Measuring Set Using Swept-Band Techniques, A. Lent.........570–6
Voice Immunity of Tone Operated Switching Centers. Guenther, Shirman.........553–7
Voltage Between Dielectric and Metal Dielectric Surfaces, The Measurement and Influence of Surface Charges on the Inception. Reynolds.........310–14
Voltage Converters for Accurate Voltage Measurements to 30 Megacycles Per Second, Thermal. Hermach, Williams.........200–05; disc. 205
Voltage Reference for Industrial Recorders, A Precision, Continuous. Robinson.........197–200
Voltage Relationships in Negative Pulsed Corona, Current-. Thomas, Williams.........136–9
Voltage Transients Due to Arc Extinction. Steiner, Strecker.........139–44

W

Wide-Band D-C Amplifiers, Stable Transistor. Okada.........26–33
Wide-Chart Recorder, Design and Performance Characteristics of a High-Speed. Garrigus.........163–70
(Wire Communication Systems) A Delay Distortion Simulation Set. Dunbar.........183–5
(Wire Communication Systems) A Military 4-Wire Field Telephone Incorporating an Electronic Signalling System. Faherty, Howell.........177–83
(Wire Communications Systems) A Transistor Automatic Gain Control System for Audio Frequencies. Shirman.........664–9
(Wire Communication Systems) A Transistorized Cable Carrier Repeater. (60–1251).........675–80
(Wire Communication Systems) A Voice-Band Transmission-Measuring Set Using Swept-Band Techniques. Lent.........570–6
(Wire Communication Systems) An All-Transistorized Trunk Carrier System. Gardner.........212–16
(Wire Communication Systems) Telephone Influence Factor (TIF) and Its Measurement. Ball, Poarch.........659–64
(Wire Communication Systems) The E6 Telephone Repeater Background, Description, and Theory of Operation. Doyle, Talley, Hochgraf, Pedersen, Smethurst.........626–42
(Wire Communication Systems) The Effect of Delay Distortion on Data Transmission. Mertz.........228–32
(Wire Communication Systems) The REA-1 Transposition System. Chapman, Buscemi, Flanigan.........440–8
Wire Line and Carrier Communications on the Union Pacific Railroad. Jett.........520–5
Wire Operation of N Carrier Systems, Two-. Dean, Karkar.........594–7
Wired-Memory Translator with Shared Access, A. Pace, Ostendorf.........216–20
Wiring, Automation of Computer Panel. Altman, DeCampo, Warburton.........118–25

Z

Zero Locations for Nondecreasing Stop Responses, The Properties of Pole and. Zemanian.........421–6

Power Relationships and Temperature Dependence in the D-C Corona Field

J. B. THOMAS
MEMBER AIEE

T. R. WILLIAMS

T. SUZUKI
NONMEMBER AIEE

THE STUDY of d-c corona discharge over a period of many years has resulted in a considerable body of literature on the subject. However, relatively little has been reported on corona properties over extended temperature ranges. At least two experimental studies have been published, both using coaxial cylindrical geometry. The first, by Koller and Fremont,[1] treats negative corona at temperatures to 1,400 R (degrees Rankin) and pressures to 5 atmospheres. The second, by Thomas and Wong,[2] treats both positive and negative corona at temperatures to 2,000 R and pressures to 8 atmospheres.

This paper is, in some ways, an extension of reference 2 and was undertaken in an attempt to determine two effects: first, the effect of heating only the discharge electrode in a coaxial cylindrical arrangement and, second, the effect of the voltage waveform on the d-c power dissipated in the corona field.

Apparatus and Procedure

The test cell and associated equipment are shown schematically in Fig. 1. The cell itself consisted of a vertical aluminum tube 12 inches long and 0.5 inch in inside diameter, and a coaxial nichrome wire 14 inches long and 0.010 inch in diameter. The ends of the tube were flared to prevent field concentrations. The wire was attached to a heavier bus wire as shown and was held taut by brass weights. Porcelain insulators supported the tube, the wire, and a weight guide structure which facilitated the centering of the wire in the tube.

The wire (or discharge electrode) was heated by having passed through it a current obtained from an isolating heater transformer supplied by a variable 60-cycle source. The temperature of the wire was determined by means of measuring its linear expansion with the aid of a simple ratio arm which served as a mechanical amplifier.

The average current flow to the tube (or collecting electrode) was measured by means of a d-c milliammeter connected between the tube and ground while effective voltage across the corona gap was determined by an electrostatic voltmeter.

Three types of voltage waveforms, as shown in Fig. 2, were used to energize the test cell. That of Fig. 2(A) was a flat d-c voltage with a ripple less than 1.0%. That of Fig. 2(B) was obtained by the full-wave rectification of a 60-cycle per second voltage. In this case the power supply was heavily loaded with a bleeder resistor to prevent capacitive filtering by the test cell and to retain essentially the shape shown. In the third case a pulse generator was used to provide the energizing voltage. The pulses were each one microsecond in width and were repeated at a rate of 5,000 per second. The basic pulse shape from the generator is shown in Fig. 3. A blocking diode was added in series with the generator and test cell to prevent the test cell from discharging below corona onset voltage. The resulting voltage applied to the test cell is shown in Fig. 2(C).

Both positive and negative polarities of the three waveforms just discussed were used. The blocking diode for the pulse generator is shown in Fig. 1 for the negative pulse case and was, of course, reversed for positive pulses.

Also given in Fig. 2 are the approximate corresponding current waveforms. They are all drawn for high current densities; the small random components are not shown. Fig. 3 shows in more detail a typical current pulse for the pulse-energized case.

The basic data taken were average current through the test cell, effective voltage across the cell, and wire temperature. In all cases the test cell was operated in air at atmospheric pressure and room temperature.

Considerable care had to be exercised to obtain reproducible data. The wire used had a rather small diameter and was easily damaged. It was cleaned with carbon tetrachloride before mounting, then operated for approximately one hour at high negative corona currents which tended to "clean up" the surface and stabilize discharge. The wire was replaced frequently since it tended to be permanently stretched, particularly after operating at high temperatures. This stretching reduced wire diameter and increased discharge currents.

When current-voltage readings were taken for a fixed heater current to the wire, it was found that the wire temperature varied greatly over the range of discharge current values. Specifically, the wire temperature decreased rapidly as soon as corona current began. As the corona current was increased, the wire temperature reached a minimum and then increased slightly. The total temperature change was as much as 300 F (degrees Fahrenheit) at the higher temperatures. It was presumed that the initial large temperature decrease was due to air convection currents caused by the corona discharge and that the final slight increase in temperature resulted from the heating of the air space by corona losses. Although the results were the same in both cases, it was found more convenient, particularly at higher temperatures, to hold the wire temperature constant by varying the heater current rather than operating at a fixed heater current.

Current-Voltage Characteristic

Current-voltage characteristics were obtained for the three voltage waveforms of Fig. 2 for both positive and negative polarity; thus six cases were studied. The data from these are presented in Figs. 4(A), 5(A), 6(A), 7(A), 8(A), and 9. It was convenient to plot voltage versus relative air density, with corona current as

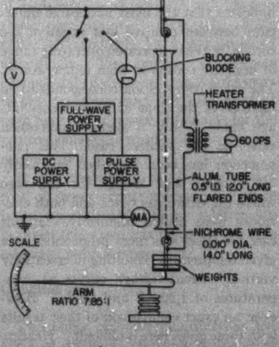

Fig. 1. Diagram of apparatus

Paper 59-234, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1-6, 1959. Manuscript submitted November 6, 1958; made available for printing September 17, 1959.

J. B. Thomas, T. R. Williams, and T. Suzuki are with Princeton University, Princeton, N. J.

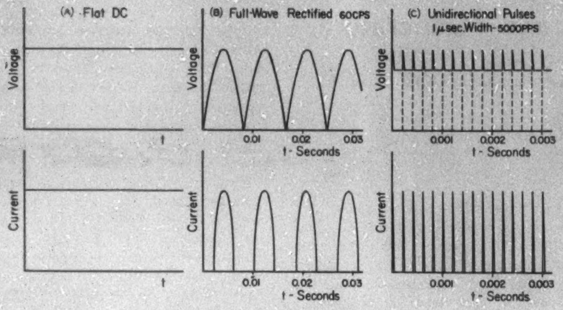

Fig. 2. Voltage and current waveforms

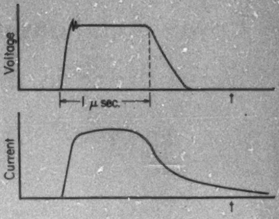

Fig. 3. Detail of pulse shapes

a parameter. The density scale used was chosen for convenience and unit density was taken to be that at 1,000 R. The relative density range shown corresponds to a temperature range of approximately 70 to 1,200 F.

The current-voltage characteristics were obtained over as wide a voltage range as possible, the lower limit of the range being determined by corona onset, and the upper by sparkover. The voltage sparkover values are not given; they correspond roughly to the upper curve in each of the six figures previously mentioned, i.e., curves are given for as high a current as could be obtained consistently without sparkover. The 10-microampere curves can be used as a measure of corona onset voltage, and thus the vertical distance between the lower and upper curve for each of the figures corresponds to the voltage operating range of the cell as a corona device for a given temperature and type of energization.

Flat D-C Energization

A comparison of Figs. 4(A) and 5(A) indicates that the most noticeable difference between positive and negative d-c corona is the compressed operating range of negative corona at high temperatures. The range compression corresponds to an increase in the slope of the current-voltage curve. Only a slight compression exists in the positive case. This phenomenon has been described previously by Thomas and Wong[2] for the case where the entire gas space and both electrodes were heated uniformly. In this case the effect was more pronounced at a given temperature, resulting in essentially vertical current-voltage curves at temperatures of 1,200 F and above. However, an exact comparison of their results with those given here is difficult. Heating the wire alone insures that the gas immediately surrounding the wire is also heated to approximately the same temperature. However, the temperature gradient across the corona gap is quite large since the outer electrode is at a temperature roughly equal to room temperature. The temperature gradient is also unknown since it appears to be affected by corona current.

Two other points should be mentioned briefly in the comparison of positive and negative d-c corona. The curves of Figs. 4(A) and 5(A) are not monotonic but contain points of inflection. It seems reasonable to assume that these are the result of the convection effects previously discussed. In addition, the well-known phenomenon[3,4] should be noted that the corona-starting voltages are not as well-behaved in the negative case as in the positive.

Full-Wave Energization

As might be expected, a lower effective voltage is required for the full-wave case

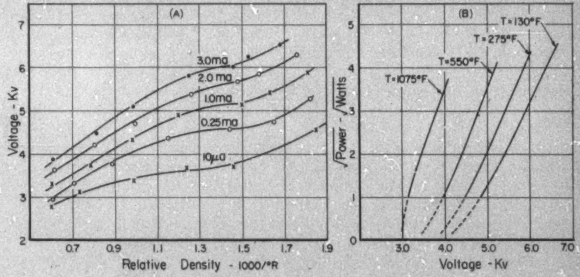

Fig. 4. Negative corona characteristics, flat d-c voltage

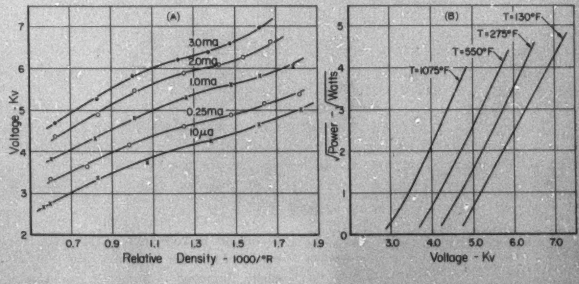

Fig. 5. Positive corona characteristics, flat d-c voltage

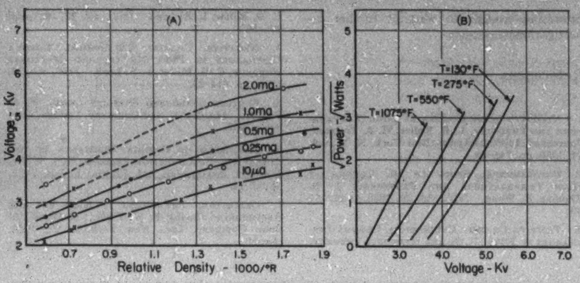

Fig. 6. Negative corona characteristics; full-wave d-c voltage

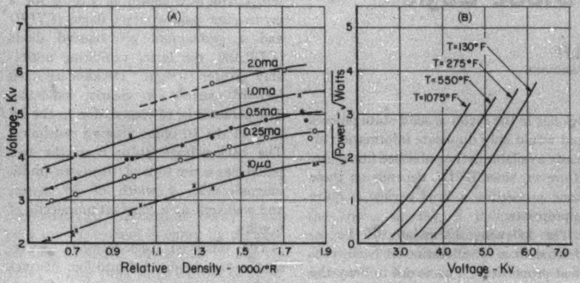

Fig. 7. Positive corona characteristics; full-wave d-c voltage

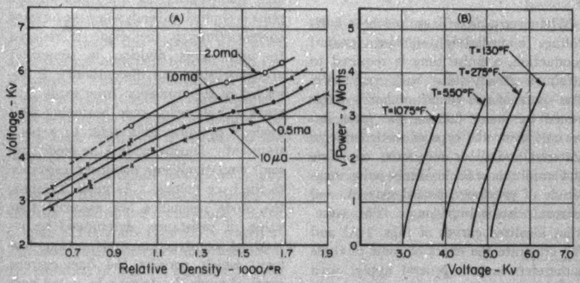

Fig. 8. Negative corona characteristics; pulsed voltage

for the same current. Hence the curves of Figs. 6(A) and 7(A) are displaced downward compared with those of Figs. 4(A) and 5(A). This is a result of the nonlinear corona current-voltage relationship. The same voltage range compression may be seen in Fig. 6(A) for the negative full-wave case as in Fig. 4(A) for negative flat direct current.

In addition, sparkover occurs at a lower effective voltage than before, since it is determined by the peak value of the voltage. As a consequence, the maximum currents obtainable are lower than for the previous case.

Parts of some of the curves of Figs. 6(A) and 7(A) are shown as broken. Over these regions the discharge wire tended to vibrate, and sporadic arcing occurred. Sufficient weight could not be added to stop the vibration without exceeding the elastic limit of the wire.

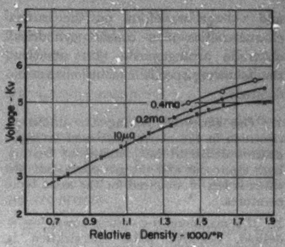

Fig. 9. Positive corona characteristics; pulsed voltage

PULSE ENERGIZATION

The positive and negative pulse corona characteristics differ radically from each other. Negative pulse data are given in Fig. 8(A); they are quite similar to the negative flat direct current data except that the voltage range is considerably compressed at all temperatures and maximum currents obtainable are lower. The reasonably high voltages and currents are all the more interesting when the short pulse length and low repetition rate are considered. No attempt was made to determine optimum pulse lengths and repetition rates.

Positive pulse characteristics were limited by sparkover to a very narrow range, as shown in Fig. 9. A comparison with Fig. 5(A) shows that the curves which were obtained are similar to those of positive flat direct current.

Power Relationships

One of the purposes of this study was to obtain a measure of the d-c power dissipated in the various corona fields just discussed. This dissipation is important in such applications as the design of high-voltage regulators[5] and electrostatic precipitators.[6] Figs. 4(B), 5(B), 6(B), 7(B), and 8(B) have been prepared accordingly. The product of average current and effective voltage is a measure of the d-c power and has been used as such here. The power obtainable for the positive pulse case was too low to warrant consideration.

It was convenient to plot the square root of power versus voltage since there is an approximately linear relationship between these two quantities for positive corona at room temperature.[7]

Conclusions

This paper presents quantitatively the effect of discharge electrode temperature and voltage waveform on the corona characteristics of a coaxial cylindrical electrode arrangement. In addition, the following specific conclusions are indicated:

1. The effect of heating the discharge electrode in the above-mentioned arrangement is similar to that obtained by heating both electrodes and the gas space, but the effect is less pronounced for the same temperatures.

2. If a maximum d-c corona power loss is desired, negative pulse energization is promising enough to warrant further investigation.

Back-Transient Diode Logic

G. WOLFF
ASSOCIATE MEMBER AIEE

CONVENTIONAL diode switching circuits show a significant decline in performance and efficiency as their speed of operation is increased. Faster rise and fall times require correspondingly greater peak currents to charge and discharge circuit capacitance, at the cost of increased static power dissipation, drive requirements, and noise. These peak currents are in demand for only a brief initial and final fraction of the total signal-time duration and might ideally be gated by a 2-step switch having a low resistance during these brief time intervals, with a much greater resistance for the remainder of the signal duration. The semiconductor diode approximates this function when rapidly switched in a low impedance circuit immediately following forward conduction. This is due to the well-known hole-storage effect, a property of diodes generally considered detrimental for rapid switching operations. However, it will be shown that hole storage may also serve as the design basis for a new type of diode-switching circuit, henceforth referred to as back-transient diode logic (BTDL), which exhibits good efficiency, low noise, and excellent compatibility with vacuum tubes or transistors at switching speeds as high as 30 mp (megapulses) per second.

Diode Transient Properties

The forward and reverse transients associated with semiconductor diodes have been the subject of extensive analysis in the past 10 years, ranging from highly theoretical treatises to practical considerations of devising suitable test methods.[1–8] A full discussion properly belongs in the realm of solid-state physics and would only duplicate information already available in the published literature. However, since BTDL depends on these same properties, a brief review is quite appropriate.

The following discussion will be restricted to a consideration of back-transient properties. This is not to deny the importance of forward-transient effects, but their presence does not significantly affect the operation of the circuit to be discussed.

Whenever a diode is pulsed by a back voltage immediately following forward conduction, a finite time is required to attain a steady-state back resistance. The shape of this time function is determined by many factors, the most important being the type of semiconductor material and diode structure, rise time and amplitude of back-voltage pulse, magnitude of previous forward current, and external circuit impedance. The somewhat idealized curves of Figs. 1(A) and (B) illustrate the effect of some of these parameters and in general apply, with only a change of scales, to all types of semiconductor diodes presently available.

The simple test circuit of Fig. 2 was constructed to observe the back-transient current of a given diode with the aid of a high-speed oscilloscope. The current viewing resistance as well as the internal impedance of the pulser were kept as small as was practically possible. It will be shown later that this corresponds to circuit conditions encountered in high-speed diode logic circuits. Voltage *V* can be adjusted for any desired forward current through the test diode. Some typical waveshapes obtained with this test circuit are shown in Fig. 3 for a germanium point-contact diode (*IN191*) and a germanium gold-bonded diode (*CTP309*), the latter exhibiting noticeably greater storage. Dependence upon forward current is clearly indicated. The pedestal is, of course, due to the *IR* drop in the 10 ohms viewing resistance. The back-voltage pulse from the test pulser has a rise time of 10 mμsec (millimicroseconds), a width of 70 mμsec, and was kept at a constant amplitude of 6 volts.

The observed back-transient waveshapes may be divided into four distinct modes of operation, indicated in Fig. 4. Mode *1* represents the steady-state forward conduction period. Mode *2* begins immediately as the back-voltage pulse is applied and ends when the forward current through the diode is reduced to zero. This division is somewhat arbitrary since no discontinuity is involved in the transition from mode *2* to mode *3*. However, only beginning with mode *3* can one truly refer to a back transient. During mode *2* the diode presents a relatively low, nonlinear resistance to the back voltage. As mode *3* begins, the diode resistance has assumed that value of resistance, determined by its material, construction, and previous history, which permits the back-current surge of mode *3*. It may be noted here that two distinct time constants are indicated by modes *3* and *4*, whereas a single

time-constant exponential decay from peak reverse current is shown by the previously discussed waveforms of Fig. 1. However, the peak-surge current of mode *3* is clearly evident in the recorded observations of Fig. 3 and agrees with the findings of at least one investigator.[8] Larger values of series resistance and slower oscilloscopes tend to mask this effect; perhaps this explains why little attention has been paid to it so far in the literature. Thus mode *3* actually represents the major part of the back transient since even at the beginning of mode *4*, the diode back resistance is already in the order of thousands of ohms.

A severe limitation in experimentally observing these transients is imposed by the rise time of the oscilloscope. Even though a Tektronix type *517A* (rated at 7 mμsec maximum rise time) was used, the duration of mode *3* was shorter than the traces of Fig. 3 indicate. More accurate results are obtainable by means of very wide bandwidth oscilloscopes, such as the Edgerton, Germeshausen, & Grier travelling-wave tube type, but this is not a necessity for relative measurements of a practical nature.

High-Speed Considerations of Diode Switching Circuits

The general operation and design principles of diode switching circuits have been extensively described,[9–13] and the following brief discussion will be restricted to problems of high-speed operation, including the effects of the diode transient properties described previously.

A typical AND gate having *n* inputs is shown in Fig. 5. All voltages are referred to ground, *C* includes the capacitance of stray wiring, diode D_s, and connected load. Three considerations are of main concern:

1. The rise time of the output signal when all inputs are present.
2. The fall time of the output signal when one or more inputs are removed.
3. The output noise when all inputs but one are present.

In order for the gate to function correctly, the following conditions must be satisfied:

$$V_1 > V_3 > V_2, \quad I_2 > I_1$$

When all inputs are present and assuming ideal diodes, the output voltage, e_0, will rise exponentially as follows:

$$e_0 = (V_1 - V_3)(1 - e^{-t/R_1C}) + V_3 \qquad (1)$$

In practical designs the voltage drop across R_1 is made to be much greater than the final output amplitude so that I_1 may be assumed constant. In that case the output voltage can be expressed by the simple relationship:

$$e_0 = I_1 t_r / C \qquad (2)$$

where t_r = rise time of e_0.

The fall time of the output voltage is governed by similar considerations with V_2 and R_2 as added parameters. Also e_0 cannot exceed in amplitude any of the inputs present.

In order to increase switching, speed must be decreased and I_1 correspondingly increased to maintain a constant output. For rise times of several mμsecs, currents in the order of tens of milliamperes (ma) and resistors dissipating watts are not unusual. Unfortunately, this power is to a very large degree wasted since it is required for only a brief initial fraction of the total signal-time duration.

It has been noted previously that one

B—Diode type IN191

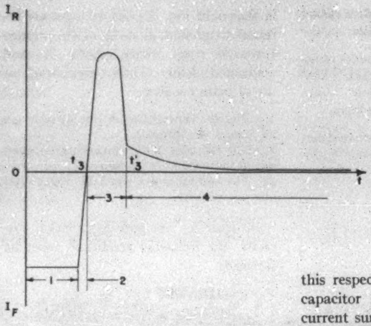

Fig. 4. Back-transient current characteristic showing modes of operation

of the conditions which must be satisfied is that $I_2 > I_1$. As I_1 increases with speed, I_2 does likewise, and this creates several problems. Thus the number of inputs that can be driven from a given source is successively reduced as switching speed goes up. Still more troublesome is the effect of this heavier current upon the conducting diodes. We have seen that the back transient is directly proportional to the forward current passed by the diode prior to being back-biased. The clamp diode, D_c, carries the heaviest load. Its current is defined by:

$$I_3 = nI_2 - I_1 \qquad (3)$$

Therefore a large back-current surge is passed by diode D_c before it can attain a reasonably high back resistance. In this respect its behavior is similar to a capacitor and the time integral of this current surge is sometimes referred to as "lost charge."

The problem of output noise in the presence of all but one input remains to be considered. The origin of such noise is twofold. Static noise is caused by variation in the forward voltage drop of diode D_c due to changes in steady-state current conditions. For example, when only one input remains unpulsed, I_3 decreases from its quiescent value of $nI_2 - I_1$ to $I_2 - I_1$. This is often a substantial change and may give rise to an output ranging from several tenths of a volt to almost a volt, depending upon the type of diode chosen for D_c. Dynamic noise is usually the more serious source of unwanted output at high switching speeds. It is the result of back transients passed by n-1 diodes, assuming worst condition, plus the effect of any parallel capacitance. The currents thus passed may be quite considerable, even when the fastest, high-quality diodes are used. The series circuit impedance seen by each back-biased diode consists of the signal-source output impedance and the dynamic forward resistance of the clamp diode D_c. All of these are generally quite low, confirming the applicability of the results obtained with the test circuit of Fig. 2. The effectiveness of these transients in contributing to output noise is enhanced by the large reduction in forward current through diode D_c, requiring less current to shut off forward conduction and raise its back resistance. A means of reducing dynamic noise, which is sometimes resorted to, consists of eliminating diode D_c and instead clamping each input with a separate diode.[14] This reduces the current in the AND diodes and thus also the back transient. However the static noise is now increased by the addition of one diode. The loading effect upon the pulse by the clamp diodes is another undesirable feature of this circuit.

OR gates present much less of a problem than AND gates at high switching speed. OR diodes should be chosen primarily for optimum forward transient properties. Their back transients are usually not deleterious; on the contrary, they often serve as a means of obtaining a more rapid discharge of circuit capacitance at signal termination.

As switching circuits are successively cascaded, impedance levels decrease rapidly.[12] Since the initial resistances of high-speed diode switching circuits are

quite low to begin with, cascading without interposition of an active element is usually limited to three levels.

Back-Transient Diode Logic

It is apparent from the preceding discussion that two major problems are encountered in the operation of conventional diode switching circuits at high speeds: 1. greatly increased quiescent power dissipation, and 2. undesirable effects of diode transient properties.

A new type of diode switching circuit will now be described for which quiescent power dissipation is not dependent upon speed of operation. Since diode back transients are an essential element of these circuits, providing low-impedance paths for charge and discharge currents, the name back-transient diode logic is an apt designation.

Fig. 6 represents an AND circuit which upon closer examination is seen to differ from the one of Fig. 5 only by the absence of V_1 and R_1, nevertheless this is sufficient to result in radically different circuit operation. The following steady-state conditions must be satisfied:

$$I_3=nI_2,\quad V_3>V_2$$

When all inputs are pulsed, the output voltage, e_0, is now determined by the following equation:

$$e_0=\left(\int_{t_3}^{t_3'} i_{D1}\,dt+\int_{t_3}^{t_3'} i_{D2}dt+\dots \int_{t_3}^{t_3'} i_{Dn}dt-\int_{t_3}^{t_3'} i_{Dc}dt\right)1/C \qquad (4)$$

The integral term in each case represents the back current passed by the subscript diode during the time interval defined as mode *3* in Fig. 4. As in conventional diode AND circuits, e_0 cannot exceed in amplitude any of the inputs present.

Strictly speaking this equation defines e_0 for only the initial portion of the signal period. During this time the AND diodes represent a low resistance, in order of magnitude ranging perhaps from tens to hundreds of ohms, and the current passing through them must be sufficient to supply the back current of diode D_c in addition to charging the parallel circuit capacitance to the desired voltage. For the remainder of the signal duration, e_0 is determined by the diode characteristics of mode *4*. The magnitude of time constants during this mode causes e_0 to change very slowly compared to mode *3*. The effect upon signals of long-time duration will be considered later. In pulse-type synchronous system of logic, clock rates of 10 mp per second and higher correspond to pulse widths of 50 mμsec and less. For such short-time intervals mode *3* is essentially the sole determinant of output amplitude.

When all inputs but one are pulsed, the expression for the output noise voltage becomes:

$$e_0=\left(\int_{t_3}^{t_3'} i_{D1}dt+\int_{t_3}^{t_3'} i_{D2}dt+\dots \int_{t_3}^{t_3'} i_{Dn-1}dt-\int_{t_3}^{t_3'} (i_{Dc}+I_2)dt\right)1/C \qquad (5)$$

The total charge available to produce an output has now been reduced by

$$\int_{t_3}^{t_3'} i_{D_n}\,dt$$

At the same time the charge demand has been increased by

$$\int_{t_3}^{t_3'} I_2dt$$

This combination makes it possible, if parameters have been correctly chosen, to keep dynamic noise at very low levels and still obtain the desired output voltage when all inputs are present. Since the integral terms of these equations are, for the particular diode concerned, primarily functions of forward current, the choice of diodes and currents determines the design of BTDL circuits to a large extent.

The fall time of e_0 is not necessarily governed by the value of R_2. In general the inputs are coupled through OR diodes whose back transients can be utilized for low-impedance discharge paths. The output will then follow the signal source, as it also would do in the case of capacitor coupled inputs.

Data obtained by means of the test circuit of Fig. 2 have proved very useful in designing practical BTDL circuits. The area under the back-transient current trace during mode *3* is obtained most easily by assuming a triangular shape. With a properly calibrated oscilloscope this permits a very rapid determination of a diode's storage capability at any desired value of forward current. The results are sufficiently accurate for a preliminary design which may then be empirically optimized. As a simple example, consider a 2-input AND gate which is to have an output of 3 volts across the clamp diode in parallel with a capacitance of 10 μμf (micromicrofarads). This requires that 30×10^{-12} coulombs be supplied to charge the capacitance. A Hughes *HD2109* point-contact diode (30×10^{-12} coulombs storage for 4-ma forward current) was selected as the clamp diode and two Transitron *T15G* gold-bonded diodes (30×10^{-12} coulombs storage each for 2-ma forward current) as the AND diodes. The choice is quite arbitrary, of course, since an infinite number of combinations is possible. When both inputs are pulsed, apply equation 4 to calculate the resultant output voltage, which is 3 volts as desired. A similar substitution in equation 5 makes it apparent that no net output voltage will result when only one input is pulsed.

Fig. 7(A) shows the waveforms obtained with this AND gate. The largest one is the input signal, capacitor coupled from a Hewlett-Packard type *212A* pulse

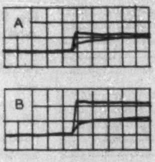

Fig. 10. **Effect of input pulse amplitude variation upon input. $I_2 = I_3 = 2$ ma, $C = 8 \mu\mu f$. Vertical, 10 volts per division, horizontal, 0.1 μsec per division**

A—11-volt input
B—22-volt input

generator. Its repetition rate is 5 kc. The output pulse is superimposed and its leading edge can be seen to rise to an amplitude of from 3 to 4 volts. During the flat-top portion of the input pulse, the output continues to increase, though at a much slower rate, being now determined by conditions of mode *4*. The ratio of parallel static back resistances of the AND diodes to the static back resistance of the clamp diode determines the final value of output voltage, assuming the input signal continues long enough for static conditions to be reached. The output with only one input signal present is shown by the virtually straight line at the base of the pulses, indicating negligible noise.

The addition of inputs using similar diodes, with the forward current in each maintained at 2 ma, will cause an increase in output voltage. Since there is a corresponding increase in current through the clamp diode, the net output voltage will not necessarily vary in direct proportion to the number of inputs. Figs. 7(B) and (C) show input, output, and noise voltage waveshapes for a 3- and 4-input AND gate respectively. The steeper rise of the output voltage during the flat-top portion of the input pulse as more inputs are added reflects the resultant lowering of the parallel AND diode resistance.

So far the number of inputs has been the only parameter which was varied. Figs. 8 and 9 clearly show the dependence of output voltage upon forward current and output capacitance. Again the larger pulse always represents the input signal, the superimposed smaller pulse the output voltage. The noise voltage is not included in these pictures. As in Fig. 7 it is insignificant.

Further insight into some aspects of BTDL may be gained by eliminating all but one of the inputs of the circuit shown in Fig. 6. For example, Figs. 10(A) and (B) show the influence of input-voltage amplitude variation upon the output. It can be seen that doubling this amplitude causes no noticeable change in the initial value of output voltage. Fig. 11 illustrates an effect that has already been referred to at some length. Diodes having similar transient properties are used in the same relative position. However, in one case the input diode has a much higher static resistance than the clamp diode, in the second case this relationship is reversed. The result in the presence of an input signal of long-time duration (10 μsec) is clearly evident. The larger pulse is the input and its noticeable droop is caused by capacitor coupling. The ratio of input to output voltage at the trailing edge of the pulse in each case closely corresponds to the ratio of measured static back-resistance values of the two diodes concerned. An indication is thus given that BTDL does not necessarily have to be restricted to very high speeds or clocked systems.

Several considerations of a more practical nature remain to be examined. In view of the temperature dependence of diode transient properties, circuits based upon these properties might well be expected to exhibit a similar dependence. However, BTDL is relatively temperature insensitive because variations in the AND diodes tend to be compensated by similar variations in the clamp diode.

The problem of diode selection and matching becomes very important when large quantities are required. Measurement of the peak amplitude of mode *3* at only one value of forward current is adequate for production purposes and may be performed very rapidly by means of the test circuit of Fig. 2.

Under actual operating conditions, noncoincident arrival of signals at a multi-input switching circuit is commonly encountered. In addition, one or more of these signals may be static rather than dynamic. BTDL AND gates will respond correctly and no output will appear until the last input is present. However, this does not imply that there will not be some difference in output amplitude when all inputs appear either simultaneously or successively. Allowance for this variation can be made in the original design, especially in view of the fact that signals are often limited by clamping to a predetermined level.

BTDL circuitry must, of course, be combined with active elements such as vacuum tubes or transistors in any but the most elementary logic elements. Vacuum tubes require rapid charge and discharge of their grid capacitance when used as high-speed switches and the suitability of BTDL is immediately apparent. The output from BTDL gates is likewise an excellent base drive for fast switching transistors, which demand high forward and reverse-current surges at the start and finish of pulse inputs.

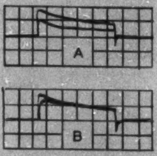

Fig. 11. **Effect of diode static-back resistances with pulses of long-time duration. $I_2 = I_3 = 2$ ma, $C = 8 \mu\mu f$. Vertical, 10 volts per division, horizontal, 2 μsec per division**

A—Low back-resistance clamp diode
B—High back-resistance clamp diode

Experimental National Bureau of Standards SEAC-type computing circuits, some of considerable complexity, have been constructed and operated successfully at clock frequencies as high as 30 megacycles. No changes need to be made in the BTDL parameters when clock frequencies are altered. A description of these circuits is properly the subject of another paper.

Conclusions

A new type of diode switching circuit has been presented which has several unique advantages over conventional diode switching circuits at high speeds. The normally detrimental back transients associated with semiconductor diodes are here utilized as an essential feature of these circuits, which therefore have been named back-transient diode logic. Quiescent power dissipation is not only much reduced but at the same time has been freed from its dependence upon switching speed. Low-priced and readily available diodes may be used. It is felt that BTDL offers a new approach to designers of high-speed switching circuits worthy of their serious consideration.

A Nondestructive Breakdown Phenomenon in Selenium Rectifiers

A. C. ENGLISH
ASSOCIATE MEMBER AIEE

W. H. TOBIN
NONMEMBER AIEE

UNDER CONDITIONS of excessive current or voltage overload a rectifier will exhibit some form of breakdown. Under practical conditions, breakdown is normally destructive although, with proper safeguards, it may be controlled. A voltage-induced electric breakdown is the type most commonly cited in theory, while in practice a considerable contribution from thermal effects is observed. Selenium rectifiers frequently exhibit the property of recovering from an overvoltage breakdown. The symptoms in this case range from the appearance of minor sparking and fumes of selenium to a very generous arc blowing a cavity in one of the cells. Two physical mechanisms of recovery are apparent; in one, small areas of separation occur between the selenium and the counter-electrode, without necessarily rupturing the latter; in the other, greater burnouts involve craters reaching down to the baseplate, with walls of insulating vitreous selenium, and all counter-electrode removed from the immediate vicinity.

It is possible to observe another kind of failure which, for want of a better name, is labeled "stabilized breakdown" (SB), a nondestructive, essentially reversible phenomenon involving a thermal "runaway" to a limiting stabilization point.[1]

Experimental

Primary Phenomenon

A small size, e.g., $1^1/_2$ inches square, selenium rectifier is chosen, with a counter-electrode, such as cadmium, having a melting point higher than that of selenium, and connected to a normal a-c source and resistive load. Without imposing excessive voltages on the cell an overload condition is induced by increasing the forward current and, or, by raising the ambient temperature. While some cells show remarkable stability even above 200 C (degrees centigrade), all cells succumb to some combination of current and heat and enter a thermal "runaway" which continues until, nearing the melting point of selenium, it is halted by a stabilizing process. The events are best described in terms of typical instrumentation, whereby the current-voltage characteristics of the rectifier are displayed on an oscilloscope, and measurements are made of cell temperature (superficial), ambient temperature, and the output d-c average through the load.

Fig. 1 shows a set of concurrent events for a particular selenium cell under conditions where only the ambient temperature is varied. As the temperature rises the reverse current increases until, above 160 C, its effect appears as a reduction in the d-c output, while the cell temperature rise shows an acceleration because of increased heat generation. The cell is by now unstable and "runs away" until two distinguishable events interfere. At the first, a peak in reverse current is reached and a rapid fall to a lower value occurs. The output d-c current rises somewhat in response and the cell temperature continues its unabated climb. A momentary rise in reverse current is visible before the onset of the second event, in which, simultaneously, the output d-c current falls precipitously to a low value, the reverse current and forward current fall sharply, and the cell temperature stabilizes at a thermocouple reading between 210 and 220 C depending on the heat transfer conditions. The voltage-current patterns on the oscilloscope, Fig. 2, show that at 180 C (temperatures meas-

Temperatures are thermocouple readings on the aluminum baseplate

ured on the aluminum plate) the reverse current is high while the forward characteristic is very little changed. At 210 C the reverse current has suddenly diminished. At 215 C the whole pattern swings uniformly, in the direction of increased resistance in both forward and reverse direction.

In the state now existing the cell shows a remarkable response to changes in imposed conditions. Within the limits of thermocouple measurements under variable heat transfer rates, the cell temperature is remarkably constant (about 1 C with only moderate precautions in technique) even when the ambient temperature is varied 50 C, the series load resistance varied widely, or the input voltage increased two or three times. On the oscilloscope, the current-voltage trace can be made to swing at will in response to the various stimuli. A change which would normally raise the temperature of the cell by any of these methods appears to result merely in an increase of over-all cell resistance. This effectively reduces the electric power being dissipated in the cell and so compensates with negligible change in cell temperature.

In anticipation of more detailed discussion, the phenomenon described would be quite plausible if the temperature were held constant because of a phase change, such as melting. The obvious material in this experiment, in view of the temperature, is selenium. A number of experiments help to clarify the details.

TEMPERATURE STABILIZATION

An attempt was made to determine with some accuracy the temperature at which the cell stabilized. The main problem lies in the fact that the region of highest temperature, presumably the rectifying junction, is inaccessible to measurement and that it is too difficult, because of destructive breakdown, to experiment with SB under equilibrium temperature conditions. The best compromise, a slowly rising temperature in well-insulated conditions, is limited by the necessity of clearly establishing that the cell actually experiences SB when the voltage is of necessity reduced.

A thermocouple was calibrated under our experimental conditions against the melting point of pure tin (accepted value 231.9 C) and then used to measure the selenium cell temperature, in SB, with the cell well insulated in packed asbestos and the temperature slowly rising. Because of the restricted heat transfer it was difficult to prevent destruction of the cell in a short time, although the electrical conditions were controlled. In one experiment with the thermocouple on the aluminum base-plate, the last 4 minutes of the run before a short circuit occurred showed a temperature change from 218.9–219.3 C. With the thermocouple on the cadmium counter-electrode the last 8 minutes showed a temperature change from 219.6–220.7 C. All factors considered, these temperatures as listed are probably not reliable within 2 C as a measure of the rectifying junction temperature.

The essential constancy of the temperature of a cell under SB was established under a wide range of electrical conditions, which include a-c, d-c, both forward and reverse, and a variety of square waveforms of 60 cps (cycles per second), with independent reverse and forward voltage values. One interesting confirmation of a constant temperature condition is found in the fact (considered later) that in constant ambient temperature conditions, wide variations in the imposed electrical conditions do not significantly change the amount of energy being liberated within the rectifier. The sensitive temperature measurements made while studying transient effects show cell temperature variations of a few tenths of a degree C for steady-state SB conditions.

ELECTRICAL PHENOMENA

The early experiments on SB were performed under typical a-c conditions with pure resistance or resistance- and capacitance-type loads. Oscillographic analysis was sufficient for a semiquantitative description of the events taking place. For more detailed analysis, a variety of conditions were investigated, in-

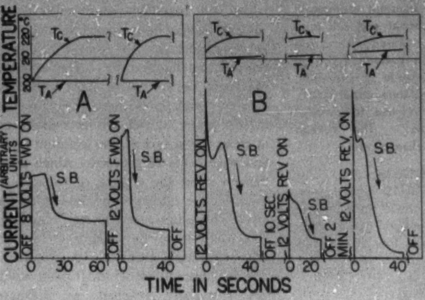

Fig. 3. SB induced by forward and reverse direct current

A—SB caused by forward current alone. For this experiment, voltages, though not currents, are much higher than usual

B—SB caused by reverse current alone. Ambient temperature T_a, cell temperature T_c and currents are taken from strip-chart records

cluding direct current, so as to separate completely the forward and reverse characteristics, and square-wave input derived from batteries and a 60-cps vibrator-chopper to evade some of the complexities of analyzing nonlinear characteristics and sine waves.

One experiment using the square-wave input was designed 1. to show the constancy of electric energy dissipated in the cell, and 2. to investigate the resistance changes in the cell. Under constant ambient temperature conditions and with the cell in the SB condition, changes were made in the forward or reverse voltage on the cell and measurements made of forward and reverse voltage and current. These data are recorded in the first four columns of Table I. Columns 5 and 6 show the power dissipated in the cell in the forward and reverse directions, and column 7 the total power dissipated. It will be observed that the total power column shows an average deviation from the mean of only 1% (even excluding repeated identical settings).

The same data were further analyzed to determine in what way the melting process added resistance to the cell. Of the four obvious cases tested it was found that a change in the SB condition had the effect of removing or adding a resistance in parallel with the cell rather than one in series, or than a nonlinear resistance in series or parallel, where the nonlinearity is matched to the cell characteristic at the time.

In Table I, columns 8 and 9 give the forward and reverse resistance of the cell at the various SB settings. Columns 10 and 11 may be compared for equality. They represent the "removed" parallel resistance when the cell at a higher power level is compared with its state at a lower power level and the two columns give, respectively, the values for forward and reverse measurements. Columns 12 and 13 give similar figures for the "added" series resistance, and comparison shows this case to be a poorer choice. It was verified that both voltage and current in both directions were essentially square waves and that no obvious changes in cell characteristics occurred during the 1/120th second of the cycle.

Fig. 3(A) shows the behavior of the cell when SB is induced by forward direct current alone. The chart record shows the cell entering the SB condition soon after 8 volts forward current is applied, recovering during an off period and repeating the process at 12 volts forward current. It will be seen that before SB a higher voltage gives higher current, afterwards, a lower current.

The behavior for reverse direct current shown in Fig. 3(B) is somewhat more complex. Usually the reverse current rises to a high value just before SB and in most cases then passes through a sharp fall and small rise before dropping to a steady low value. This "second peak" of current is most easily seen when the cell moves rapidly into SB and can be seen in all the circuit conditions when reverse voltage is present if the energy input is high enough.

An almost trivial experiment was devised to demonstrate that some of the phenomena of SB may be observed when only a part of the selenium rectifying area is in SB as might be the case when there are local hot-spots on a cell. Under a-c conditions, two cells were connected in parallel, with one of the cells in an oven. It was then possible to subject the one cell to SB while the other functioned normally.

Since the reverse current of such a combination is essentially dominated by the hotter cell the events recorded in reverse are quite typical of SB. Thus the fact that the reverse SB phenomena are observed is no guarantee that the whole of the cell surface is participating. Likewise, in the forward direction, the combination shows mainly the characteristics of the cool cell even though a part of the rectifying area had entered SB. Thus, it is possible to observe reverse SB phenomena without, or before, observing clear-cut changes in the forward direction.

Fig. 4 is a strip-chart recording of events while subjecting a rectifier to 5 cycles of entering and leaving the SB condition, the controlling variable being the ambient temperature T_1. The power source in this case was chopped d-c, 2 volts in the forward direction, 12 volts in reverse. The chart is of interest as a record of some complex events, not otherwise easily described. The inter-

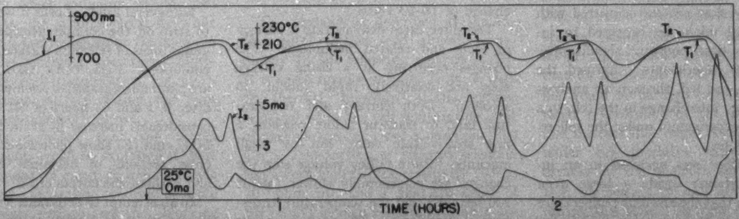

Fig. 4. **Rectifier subjected to 5 cycles in and out of SB. The current is a square wave obtained by chopping direct current at 60 cps. The forward current I_1 is at 2 volts input, reverse current I_2 at 12 volts. The recorded cell temperature T_2 is sensitive to changes in the ambient temperature T_1 and is not an accurate measure of the rectifying junction temperature**

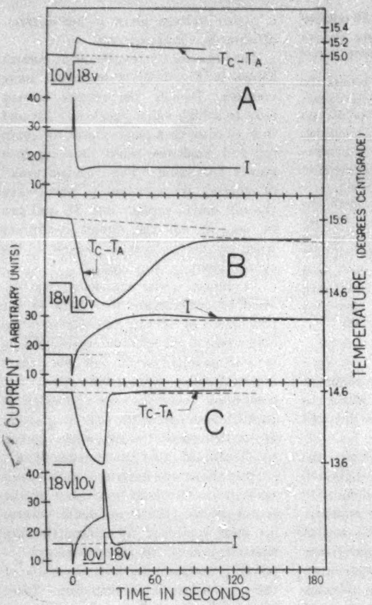

Fig. 5. Transient changes in reverse current and cell temperature caused by step changes in reverse d-c voltage on a rectifier in SB condition. Cell temperature, about 220 C, is given relative to ambient temperature. The voltage changes are

A—From 10–18 volts
B—From 18–10 volts
C—From 18–10 volts, and, at the temperature minimum for the transient, from 10–18 volts

relationship between the various curves is of primary interest. The peaks in the reverse current show a smooth trend with time, the forward current curve is somewhat less simple.

TRANSIENT PHENOMENA

The concept that SB depends upon a part of the selenium existing in the molten state suggests that in making a change of input voltage a part of the selenium should either freeze or melt. The time constant of the change in current observed after a step change in the voltage should then be related to the speed with which the two processes, freezing and melting, can occur. In selenium, crystallization is a relatively slow process compared with melting and might be expected to increase the time constant significantly. Preliminary experiments confirmed the predictions and led, through an analysis of the energy interchange in the cell, to a variety of experiments under the following conditions.

The rectifier was enclosed in an insulated container inside a large oven arranged so that the ambient temperature changes could be kept below 0.05 C per minute and with only long-period drift. Two opposing thermocouple junctions measured the temperature difference (about 20 C) between the air in the container and the rectifier. The resulting voltage was measured directly, or was balanced almost to zero and then amplified so that the recorder chart sensitivity became 0.07 C per cm (centimeter). (Noise level was about 0.3 cm.) The rectifier was subjected to step changes of reverse voltage in the range 10–18 volts and the current recorded. Fig. 5 shows the results of three switching operations: Fig. 5(A) from 10–18 volts, Fig. 5(B) from 18–10 volts, and finally Fig. 5(C) where the voltage was switched from 10–18 volts at the moment when the cell temperature had reached a minimum during a transient resulting from a change of 18–10 volts.

The three cases demonstrate a variety of facts and related deductions. The changes occurring at a rising voltage step are relatively rapid (about 15 seconds). Both current and temperature tend to transcur before reaching a new steady-state value, but by small amounts. For a falling voltage step the changes are considerably slower (about 100 seconds) and the temperature transcursion very large. The positive energy increment which the cell receives during the transient in Fig. 5(A) is considerably smaller than the negative increment of (B) which fact, together with other details in the events, may be explained by changes in heat transfer to the ambient during temperature fluctuations. The essential difference between Figs. 5(A) and 5(B) may be correlated with a melting process, in the former, driven by heat produced in, or on the surface of, the selenium itself, and with a freezing process which must depend upon the cooling of the cell to produce the supercooling which is the driving force in the latter case. A superficial analysis of the recordings for Fig. 5(B) indicates that at the temperature minimum (at 30 seconds) the freezing has essentially reached its ultimate steady-state condition, since the current also is very close to its final value. However, since the cell temperature is 1 C lower than it final value, crystallization continues to about the 60-second mark, with a coincident current overshoot which provides the increment of energy required to bring up the cell temperature and to remelt the excess of crystals. A similar argument applies to the much smaller temperature overshoot in Fig. 5(A) except that if the "superheating" of a crystal above its melting point is not permitted than the higher temperature requires additional explanation. Two possibilities seem to be that a semiconductor like cadmium selenide on the selenium surface may be a source of heat and can reach higher temperatures, or that selenium grains, of higher purity than the melt, may reach a higher temperature without passing their melting point and would not dissolve in the melt faster than the impurities in the melt diffuse to the grain surface.

MICROSCOPE STUDIES

A number of investigations were made to determine whether a momentary or prolonged experience of SB resulted in identifiable physical changes in the cell structure. It was natural to expect some obvious effects because of the high temperature.

On several kinds of cells it was possible to strip off the counter-electrode and examine areas of selenium surface in various conditions. Figs. 6(A), (B), and (C), are photomicrographs of selenium surfaces after 0, 1 and 63 hours of SB showing a considerable increase in grain size. Fig. 6(D), and (E) show photomicrographs of cross sections of selenium cells with and without the effects of SB.

In an attempt to determine whether the degree of grain growth at the selenium surface could be explained completely by the temperature of the cell during SB, a selenium cell was prepared in which a

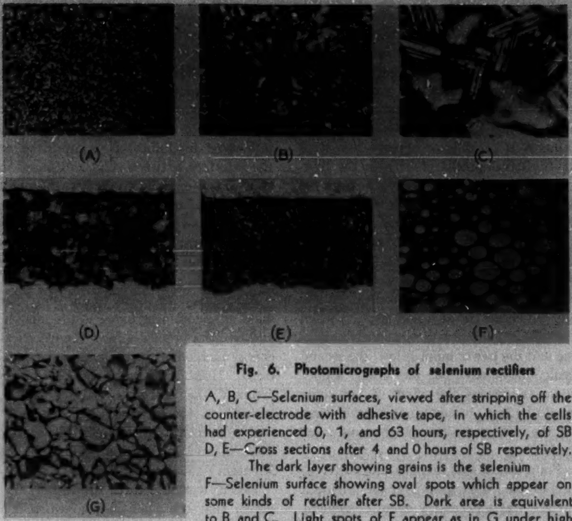

Fig. 6. Photomicrographs of selenium rectifiers

A, B, C—Selenium surfaces, viewed after stripping off the counter-electrode with adhesive tape, in which the cells had experienced 0, 1, and 63 hours, respectively, of SB
D, E—Cross sections after 4 and 0 hours of SB respectively. The dark layer showing grains is the selenium
F—Selenium surface showing oval spots which appear on some kinds of rectifier after SB. Dark area is equivalent to B and C. Light spots of F appear as in G under high magnification where the crystal grains look fire-polished
All except F are magnified 250×, F is 2.5×

small area was isolated electrically by slicing down to the aluminum with a razor blade. After SB the grain growth of the selenium surface which had not experienced the electrical conditions of SB was only about one third that of the rest of the cell. It seems unnecessary to search for more complex explanations than the temperature gradients which must exist between the rectifying junction under SB and any other parts of the cell.

On some cells, stripping the counter-electrode after SB uncovered selenium surfaces on which varying densities of irregular oval spots could be seen. A "negative" effect, Fig. 6(F), could be seen on the inner surface of the counter-electrode. Microscopic studies showed that the oval spots on the selenium were areas over which cadmium selenide had adhered to the counter-electrode while elsewhere it had remained on the selenium during the stripping operation. Moreover, under high magnification, Fig. 6(G), the selenium surface within the spot had a ' fire-polished" aspect.

It was surmised that the aspect of these spots could be explained if there was a sequence of events in which at some early stage a separation occurred between the selenium surface and the "blocking layer" and subsequently this free selenium surface was subjected to high enough temperatures that vaporization of the selenium would fire-polish the crystal grains. This concept was supported by experiments in which the characteristics of Fig. 6(G) were duplicated, first on a stripped selenium surface, open to the air during an SB run on adjacent rectifier area; and second on a similar partly stripped cell in which a piece of mica was laid over the open selenium to simulate, as for the oval spots, the presence of the counter-electrode. In both these cases the selenium appearance obtained was indistinguishable from that in the oval spots, and a deposit of selenium crystals on the mica sheet gave ample evidence of a mechanism involving evaporation of selenium.

Discussion

The phenomena described in the experimental section lead almost immediately to the following analysis of SB. It is based mainly on three facts: 1. that the thermal "runaway" of the rectifier is halted when the cell temperature is at or near the melting point of selenium (220 C), 2. that molten or vitreous selenium has a very high electric resistivity (10^5 to 10^{12} ohm-cm), and 3. that the onset of SB results in high electric resistance appearing suddenly in the cell in a manner peculiarly sensitive to imposed conditions which would normally produce a temperature change. The essential result is that once the cell enters SB a controlling mechanism appears which maintains the cell at almost a constant temperature over a very wide range of electrical or ambient temperature conditions. The "thermostat" is quite simple in function—for any increase in ambient temperature or forward or reverse voltage, the cell resistance increases, and the power dissipated in the cell E^2/R decreases enough to compensate, and vice versa.

It must first be recognized that a high proportion of the electric power dissipated in the cell appears in a very thin layer, the rectifying junction, and physical changes in this layer could completely account for all the observed phenomena. It is not necessary to maintain the junction, and the heat generated, within the selenium. A second semiconductor, such as a metal selenide, which may be naturally[2] or artificially present on the surface, so long as its melting point is higher than that of selenium, could function as the hottest layer. The minimum requirement seems to be that in the region of highest temperature, at the selenium surface, the path of current flow should be obstructed by molten selenium. On the question of how much selenium melts, it might be argued that an extremely thin layer (say 0.1–1 micron) would be enough to account for the increased resistance and that no more than this could be formed without violating the thermostatic principles. Since the selenium is a polycrystalline mass it is unlikely that the current flow or the thickness of the rectifying junction is uniform, so that the regions which melt may be of peculiar shape, as for example thin filaments of grain boundaries. It is possible that the crystal grains themselves are of high resistivity and that the doping impurity is segregated to the grain boundaries, which latter may be the primary current path, either of themselves or through the influence of surface charges on the grains. Whether this is so or not, grain boundaries are probably of prime importance in the melting process postulated since their melting temperatures would be somewhat lower than for the grains. Any extensive melting would be hard to correlate with the rapid reversibility of the phenomenon, and the fact that many hours of running under SB produces extremely large crystals on the selenium surface implies that the surface crystals are not molten during this time. In view of the claim by Burke[3] (brought to the author's attention by U. Martius) that melting of grain boundaries prevents grain growth, grain boundary melting below the uppermost layer of grains is not indicated.

If the controlling mechanism depends upon a very small amount of molten selenium at the rectifying junction (and the amount need not vary much to cover the experimental range of conditions), the essentially constant temperature of the cell can be easily understood. This is best observed with heat-transfer conditions from the cell to its environment held constant when, as described previously, it is found that the power dissipated within the cell is controlled at a constant value in spite of changes in the forward or reverse voltage. The change in the amount of molten selenium necessary to adjust the cell resistance would not be readily detectable since the structure and temperature distribution in the cell are not significantly modified.

From the treatment of data given in Table I it would appear that, if one regards the rectifier as an aggregate of parellel current carriers, the increased melting of selenium has the effect of removing some of the parallel conduction from the system. The picture would be a little more pleasing if the conductance removed had the identical nonlinear characteristic of the cell as a whole at the moment of change, but the evidence at present favors, if anything, a conductance which is about the same for forward and reverse. This may mean that in the general inhomogeneity of the rectifying junction the regions that will be involved in a change of SB conditions are those which are least rectifying in character, i.e., those which have deteriorated the most in rectifying ability.

In addition to inhomogeneities on a microscopic scale there are certainly larger scale irregularities, commonly thought of as "hot spots." It is convenient to explain some of the secondary phenomena of SB with the aid of hot spots. The presence of two peaks in the reverse current as a cell moves into SB may be explained as follows. During the thermal runaway the hot spots, being highest in temperature, are the first areas to reach the SB condition, and are therefore the first areas to change from contributing largely to reverse current to passing much smaller currents. Thus the large, first peak seen in the reverse current would represent the most "leaky" areas of a cell reaching the SB condition. The second peak, which is quite variable in form and size, seems to represent first the continued increase of reverse current through areas which are still rising in temperature, and finally the fall in reverse current when the total rectifying area enters SB. This idea is made more plausible by the fact that a distinct and rapid change in the forward characteristic occurs only at the second peak. Thus it is possible to observe two steps in the development of SB; in the first, only a part of the cell is involved and the main changes are in the reverse characteristics, in the second, the whole cell participates and forward and reverse changes are simultaneously observed. An experiment has been described which represents part of this process. When the cell enters SB at a slow rate, as when the ambient temperature is slowly changing and the power input is low, the second peak may not be observed. Under these conditions the effect of hot spots would be less obvious since there is time for the cell temperature to become more uniform.

For a time it was thought that the creation of the "oval spots" on the selenium surface was a necessary event coincident with the first main peak in the reverse current, i.e., hot spots were irreversibly being removed by open circuit. However, it appears that the oval spots are not always present, and whether or not they represent an irreversible change, the observed electrical phenomena are always about the same, and essentially reversible; which is, perhaps, to say that there are various kinds of hot spots always available, as would be expected.

The experiments analyzing the freezing and melting of selenium may be discussed from several viewpoints. When the voltage input to the cell is suddenly reduced, the cell does not adjust instantaneously. Nor does the freezing process deliver heat to the cell rapidly enough to maintain constant temperature until the correction of cell resistance returns the power dissipation to the SB level. The change in temperature experienced by the cell would seem to violate the steady state requirements of an equilibrium temperature controlled by a phase change until it is realized that the cell continues to exist in SB by virtue of the presence of insulating selenium rather than through the temperature *per se.* Transient conditions can result in temporary supercooling of the melt without changing the electrical properties, upon which the supercooling drives the system back to equilibrium at a rate controlled by the crystallization velocity.

It is possible that the major part of the difference in velocity between crystallizing and melting is caused by the difference in times required to orient and disorient selenium chains which exist in both the liquid and the solid state. However, both of the processes are probably influenced by diffusion of impurities at the interface between solid and liquid in view of two experimental facts: the slight overshoot of temperature in the melting transient and the fact that the steady-state temperatures before and after a voltage step differ by tenths of a degree centigrade; see Fig. 5(A) for example

Attempts were made to calculate the mass of selenium involved in the melting and freezing processes from the electrical energy increments in the transient conditions. However, it was never possible to estimate the energy involved in heat transfer to the environment sufficiently well to identify convincingly the energy used in melting a few milligrams of selenium (0.065 joule per milligram).

Recent work by one of the authors has shown that the phenomenon which has been described in this paper provides an almost complete explanation of creep and forming effects in the selenium rectifier.

Conclusions

A unique phenomenon in selenium rectifiers is described and analyzed. The rectifier is subjected to overload conditions and after a thermal runaway suddenly stabilizes near the melting temperature of selenium. Under the stabilized condition it is hypothesized that the rectifier is held at almost constant temperature under a wide range of electrical and ambient conditions by a sensitive mechanism which compensates for a change imposed on the cell by melting or freezing selenium. This adjusts the cell resistance and thereby the electric power dissipation in the cell.

The Effect of Source and Sink Thermal Resistance on Thermoelectric Generator Performance

P. E. GRAY
NONMEMBER AIEE

A STATIC ANALYSIS of the thermoelectric generator is necessary in order to specify the electrical loading condition for maximum energy conversion efficiency and to determine the corresponding efficiency. Ioffe has done this for the simple case of a single *p-n* junction thermocouple, and his analysis has been extended to include the effect of temperature dependent parameters by Borrego, Lyden, and Blair.[1,2] Harman has considered a cascade generator and has shown how its design can be optimized.[3]

All previous writers on the subject have assumed that the temperatures of the thermal source and sink are fixed. It is also of interest to investigate the static analysis of a thermoelectric generator for the more realistic case in which the source and sink temperatures are not fixed but depend upon the heat flows from the source and to the sink. This case of nonideal thermal sources becomes of greater importance as the conversion efficiency of the device is increased, since the electrical loading will then have a greater effect on the heat flows and thus on the temperatures at the ends of the couple.

The purpose of this paper is to analyze the static performance of a thermoelectric generator which operates between a thermal source and a thermal sink having nonzero thermal resistances. In particular, the dependence of junction temperatures and heat flows on electrical loading is determined. Also, the effect upon the condition for optimum loading and upon the optimum efficiency is assessed. It is shown that the corrections produced by this analysis are not negligible in several numerical examples.

The Device Model

The model which has been studied is shown in Fig. 1. T_h and T_c represent the fixed zero-heat-flow temperatures of the source and sink respectively. T_l and T_0 represent the corresponding temperature of the hot and cold junctions. P_l and P_0 are the heat flows out of the source and sink, and R_h and R_c are the thermal resistances of the source and sink respectively. It was assumed that the temperatures and heat flows can be related by the following equations

$$T_l = T_h - R_h P_l \qquad \text{(1A)}$$

$$T_0 = T_c - R_c P_0 \qquad \text{(1B)}$$

These linear relationships between junction temperatures and the power flows may be regarded as the first terms of power series expansions of the junction temperatures. They are assumed to be adequate approximations for the case being considered.

It is also assumed that the thermal conductivities of the two legs of the couple k_1 and k_2, the electrical resistivities ρ_1 and ρ_2, and the Thomson coefficients, τ_1 and τ_2, are not functions of temperature. The Peltier coefficients of the two junctions are $\pi_l = \alpha_l T_l$ and $\pi_0 = \alpha_0 T_0$ where α_l and α_0 are the Seebeck coefficients of the two junctions, which will be functions of temperature. The two legs of the couple are of uniform cross-sectional areas A_1 and A_2 and are both of length l. The electrical terminal voltage and current are E and I respectively.

Determination of Junction Temperatures and Heat Flows

It is first necessary to determine the heat flows P_l and P_0, as functions of the junction temperatures T_l and T_0, and of the electric current I. This problem has been solved for the one-dimensional case in which the total Thomson heat is small compared to the conduction heat.[1] This assumption with the results thus obtained will be used here in the following forms

$$P_l = \alpha_l T_l I + \left(\frac{k_1 A_1}{l} + \frac{k_2 A_2}{l}\right)(T_l - T_0) + \frac{1}{2} I(\tau_1 - \tau_2)(T_l - T_0) - \frac{1}{2} I^2 \left(\frac{\rho_1 l}{A_1} + \frac{\rho_2 l}{A_2}\right) \qquad \text{(2A)}$$

$$P_0 = -\alpha_0 T_0 I - \left(\frac{k_1 A_1}{l} + \frac{k_2 A_2}{l}\right)(T_l - T_0) + \frac{1}{2} I(\tau_1 - \tau_2)(T_l - T_0) - \frac{1}{2} I^2 \left(\frac{\rho_1 l}{A_1} + \frac{\rho_2 l}{A_2}\right) \qquad \text{(2B)}$$

Equations 2 can now be written in the following forms which will be more useful for our purposes

$$P_l = g_{ll} T_l - g_{l0} T_0 - p_l \qquad \text{(3A)}$$

$$P_0 = -g_{0l} T_l + g_{00} T_0 - p_0 \qquad \text{(3B)}$$

in which the six coefficients are defined as

$$g_{ll} = \alpha_l I + \frac{1}{R_E} + \frac{1}{2} I(\tau_1 - \tau_2) \qquad \text{(4A)}$$

$$g_{l0} = \frac{1}{R_E} + \frac{1}{2} I(\tau_1 - \tau_2) \qquad \text{(4B)}$$

and

$$g_{00}=-\alpha_0 I+\frac{1}{R_E}-\frac{1}{2}I(\tau_1-\tau_2) \qquad (5A)$$

$$g_{0l}=\frac{1}{R_E}-\frac{1}{2}I(\tau_1-\tau_2) \qquad (5B)$$

$$p_0=\frac{1}{2}I^2r_E \qquad (5C)$$

Here two coefficients, R_E and r_E, have been defined for convenience, which are the total thermal resistance of the couple (two legs thermally in parallel) and the total electric resistance of the couple (two legs electrically in series) respectively

$$R_E=\frac{1}{\frac{k_1A_1}{l}+\frac{k_2A_2}{l}}=\frac{1}{\frac{k'A_1}{l}} \qquad (6)$$

$$r_E=\frac{\rho_1 l}{A_1}+\frac{\rho_2 l}{A_2}=\frac{\rho' l}{A_1} \qquad (7)$$

The latter forms of the foregoing equations express the thermal and electric resistances in terms of equivalent conductances and resistivities which will be useful later and which are defined by the following equations

$$\rho'=\rho_1+\frac{\rho_2}{Q} \qquad (8A)$$

$$k'=k_1+k_2Q \qquad (8B)$$

where Q is the area ratio

$$Q=\frac{A_2}{A_1} \qquad (9)$$

Equations 1 and 3 constitute a set of four linear algebraic equations in four unknowns T_l, T_0, and P_l, and P_0, and can be solved simultaneously for the four dependent variables. The equivalent circuit interpretation of this problem is shown in Fig. 2.

The solution of equations 1 and 3 for the heat flows is straightforward and the results are shown below:

$$P_l=\frac{P_{lf}(1-yR_Eg_{00})+P_{0f}(yR_Eg_{l0})}{(1+xR_Eg_{ll})(1+yR_Eg_{00})-(xR_Eg_{0l})(yR_Eg_{l0})} \qquad (10A)$$

$$P_0=\frac{P_{0f}(1-xR_Eg_{ll})+P_{lf}(xR_Eg_{0l})}{(1+xR_Eg_{ll})(1+yR_Eg_{00})-(xR_Eg_{0l})(yR_Eg_{l0})} \qquad (10B)$$

Some comment on the notation is necessary at this point. The subscript f on P_{lf} and P_{0f} in equations 10 means that these expressions are to be evaluated according to equations 2 with the understanding that the fixed temperatures T_h and T_c are to be used in place of T_l and T_0 respectively. Furthermore, the dimensionless parameters x and y represent the thermal resistances of the source and sink normalized to the thermal resistance of the couple which is defined by equation 6. That is,

$$x=R_h/R_E \qquad (11A)$$

$$y=R_c/R_E \qquad (11B)$$

The dependence upon x and y which is found in equations 10 is sufficiently complicated to make the subsequent analysis very complicated and difficult to interpret. Therefore it is desirable to make an approximation at this point which will simplify these expressions. Specifically it shall be assumed that x and y are small compared to unity. Now if the coefficients of x and y in equations 10 are not large compared to unity, terms in the denominator of order x^2, y^2, and xy can be dropped, and the linear terms expanded by the binomial theorem. After multiplying out and again dropping terms of second order or higher the following linear relations are obtained:

$$P_l\simeq P_{lf}(1-xR_Eg_{ll})+P_{0f}(yR_Eg_{l0}) \qquad (12A)$$

$$P_0\simeq P_{lf}(xR_Eg_{0l})+P_{0f}(1-yR_Eg_{00}) \qquad (12B)$$

In order to test the validity of this approximate expansion, second-order terms have been examined for the case in which the Peltier heat terms in equations 4 and 5 are 40% of the conduction terms and the Thomson heat terms are 10% of the conduction terms. These assumed values are large enough so that the estimate of error will be conservative for thermocouples with figures of merit as large as 3×10^{-3} even under short-circuit conditions. For the numbers chosen the error in P_0 and P_l made by neglecting terms in x^2, y^2, and xy in the expansion is less than 5% if $x=y=0.1$. Since this represents an upper bound on the error for practical thermocouples, it can be concluded that the approximations contained in equations 12 are not severe.

Equations 12 can now be substituted into equations 1 in order to determine the junction temperatures. To the first order in x and y these are

$$T_l=T_h-xR_EP_{lf} \qquad (13A)$$

$$T_0=T_c-yR_EP_{0f} \qquad (13B)$$

This completes the determination of the approximate junction temperatures and heat flows in the presence of source and sink thermal resistance. We have succeeded in expressing these quantities in such a way that all dependencies upon the electric current I are explicit. This was not true for equations 2 since the temperatures T_l and T_0 were at that point implicit functions of current. It should be noted at this point that the implicit dependence of α_l and α_0 on current through their temperature dependence has been ignored. This has been done because it is difficult to generalize about the temperature dependence of the Seebeck coefficient and also such a generalization would have led to equations relating heat flow and junction temperature which were nonlinear or transcendental. Furthermore, the error thus made is certainly small in a practical thermocouple.

Effect upon Terminal Volt-Ampere Characteristics

The effects of x and y, the normalized source and sink thermal resistances upon the terminal volt-ampere characteristics of the generator can readily be assessed by applying the principle of conservation of energy, which requires that

$$P_I+P_0=EI \tag{14}$$

When equations 12 are substituted into equation 14 a factor of I can be eliminated after considerable algebraic manipulation, and the following result is obtained for the terminal voltage

$$E=E_0-Ir+I^2s \tag{15}$$

E_0 the open-circuit voltage, r the coefficient of the linear term, and s the coefficient of the quadratic term are given by the following expressions

$$\begin{aligned}E_0=&(\alpha_l+\tau_1-\tau_2)[T_h-x(T_h-T_c)]-\\&(\alpha_0+\tau_1-\tau_2)[T_c+y(T_h-T_c)]\end{aligned} \tag{16}$$

$$\begin{aligned}r=r_E+&[xR_E\alpha_lT_h(\alpha_l+\tau_1-\tau_2)+\\&yR_E\alpha_0T_c(\alpha_0+\tau_1-\tau_2)]+\\&[xR_E(\alpha_l+\tau_1-\tau_2)-yR_E(\alpha_0+\tau_1-\tau_2)]\times\\&\left[\frac{1}{2}(\tau_1-\tau_2)(T_h-T_c)\right]\end{aligned} \tag{17}$$

$$s=\frac{1}{2}r_E[xR_E(\alpha_l+\tau_1-\tau_2)-yR_E(\alpha_0+\tau_1-\tau_2)] \tag{18}$$

As is clear from equations 14–18, the effects of thermal resistance on the volt-ampere characteristics are threefold:

1. The open-circuit voltage is reduced because of the temperature drop in the thermal resistances caused by conduction heat flow.
2. The apparent electric resistance is increased because of the additional temperature drop in the thermal resistances because of the Peltier heat flow (second term); and may be either increased or decreased for the same reason by Thomson heat flow (third term).
3. A nonlinear contribution to the terminal voltage is caused by the temperature drops in the thermal resistances because of Joulean heat flow.

In order to assess the relative importance of these three effects, numerical results have been obtained for a simple example in which the Thomson heat is neglected and the parameters shown in the Nomenclature apply.

When these numerical parameters are substituted into equations 16–18 the following expressions result:

$$\begin{aligned}&E_0=120(1-x-y)\text{ millivolts}\\&r=2+3.2x+1.6y\text{ milliohms}\\&s=13.3\times10^{-3}(x-y)\text{ millivolts/ampere}^2\end{aligned} \tag{19}$$

In Fig. 3 terminal-volt-ampere curves are shown for the generator previously described corresponding to the four choices of normalized thermal resistance indicated on the curves. For the numerical values shown $R_E=33$ K (degrees Kelvin)/watt. The dashed lines in Fig. 3 show the resulting curves for cases B and C if the quadratic term in equation 15 is ignored. It is clear from these curves that the quantitative effect of this term is not large, particularly at currents near the normal operating current of the generator. For example, if $I=20$ amperes, the error in voltage made by neglecting the quadratic term is less than 1% for both cases B and C. On the other hand, the quantitative effect of the increase in r is not negligible and would lead to an error in voltage of about 9% at $I=20$ amperes if it were neglected.

Calculation of Optimum Current

One would now like to determine the effect of the normalized thermal resistances upon the condition for optimum loading of the generator. This can be accomplished by determining the value of current, I, which maximizes the conversion efficiency of the generator. Defining the efficiency η as the electric power output per unit heat input one has

$$\eta=\frac{EI}{P_I}=\frac{E_0I-rI^2+sI^3}{P_{If}(1-xR_Eg_{Il})+P_{0f}(yR_Eg_{I0})} \tag{20}$$

One can maximize this efficiency by the usual procedure of setting $d\eta/dI$ equal to zero. The resulting expression for the optimum current is fifth order in I, and one must resort to numerical methods to extract a root. Therefore, it appears desirable at this point to make a further approximation which will reduce the order of the equation that must be solved to yield I_0, the optimum current.

The numerical example discussed in the previous section suggests one approximation which will reduce the order of the numerator of equation 20. It was pointed out then that for currents of the order of one-half the short-circuit current, the error in terminal voltage made by dropping the quadratic term was less than 1%. Therefore, the corresponding term will be neglected in the numerator of the efficiency expression.

Even with the foregoing approximation the problem is formidable and some simplification of the denominator is also necessary. When equations 2 and 4 are substituted in the denominator of equation 20 (using fixed temperatures T_h and T_c), and the resulting multiplications are carried out, it is found that the troublesome terms in I^2 and I^3 arise physically from the products of Peltier heat coefficients, Thomson heat coefficients, and Joulean heats. Accordingly a reasonable approximation would be to neglect terms such as these which in practical thermocouples are certainly small in comparison to products involving the conduction heat coefficient.

When these simplifying approximations are made the resulting equation for I_0 can be shown to be a quadratic since the coefficient of the cubic term reduces to zero. This equation for I_0 is

$$\begin{aligned}I_0^2\Big[-\frac{1}{2}&E_0r_E(1-x-y)+r\{\alpha_lT_h(1-x)-\\&\alpha_0T_0y-\alpha_l(T_h-T_c)x\}+\\&\frac{1}{2}(\tau_1-\tau_2)(T_h-T_c)(1-2x)\Big]+\\&I_0\left[2r\frac{(T_h-T_c)}{R_E}(1-x-y)\right]+\\&\left[-E_0\frac{(T_h-T_c)}{R_E}(1-x-y)\right]=0\end{aligned} \tag{21}$$

Equation 21 can be solved by formula for the optimum current which will maximize the efficiency. In order to reduce the algebraic complexity involved in doing this it will be assume that Thomson heat is negligible. In this case $\tau_1=\tau_2=0$ which implies that $\alpha_l=\alpha_0=\alpha$.

After making the approximations just outlined and dropping terms higher than first order in x and y the solution to equation 21 can be put in the following form by considerable algebraic manipulation

$$I_0=I_{00}[1-\epsilon(x,y)] \tag{22}$$

where

$$I_{00}=\frac{\alpha(T_h-T_c)}{r_E(M+1)} \tag{23}$$

and

$$\epsilon(x,y)=(x+y)+(xT_h+yT_c)Z\left(\frac{\frac{1}{2}ZT_h+M}{M(M+1)}\right) \tag{24}$$

In these equations Z, $\bar{T}$, and M have their usual definitions[1]

$$Z=\frac{\alpha^2R_E}{r_E}=\frac{\alpha^2}{\rho'k'} \tag{25A}$$

$$\bar{T}=(T_h+T_c)/2 \tag{25B}$$

$$M=\sqrt{1+Z\bar{T}} \tag{25C}$$

Table I. Comparison of Actual and Predicted Values of Optimum Current and Efficiency

Curve	x	y	Current at Maximum Efficiency, Amperes	I_0, Amperes	Maximum Efficiency, %	η_0, %

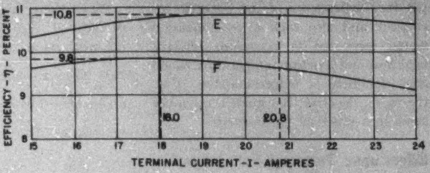

Fig. 4. Efficiency-current curves

E—$x=0.03$, $y=0.05$
F—0.10, $y=0.05$
Note supressed zeros

It is clear from equation 22 that the optimum load current is invariably reduced in the presence of thermal resistance. Equation 23 agrees with the results obtained by Ioffe for the zero-thermal resistance case although his analysis was put in terms of an optimum load resistance. Since the optimum load resistance is MR_E, and since $\alpha(T_h-T_c)$ is the open-circuit voltage, the current at the optimum point, which is the open-circuit voltage divided by the total resistance, is given by equation 23.

In the case of thermoelectric generators which use materials having a small figure of merit Z, the second term in equation 24 vanishes and the correction factor in equation 22 is simply $(1-x-y)$. To the first order in x and y this is the correction one would obtain if the junction temperatures T_l and T_0 were assumed to differ from the source and sink temperatures T_h and T_c only by the drop in the source and sink thermal resistances caused by the flow of conduction heat. The second term is therefore the consequence of a change in junction temperatures because of loading and becomes of greater importance as the figure of merit becomes larger.

The results presented in this section will be discussed in terms of two simple numerical example in the section on "Evaluation of Results." First we must consider the effect of thermal resistance on the optimum efficiency of the generator.

Calculation of Optimum Efficiency

The results of the preceding section can be used to evaluate the efficiency of the generator at the optimum current point. It is simply necessary to substitute equation 22 for the optimum current in equation 20 which expresses the efficiency as a function of current. Note that the cubic term in the numerator and certain quadratic and cubic terms in the denominator of equation 20 are neglected for the reasons discussed in the preceding section. The result of this substitution, correct to terms of first order in x and y, can be shown to be the following after considerable algebraic manipulation

$$\eta_0=\eta_{00}[1-\delta(x,y)] \tag{26}$$

$$\eta_{00}=\frac{(T_h-T_c)(M-1)}{T_h(M+T_c/T_h)} \tag{27}$$

$$\delta(x,y)=(x+y)\left[\frac{2M+1}{M}-2\frac{\dfrac{T_c}{T_h}+\dfrac{1}{M}}{\dfrac{T_c}{T_h}+M}\right]-$$
$$x\left[\frac{ZT_h}{2M}\,\frac{1-T_c^2/T_h^2}{M+T_c/T_h}\right]+$$
$$(xT_h+yT_c)Z\left[\frac{M-1}{M(M+T_c/T_h)}\right] \tag{28}$$

In these equations Z and M are as defined in equations 25(A) and (C). Note that the efficiency for the zero thermal resistance case, which is given by equation 27 agrees with results obtained by Ioffe. It is easy to show that equation 28 is non-negative for all non-negative values of x and y, so that the efficiency is invariably reduced in the presence of thermal resistance.

Again in the case of a thermoelectric generator fabricated of materials having a small figure of merit, Z the second and third terms in equation 28 become negligibly small. Furthermore, since M approaches unity the first term approaches $x+y$, and the correction factor in equation 26 is simply $(1-x-y)$. To the first order in x and y this is the correction one would obtain if the junction temperatures T_l and T_0 were assumed to differ from the source and sink temperatures T_h and T_c only by the drop in the source and sink thermal resistances caused by the flow of conduction heat. Therefore the second and third terms are consequences of the additional dependence of the junction temperatures upon the electrical loading through the Peltier heat and Joulean heat. They become of greater importance as the figure of merit is increased.

Note that the area ratio Q, which was defined by equation 9, has not yet been specified. To do so precisely would be difficult because not only is M a funtion of Q but also x and y, the normalized thermal resistances, are functions of Q for fixed value of R_h and R_c. Therefore, we will assume that the area ratio should be chosen in such a way as to maximize M, which will result in the maximum value of η_{00}. This is of course the same condition obtained by others[1,2] and requires the following value of Q.

$$Q=\left(\frac{\rho_2k_1}{\rho_1k_2}\right)^{1/2} \tag{29}$$

The results obtained in this section will be discussed for two simple numerical examples in the following section.

Evaluation of Results

The results of the preceding two sections will be checked by direct calculation of the efficiency versus current curves for two simple numerical examples in this section. Using the numerical parameters defined in the section on "Effect Upon Terminal Volt-Ampere Characteristics," curves of efficiency as a function of current have been computed directly from equation 20 without approximation for the two sets of values of x and y shown in Table I. The curves thus obtained are shown in Fig. 4 and the resulting values of optimum current and efficiency have been entered in Table I. Also the values of I_0 and η_0 predicted by equations 22 and 26 are shown in Table I. For comparison, I_{00} and η_{00} are 24.2 amperes and 12.1% respectively.

In general, the agreement between the actual values computed without approximation and the approximate values predicted by the results of the preceding two sections is quite good. It is clear from the values of I_{00} and η_{00} that large errors will be made if the junction temperatures are simply assumed equal to the internal source and sink temperatures. If on the other hand first-order corrections for the flow of conduction heat are made as previously discussed, the resulting values of I_0 and η_0 are 22.3 amperes and 11.1% respectively for case E and 20.6 amperes and 10.3% respectively for case F. In the case of the determination of optimum current, the results of this partial correction are still in error by amounts of about

7 and 14% for cases E and F respectively. In this case the complete first order correction presented in the section on "Calculation of Optimum Current" reduces the errors to less than 2% in both cases. In the case of the determination of optimum efficiency the errors are larger. The partial correction predicts an efficiency which is too large, whereas the complete first-order correction of the preceding section predicts an efficiency which is too small by about the same amount. The poorer agreement with regard to efficiency is apparently due to the neglect of higher order terms in the expansion in x and y. This conclusion is substantiated by the fact that the error is greater in case F than in case E and the second-order terms in x are larger in case F.

Since the efficiency-current curves of Fig. 4 are quite flat in the region near the maximum the question of the precise specification of an optimum value of load current may be somewhat academic. This is a consequence of the relatively low efficiency of practical thermoelectric generators and is present in the previously studied case. It is nevertheless desirable to know what constitutes optimum loading and approximately what optimum efficiency can be attained in any practical device and for this reason the preceding analysis is necessary.

Nomenclature

T_h, T_c = zero heat flow temperatures of heat source and heat sink
T_l, T_0 = temperatures of hot and cold junctions
P_l, P_0 = heat flows out of source and sink
R_h, R_c = thermal resistances of source and sink
k_1, k_2 = thermal conductivities of legs 1 and 2
$\rho_1 \rho_2$ = electrical resistivities of legs 1 and 2
τ_1, τ_2 = Thompson coefficients of legs 1 and 2
π_l, π_0 = Peltier coefficients of hot and cold junctions
α_l, α_0 = Seebeck coefficients at hot junction temperature and cold junction temperature
A_1, A_2 = cross-sectional areas of legs 1 and 2
l = length of active material
E = terminal voltage
I = terminal current
R_E = total thermal resistance of the couple
r_E = total electrical resistance of the couple
ρ' = equivalent electrical resistivity
k' = equivalent thermal conductivity
Q = ratio of the area of leg 2 to the area of leg 1
x, y = thermal resistances of source and sink normalized to the thermal resistance of the couple
E_0 = open-circuit voltage of the couple
r = coefficient of the electric current in the expression for the terminal voltage
s = coefficient of the square of the current in the expression for the terminal voltage
η = conversion efficiency of the generator
η_0 = optimum conversion efficiency
I_0 = optimum load current
Z = figure of merit of the couple
$\bar{T}$ = average of the heat source and heat sink temperatures
M = ratio of optimum load resistance to generator resistance for the zero thermal resistance case

REPRESENTATIVE PARAMETER VALUES

$l = 1$ cm (centimeter)
$A_1 = A_2 = 1$ cm^2
$k_1 = k_2 = 1.5 \times 10^{-2}$ watts/cm-K
$\rho_1 = \rho_2 = 10^{-3}$ ohm-cm
$-\alpha_1 = \alpha_2 = 200$ microvolts/K
$\alpha_l = \alpha_0 = 400$ microvolts/K
$T_h = 600$ K
$T_c = 300$ K
$Z = 2.66 \times 10^{-3}$ (K)$^{-1}$

The Effects of Nuclear Radiation on the Electrical Strength of Air

G. I. DUNCAN

B. VALACHOVIC
NONMEMBER AIEE

WITH THE EMPHASIS today upon extended environmental conditions for electronic equipment used in military aircraft and guided missiles, there is a pressing need for the simultaneous testing of such equipment under two or more of these extreme environments. This paper describes a program completed by the General Electric Company covering the testing of spark gaps in the Brookhaven National Laboratory's graphic reactor. It consisted of a 2-week in-pile exposure designed to investigate the voltage breakdown strength of air at various pressures in the presence of intense nuclear radiation of the following approximate levels:

Fast flux: 1×10^{11} fast neutrons per cm^2-sec (centimeter^2-seconds)
Thermal flux: 2×10^{12} thermal neutrons per cm^2-sec
Gamma flux: 1×10^{13} gamma photons per cm-sec^2

Present environmental goals as established by the U.S. Air Force for electronic power transformers are 100,000-foot altitude, 500 C (degrees centigrade) ambient temperature, and intense nuclear radiation, approximating the levels previously mentioned. Since terminal spacings have formerly been designed for air electric strengths to approximately 50,000 feet and temperatures up to 125 C, additional information was required on breakdown voltages under these new conditions.

Previous work on determining the voltage spacing characteristics as a function of air density up to altitudes of 150,000 feet[1] has not included high temperature or radiation. A search of the literature revealed little or no information on the subject. Consequently, an experiment was designed and conducted to obtain this information.

Test Variables and Levels

The electrical breakdown strength of air is dependent upon air density, electrode spacing, electrode material, electrode configuration, frequency of voltage, and rate of increase of voltage.

To gain the maximum amount of information, it was decided to obtain data for three levels of gap spacing and three levels of air pressure, with and without radia-

tion. The gap spacings selected were 1/16 inch, 1/8 inch, and 1/4 inch. Rod electrodes were selected for the gaps as it was felt that they would more closely approach the nonuniform fields normally encountered with terminals than would other types of gaps.

Air pressure was selected as a variable instead of air density because in free space the air pressure is not affected by changes in temperature, whereas temperature does affect air density. Air pressure can be directly related to altitude independent of temperature. The air pressures originally selected were 760, 76, and 7.6 mm (millimeters) of mercury which correspond roughly to sea level, 50,000-foot altitude, and 100,000-foot altitude respectively.

Voltage breakdown and d-c conductivity measurements were made on the spark gaps in a simulated reactor mock-up for the no-radiation condition, and in the Brookhaven National Laboratory for radiation conditions.

Because of random variations in breakdown voltage, a spark gap can be expected to give only approximate values. To obtain reasonably correct values of breakdown voltage, the average of a number of measurements was taken.

Test Specimen

Two independent, identical test specimens were built and used to insure test reliability; see Figs. 1 and 2. Each specimen consisted of an electrode holder having three gaps in a hermetically sealed stainless steel cylinder. The gap electrodes were made from 1/8-inch-diameter nickel spark plug electrodes, the faces of

which were machined flat to eliminate rounded edges. They were held in place by sheets of 1/8-inch-thick aluminum phosphate bonded muscovite mica separated by 1/4-inch-thick aluminum spacers. All electrodes on one side of the assembly, and the aluminum spacers, were connected to a stainless steel ground strap, which was resistance-welded to the front end of the test cylinder. The mica sheet on the high-voltage side of the assembly was threaded for ease in adjusting the gaps; gage blocks were used to set the gaps.

The test cylinder for each assembly consisted of a 3-inch outside diameter, a 0.065-inch-thick 7-inch-long stainless steel cylinder, with a stainless steel cap welded into each end. Two wall tubes, 1/4-inch in outside diameter, 0.035-inch thick, for the dynamic pressure system were arc-welded into the front end cap. Three alumina ceramic hermetic terminals were brazed into the front cap with the use of a 5% silver, 95% cadmium brazing alloy. The high-voltage leads for the gaps were brought out of the cylinder through these terminals. A small stainless steel screw was projection-welded to the front cap for use as a ground terminal. Both caps were arc-welded into the ends of the stainless steel cylinder.

Electric connections between the high-voltage electrodes and the hermetic terminals were made with 1/32-inch silicone rubber-insulated American Wire Gage no. *18* solid copper conductor, using mechanical connectors at the electrodes, and silver brazing to the terminals. The high-voltage leads from the terminals to the outside wall of the reactor consisted of a short length of the copper wire described above, brazed to 1/16-inch aluminum conductors insulated with a 3/64-inch wall of silicone rubber.

Instrumentation

Because of the inaccessibility of the spark gap cylinders in the reactor, remote instrumentation was required. Fig. 3 shows the circuit used for the breakdown tests. A conventional instrument-type potential transformer was used in reverse to supply the high voltage. The normal transformer secondary was used as the input in this application and a General Electric Company type *P3* voltmeter was used to measure the input voltage. In the output side of this potential transformer, which is normally the primary side, there was a limiting resistor to prevent excessive load on the transformer when the spark gap should break down.

A cathode-ray oscilloscope was used to

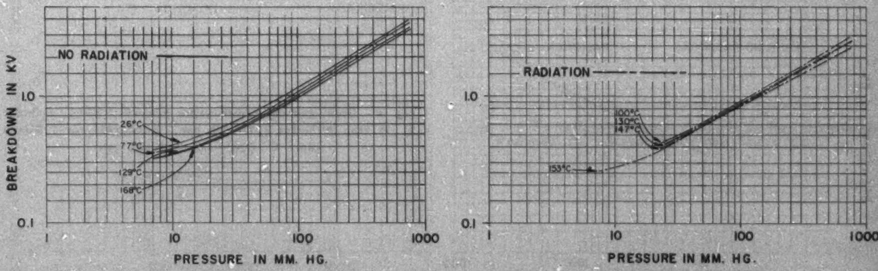

Fig. 8. Spark gap breakdown versus pressure for 1/16-inch gap. A (left)—With no radiation. B (right)—During radiation

indicate breakdown through the change in spark gap voltage waveshape. The voltage control on the input side of the transformer consisted of two variable voltage autotransformers connected to give coarse and fine control.

The d-c conductivity measurements were made using a Keithley d-c vacuum-tube voltmeter of the electrometer type as the basic measuring element. This is a battery-operated unit which measures direct voltage directly; it measures current in conjunction with a decade shunt. These measurements were made at approximately 90 volts direct current. A schematic diagram of the circuit used for insulation resistance measurements is shown in Fig. 4.

Temperature measurements were made using a chromel-alumel thermocouple located in the test container midway between the two test cylinders. Because of the gamma heating effect upon cylinder materials, particularly the stainless steel, test cylinder temperatures increased at a gradual rate throughout the test up to 153 C. Temperature measurements made in the *E-52* hole previous to the start of this test showed a hole temperature of approximately 70 C.

Dynamic Pressure System

To establish and to measure the pressure necessary to simulate the various altitudes desired in the spark gap breakdown tests, a dynamic pressure system was selected. The reasons for this selection were twofold. First, at the low pressure required to simulate a 100,000-foot altitude (approximately 7.6 mm of mercury), water vapor and other volatiles within the test cylinder would cause a drift in pressure if the system were a static one. Second, under both the 50,000-foot and 100,000-foot altitude conditions, the absorbed gases driven off the electrode surfaces at each firing would necessitate constant readjustment of the pressure within a static system. With the dynamic system, equilibrium conditions at the desired pressures were easily established and recovery after transient gas surges was automatic. A continuous flow of room air through the test cylinder also served to flush out any contaminants within the cylinder which might tend to modify the test results.

Fig. 5 shows a schematic diagram of the system used in the spark gap tests. Calibrated restrictions on the inlet and outlet sides of the cylinder were used for each pressure required below atmospheric. For atmospheric measurements in the cylinders, the outlet valves (*V2*, *V3*, and *V4*) were closed, and an inlet by-pass valve (*V1*) opened, so that the vacuum system could continue "pump-down" while atmospheric measurements were being taken. The two test cylinders were connected in parallel during pump-down. The arrangement of pressure valves permitted selection of either cylinder for measurements, as desired.

Simulated Reactor Mock-up Tests

To obtain breakdown voltage and d-c conductivity data on the spark gaps without radiation, a full-scale mock-up of a reactor hole was constructed. Fig. 6 shows a view of this mock-up. It consisted of an aluminum inner duct 1/4 inch thick, 4 by 4 inches inside dimensions, and 18 feet long, to simulate the 4-inch-square test hole in the Brookhaven reactor. By means of strip heaters surrounding the duct, it could be heated to temperatures as high as 200 C, so that reactor hole ambient temperatures could be duplicated.

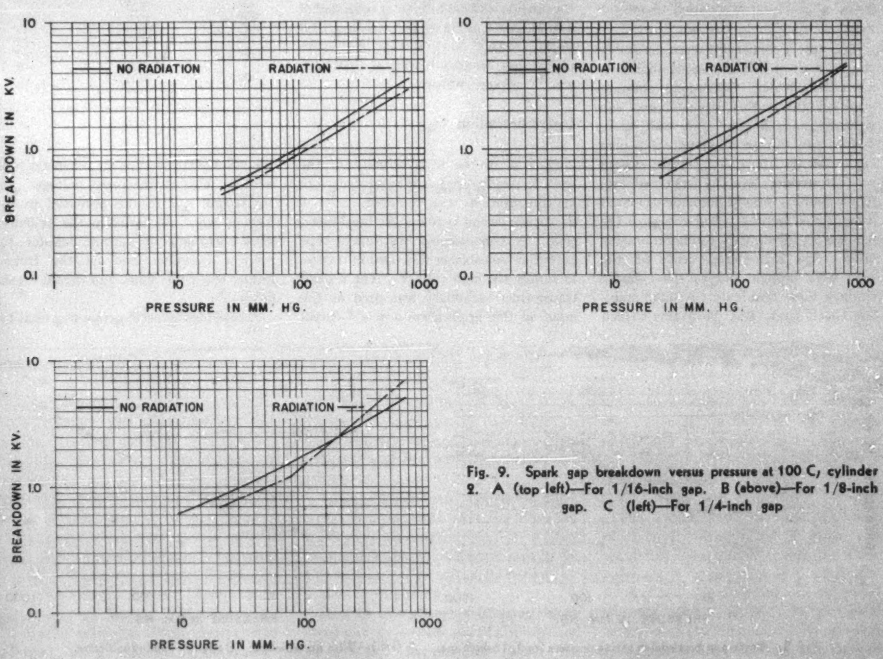

Fig. 9. Spark gap breakdown versus pressure at 100 C, cylinder 2. A (top left)—For 1/16-inch gap. B (above)—For 1/8-inch gap. C (left)—For 1/4-inch gap

Sixty-cycle-per-second breakdown voltage and d-c conductivity tests were performed with the spark gap specimens inserted into the reactor mock-up. Measurements were made at approximately 26, 75, 129, and 169 C, and at approximately 760, 76, and 7.6 mm of mercury.

The data for one of the test cylinders are shown in Tables I and II.

Radiation Tests

The radiation testing was carried on at Brookhaven National Laboratory in the *E-52* hole. Fig. 7 shows the test specimens being inserted into the reactor.

For most of the test, the reactor was operated at 13 megawatts. The test specimens were in the reactor for a total elapsed time of approximately 330 hours. During this test, measurements of breakdown voltage, d-c conductivity, and temperature were made periodically at approximately 760, 76, and 7.6 mm of mercury.

The data for one of the test cylinders are shown in Tables III and IV.

Test Results

To show the effects of nuclear radiation on the electric strength of air, a family of temperature curves was plotted as a function of breakdown voltage and pressure for each gap and condition of radiation. The curves for the 1/16-inch gap in one of the test cylinders are shown in Figs. 8(A) and (B).

From these curves, breakdown voltage versus pressure data were interpolated for specific temperatures. Fig. 9 shows these data plotted for 100 C.

Fig. 10 shows the d-c insulation resistance as a function of pressure for the gaps in one of the test cylinders for both the no-radiation and radiation conditions. The no-radiation data are shown only at 23 C.

Conclusions

The data obtained in the tests and the curves plotted from these data indicate that nuclear radiation at the high intensities investigated had a noticeable effect on breakdown voltage and d-c conductivity of a gap. The data also demonstrated, as expected, that the breakdown voltage of a gap decreases with decreasing pressure (temperature constant) and increasing temperature (pressure constant).

Test results show that under conditions of intense nuclear radiation, spark gap breakdown is lowered about 20%. This is probably due to the effect of photoelectrons during radiation. This effect makes available a large number of electrons in the gap at all times to start ionization, resulting in increased conductivity, and breakdown at lower voltage values.

Earlier investigators of spark gap breakdown found that accuracy could be increased by irradiating the gaps with ultraviolet light, with a resulting reduction in the average value of breakdown voltage by several per cent. It is to be expected that nuclear radiation would have an appreciably greater effect. Since radiation is a form of energy, the probability of photoionization is proportional to the radiation intensity.

There is no logical explanation for the

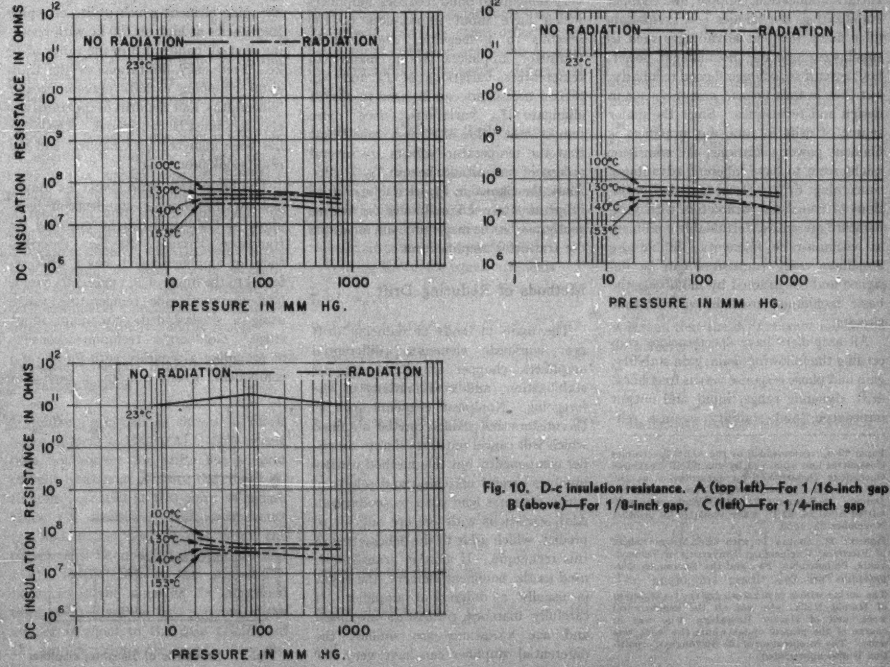

Fig. 10. D-c insulation resistance. A (top left)—For 1/16-inch gap B (above)—For 1/8-inch gap. C (left)—For 1/4-inch gap

crossover of the curves in Fig. 9(C). A close examination of the data under the heading "1/4-Inch Gap" in Table III suggests that the data for the 1/4-inch gap during radiation may be suspect.

Radiation accounted for at least a 3-decade lowering in gap d-c insulation resistance. Changes in d-c insulation resistance, under radiation conditions, as a result of varying temperatures, were less than half a decade.

Knowledge in the field of radiation effects is still sparse. The amount of general information on components under radiation is particularly limited. It is hoped that the experimental data obtained in these tests will serve to shed some light upon the theories advanced, and will be helpful in evaluating and conducting subsequent tests on all types of electronic components. These tests will serve as the basis for a designer to establish safe voltage breakdown distances between terminals, and between terminals and ground, for transformer applications under extreme altitude and radiation conditions.

Stable Transistor Wide-Band D-C Amplifiers

ROBERT H. OKADA
NONMEMBER AIEE

STABLE D-C amplification is required in many engineering applications. In the past, vacuum-tube circuits have been developed which meet most low drift requirements by utilizing differential amplification, chopper, and chopper stabilization techniques. Transistors offer many inherent advantages such as small size, long life, no filament power, low power dissipation and good reliability, but they in turn present new problems in design and techniques. Since the major source of drift in tube d-c amplifiers is filament power variations, the transistor might seem to have inherent advantages concerning drift. However, the variations of transistor parameters with temperature presents as formidable a problem as vacuum-tube filaments. Stable d-c amplifiers using transistors can be designed and constructed by modifying the basic techniques used in vacuum-tube circuits.

All amplifiers have specifications concerning the following: gain, gain stability, gain and phase response versus frequency, drift, dynamic range, input and output impedance, and stability against self-oscillation if feedback is used. Transistors differ from tubes notably in the impedance levels and d-c drift. Although most transistor circuit configurations present a low input impedance, it is not very difficult to build feedback amplifiers which have input impedances of 100 kilohms to 1 megohm. D-c drift in transistor amplifiers is due mainly to temperature variations of I_{co} and V_{be}. Silicon transistors can be used to almost eliminate I_{co} variations, since room temperature value of I_{co} is so small that that the temperature effects are several orders of magnitude below V_{be} effects. Thus, the change in V_{be} with temperature (approximately 2.5 millivolts per degree centigrade) is the major problem for stable d-c transistor amplification.

Methods of Reducing Drift

The main methods of reducing drift are: nonlinear elements, differential amplifiers, chopper amplifiers, chopper stabilization, and combinations of the foregoing. Nonlinear elements such as thermistors and diodes can be obtained which will cancel out drift due to amplifier components, but this method usually involves careful matching and selection, which does not lend itself to production. Also, variations with age are difficult to predict, which adds to the delicateness of this technique. If another transistor is used as the nonlinear element, the result is usually a differential amplifier. If carefully matched transistors are used, and age variations are similar, the differential amplifier can have very low drift. Slaughter presented a differential amplifier which had excellent drift characteristics (due to well-matched transistors).[1] Fig. 1 is a schematic of this amplifier.

Chopper amplifiers, which modulate the input signal at a fixed frequency, amplify the resulting carrier and side bands, and then demodulate, are essentially drift-free, provided the chopper itself is a stable element. Mechanical choppers can be used which introduce negligible drift but are limited in frequency to about 1 kc. The over-all bandwidth of such an amplifier is a few hundred cycles. Transistors can be used as the chopping element which utilize chopping frequencies as high as 100 kc with resulting over-all bandwidth in the range of 10 kc. Frequency limitations of the transistor chopping circuits prevent greater bandwidths, and the drift of the transistor choppers must be considered. The latter has been analyzed by Chaplin,[2] and the results look promising.

To obtain wide-band stable d-c amplification the chopper stabilization technique of Goldberg[3] can be modified for transistor circuits. Blecher describes such an amplifier which has a drift referred to the input of ±5 millivolts over a 50-degree-centigrade temperature range using a single-ended germanium input stage.[4] Goldberg's technique consists of providing a separate path for the d-c component, which contains a high-gain

Vol.
Pt. 1
196

low-drift chopper amplifier preceding the main amplifier.

By a combination of silicon transistor differential amplifier and chopper stabilization, a transistor amplifier can be built with the use of transistors which have normal production spreads of V_{be} temperature variations, and resulting in a drift referred to input of less than one half of a millivolt. By selecting matched V_{be} temperature characteristics the drift can be reduced much farther.

Transistor Operational Amplifiers

The standard voltage operational amplifier is shown in Fig. 2(A) with A_v a voltage gain (negative). The gain of the amplifier is Z_f/Z_i if $|A_v|>>1$ and $Z_1>>(Z_f/A_v)$. For a transistor amplifier the last requirement is usually not true. However, consider the current amplifier in Fig. 2(B). From the Appendix is obtained

$$\frac{I_L}{I_i} \doteq -\frac{Z_f}{Z_L} \text{ if } Z_f \gg \frac{Z_1}{A_i} \text{ and } Z_L \gg \frac{Z_f+Z_1}{1+A_i}$$

and:

$$\frac{E_L}{E_i} = \frac{-Z_f}{Z_i} \text{ if } A_i\beta_i \gg 1,\ A_i\beta_i \gg \frac{2Z_1}{Z_i}, \text{ and}$$

$$\beta_i \equiv \frac{I_f}{I_L} \doteq \frac{Z_L}{Z_f}$$

Thus, for the voltage gain to be the ratio of two impedances, the input impedance at the A_i amplifier terminals should ideally be zero, and a low input impedance transistor amplifier is ideal for an operational amplifier. These equations are a special case of Blecher's results which utilize the short-circuit current gain and source impedance in place of a current amplifier.[4] However, if it is remembered that the value of A_i is a function Z_L (and Z_f in general), these equations are useful because of their simplicity, especially since the above conditions are usually valid in practice.

Possible Chopper Stabilization Configurations

Goldberg's circuit is shown in block diagram form in Fig. 3(A). This circuit does not correct for drifts due to grid current leakage at A since the circuit interprets potential at this point as signal. Since the transistor drift components (I_{co} and V_{be}) appear at this point, the circuit must be modified as shown in Fig. 3(B). If the ratio of the primed impedances is the same as the unprimed ones, point B will be zero potential if the output is equal to the gain (E_0/E_i) of the amplifier times the input. Any discrepancy is due to drift components and the chopper amplifier will attempt to correct for the drift. Incidentally, aside from drift signals appearing at point A, point B is at the same potential as point A, and therefore the primed impedances can be removed and the two points A and B tied together. This reduces Fig. 3(B) to Fig. 3(A) and is an excellent means of explaining to the uninitiated the (at first) puzzling configuration of Fig. 3(A).

The chopper-stabilizing effects are limited (as will be shown later), which makes a differential input stage desirable in order to reduce the amount of stabilization required. In a typical example the V_{be} drift over a range of 70 F (degrees Fahrenheit) to 150 F will be 100 millivolts, which is to be compared with a ΔV_{be} in a differential input stage of 17 millivolts. The 17-millivolt figure is the maximum ΔV_{be} variation of 32 silicon transistors, type *2N479*, over the same temperature range. Thus if these figures are typical of production results, the differential input amplifier has an inherent drift reduction of about 5 to 1 without selection. The differential stage can also supply the high common mode rejection necessary if a single-ended output is required. If silicon transistors are used, the I_{co} effects are negligible compared with V_{be} effects, but the same order of inherent drift reduction applies to I_{co} drift in germanium transistor differential stages.

Analysis of Chopper Stabilization

Fig. 3(C) represents the same circuit as 3(B), in which A_i and A_i' represent actual current gains of amplifiers *G*1 and *G*2, and I_k is the current required to reduce the output to zero because of drift.

Writing Kirchoff's equations yields

$$I_0+I_0'=I_{in} \tag{1}$$

$$-(I_1+I_0+I_f+I_k)A_i=I_f+I_f'+I_L \tag{2}$$

$$-(I_0'+I_f')A_i'=I_1 \tag{3}$$

and if (see the Appendix)

$$Z_L \gg \frac{Z_{in}}{A_i},\ Z_f \gg \frac{Z_{in}}{A_i},\ Z_L \gg \frac{Z_{in}'}{A_i'}$$

and

$$Z_f' \gg \frac{Z_{in}'}{A_i'}$$

$$Z_LI_L=Z_fI_f=Z_f'I_f'$$

and if (see the Appendix)

$$A_i \gg 1,\ A_i' \gg 1,\ Z_i \gg \frac{Z_{in}}{A_i\beta_i} \tag{4}$$

and

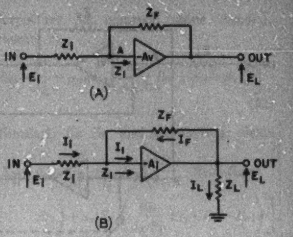

Fig. 2. Operational amplifiers. A—Voltage mode. B—Current mode

$$Z_f' \gg \frac{Z_{in}'}{A_i'\beta_i'}$$

then

$$Z_iI_0=Z_i'I_0' \tag{5}$$

Solving equations 1 and 5 simultaneously yields the load current in terms of the input current

$$I_L=-\frac{Z_f'}{Z_L}\frac{Z_i}{Z_i+Z_i'}\left[I_{in}+\frac{Z_i+Z_i'}{Z_i}\frac{I_k}{A_i'}\right] \tag{6}$$

if, as is usually the case,

$$A_i \gg 1,\ A_i' \gg \frac{1}{A_i},\ \frac{A_i'}{Z_f'} \gg \frac{1}{Z_f}+\frac{1}{AZ_L'},\ \frac{A_i'Z_i}{Z_i'} \gg 1$$

If equation 6 is compared with the analogous result using no chopper stabilization (see the Appendix), i.e.,

$$I_L=-\frac{Z_f}{Z_L}(I_{in}+I_k)$$

if

$$Z_f \gg \frac{Z_{in}}{A_i}$$

and

$$Z_L \gg \frac{Z_f+Z_1}{1+A_i} \tag{7}$$

it is seen that the drift current is reduced by a factor of

$$\frac{Z_i+Z_i'}{Z_i}\frac{1}{A_i'}$$

In terms of voltage, since in Fig. 3(C)

$$E_L=I_LR_L,\ E_{in} \doteq I_{in}\frac{Z_iZ_i'}{Z_i+Z_i'}$$

the output voltage is

$$E_L=-\frac{Z_f'}{Z_i'}\left[E_{in}-\frac{Z_i'I_k}{A_i'}\right] \tag{8}$$

The analogous result for no chopper stabilization is

$$E_L=\frac{-Z_f}{Z_i}[E_{in}-Z_iI_k] \tag{9}$$

or voltage drift reduction is

$$\frac{Z_i'}{Z_i}\,\frac{1}{A_i'} \qquad (10)$$

The choice of the ratio Z_i'/Z_i is determined by the required input impedance which is equal to the parallel combination of Z_i and Z_i'. The chopper current gain A_i' can be very high and in mechanical choppers is limited only by the electrostatic and electromagnetic pickup at the vibrating contracts, and the minimum value of Z_1 in Fig. 3(C).

Analysis of Differential Amplifiers

A differential amplifier is shown in Fig. 4(A). To study the effects of I_{co}, V_{be}, and dissimilar transistors, the equivalent circuit of Fig. 4(B) will be used. (This circuit treats the base-to-emitter voltage as an externally available voltage which can be measured experimentally. Both d-c and varying signals are included. The basic assumptions for this equivalent circuit are: 1. The constant α_n. 2. The collector impedance is very high compared with load impedance. 3. Any internal base resistance is included in R_{b1} and R_{b2}.) The branch equations are

$$E_1 - V_{be1} - V_{ee} = R_{b1}I_{b1} + (R_{e1}+R_e)I_{e1} + R_eI_{e2} \qquad (11)$$

$$E_2 - V_{be2} - V_{ee} = R_{b2}I_{b2} + R_eI_{e1} + (R_{e2}+R_e)I_{e2} \qquad (12)$$

$$I_{e1} = I_{b1} + \alpha_{n1}I_{e1} + I_{co1} \qquad (13)$$

Fig. 4. A—Transistor differential amplifier stage. B—An equivalent circuit for A

$$I_{e2}=I_{b2}+\alpha_{n2}I_{e2}+I_{co2} \qquad (14)$$

Using the relation, $\beta_n=\alpha_n/1-\alpha_n$, and solving equation 13 for I_{b1} yields

$$I_{b1}=I_{e1}\left(\frac{1}{1+\beta_{n1}}\right)-I_{co1} \qquad (15)$$

Similarly,

$$1_{b2}=I_{e2}\left(\frac{1}{1+\beta_{n2}}\right)-I_{co2} \qquad (16)$$

Equations 11, 12, 15, and 16 can be solved for I_{e2}, with the use of the knowledge that

$$E_{2o}=V_{cc}-(\alpha_{n2}I_{e2}+I_{co2})R_{L2} \qquad (17)$$

The result is

$$E_{2o}=V_{cc}-\alpha_{n2}R_{L2}\times\left[\frac{(E_{2i}-E_{1i})+(V_{be1}-V_{be2})+R_{b2}I_{co2}-R_{b1}I_{co1}-\left(\frac{R_{b1}}{\beta_{n1}}+R_{e1}\right)\frac{V_{ee}}{R_e}}{R_{e1}+R_{e2}+\frac{R_{b2}}{\beta_{n2}}+\frac{R_{b1}}{\beta_{n1}}+\frac{R_{b1}R_{b2}}{\beta_{n1}\beta_{n2}R_e}}\right]-I_{co2}R_{L2} \qquad (18)$$

provided $R_{b1}/\beta_{n1}R_e\ll 1$. A similar result is obtained for E_{1o} and, taking the difference,

$$\begin{aligned}E_{2o}-E_{1o}={}&\frac{(E_{1i}-E_{2i})(\alpha_{n1}R_{L1}+\alpha_{n2}R_{L2})}{\Delta}+\\&\frac{(V_{be2}-V_{be1})(\alpha_{n1}R_{L1}+\alpha_{n2}R_{L2})}{\Delta}+\\&\frac{(R_{b1}I_{co1}-R_{b2}I_{co2})}{\Delta}\times\\&\frac{(\alpha_{n1}R_{L1}+\alpha_{n2}R_{L2})}{1}+\\&\left(\frac{R_{b1}}{\beta_{n1}}+R_{e1}-\frac{R_{b2}}{\beta_{n2}}-R_{e2}\right)\times\\&\frac{\frac{V_{ee}}{R_e}(\alpha_{n1}R_{L1}+\alpha_{n2}R_{L2})}{\Delta}+\\&(I_{co1}R_{L1}-I_{co2}R_{L2})\end{aligned} \qquad (19)$$

where

$$\Delta=R_{e1}+R_{e2}+\frac{R_{b2}}{\beta_{n2}}\,\frac{R_{b1}}{\beta_{n1}}\,\frac{R_{b1}R_{b2}}{\beta_{n1}\beta_{n2}R_e} \qquad (20)$$

The first term in equation 19 is the desired output for a given input and it represents the voltage gain of the differential amplifier. If the transistors and external resistances are equal, the gain simplifies to

$$\frac{E_{2o}-E_{1o}}{E_{1i}-E_{2i}}=\frac{2\alpha_{n12}R_{L12}}{R_{e12}+\frac{R_{b12}}{\beta_{n12}}+\frac{R_{b}{}^{2}{}_{12}}{2\beta_{n}{}^{2}{}_{12}R_e}} \qquad (21)$$

The second term of equation 19 is the output due to differences in V_{be}. For this to be zero at all temperatures, V_{be1} and V_{be2} must be equal and must drift equally. The third and fifth terms are due to differences in I_{co1} and I_{co2}, and the fourth term is an output due to differences in β_{n1} and β_{n2}.

If R_{e1} and R_{e2} are made into a potentiometer with the movable tap connected to the common emitter resistor, the potentiometer can be adjusted to give zero output for zero input at a particular temperature. That is, the potentiometer can be of such value that it can adjust the fourth term to cancel out the sum of the second, third, and fifth terms. However, if the variation of V_{be} and I_{co} of both transistors does not vary exactly the same with temperature, the difference will be revealed as drift in the output. Since V_{be} and I_{co} variations with temperature are intrinsically a function of the semiconductor, the variations in drift between transistors is considerably less than the drift itself.

To determine the common mode rejection of the differential amplifier, the common mode gain is calculated as follows. Taking only the terms of equation 18 containing input signals, but without making the assumption of $R_{b1}/\beta_{n1}R_e\ll 1$ (since later algebraic addition makes the term important for common mode signals), results in

$$E_{2o}=\frac{1}{\Delta}\left[-\alpha_{n2}R_{L2}\left(\frac{R_{b1}}{\beta_{n1}R_e}E_{2i}+E_{2i}-E_{1i}\right)\right] \qquad (22)$$

Similarly for E_{1o}, and subtracting, yields

$$E_{2o}-E_{1o}=\frac{1}{\Delta}\left[-\alpha_{n2}R_{R2}\left(\frac{R_{b1}}{\beta_{n1}R_e}E_{2i}+E_{2i}-E_{1i}\right)+\alpha_{n1}R_{L1}\left(\frac{R_{b2}}{\beta_{n2}R_e}E_{1i}+E_{1i}-E_{2i}\right)\right] \qquad (23)$$

For a common mode signal $E_{2i}=E_{1i}=E_{cm}$, and the gain is

$$G_{cm}=\frac{E_{2o}-E_{1o}}{E_{cm}}=\frac{1}{\Delta}\times\left(-\alpha_{n2}R_{L2}\frac{R_{b1}}{\beta_{n1}R_e}+\alpha_{n1}R_{L1}\frac{R_{b2}}{\beta_{n2}R_e}\right) \qquad (24)$$

The major effect is due to difference in β; therefore it is assumed that

$$R_{L1}=R_{L2}=R_{L12},\ R_{b1}=R_{b2}=R_{b12},\ \alpha_{n2}=\alpha_{n1}=\alpha_{n12}$$

which simplifies equation 24 to

$$G_{cm}=\frac{1}{\Delta}\left[\frac{\alpha_{n12}R_{L12}R_{b12}}{R_e}\left(\frac{1}{\beta_{n2}}-\frac{1}{\beta_{n1}}\right)\right] \qquad (25)$$

Under the same assumption the differential mode gain in given by equation 21, and the ratio is

$$\mathrm{CMR}=\frac{G_{dm}}{G_{cm}}=\frac{2R_e\beta_{n1}\beta_{n2}}{R_{b12}(\beta_{n1}-\beta_{n2})} \qquad (26)$$

where CMR = common mode rejection.

As might be expected from similar tube amplifiers, the common mode rejection varies directly with the common emitter resistor R_e, and inversely with the differences in β. If identical β transistors were used, the previous assumptions would have to be re-evaluated.

It should be emphasized that the equivalent circuit of Fig. 4(B) assumes an internal collector resistance which is high compared with the collector load resistances; when this is not true, the resulting analysis becomes even lengthier than that shown here.

Analysis of Drift in Differential Amplifiers

Fig. 5(A) illustrates a typical operational amplifier with a differential input. R_{e2} is small in order to keep the impedance at point A small, and R_{e1} is made equal to R_{e2} in order to keep the circuit balanced for drift effects. R_{e1} and R_{e2} are small compared with R_i as is required for operational amplifiers. This results in some of the amplifier input current being shunted into R_{e1} where it produces no

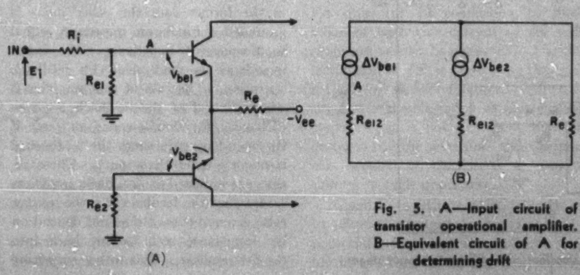

Fig. 5. A—Input circuit of transistor operational amplifier. B—Equivalent circuit of A for determining drift

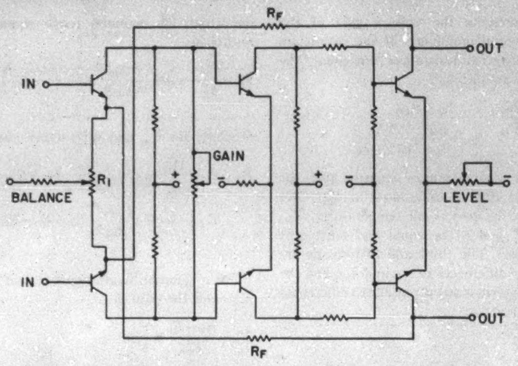

Fig. 6. Differential transistor amplifier with feedback to first-stage emitters

open-loop current gain; however, the gain can be made up in later stages.

The equivalent circuit for drift due to ΔV_{be} is shown in Fig. 5(B), where $R_{e1}=R_{e2}=R_{e12}$, and the internal emitter base impedance is considered small in comparison with R_{e12}. R_t can be neglected or the parallel combination of R_t, and R_{e1} made equal to R_{e12}.

An equal change in V_{be1} and V_{be2} causes current to flow in R_e and the result is attenuated by the common mode rejection of the differential amplifier. By Ohm's law the equivalent drift current at point A due to a difference in the change of V_{be1} and V_{be2} is

$$I_d=\frac{\Delta V_{be1}-\Delta V_{be2}}{R_{e12}+\dfrac{R_{e12}R_e}{R_{e12}+R_e}} \tag{27}$$

To calculate the output voltage due to drift current I_d, the equation for output voltage per input current of an operational amplifier is from equation 48:

$$\frac{E_L}{I_t}=-R_f$$

if

$$Z_f \gg \frac{Z_1}{A_t}$$

and

$$Z_L \gg \frac{Z_f+Z_1}{1+A_t} \tag{28}$$

and

$$E_{L1}=-I_dR_f=-\frac{\Delta V_{be1}-\Delta V_{be2}}{R_{e12}+\dfrac{R_{e12}R_e}{R_{e12}+R_e}}R_f \tag{29}$$

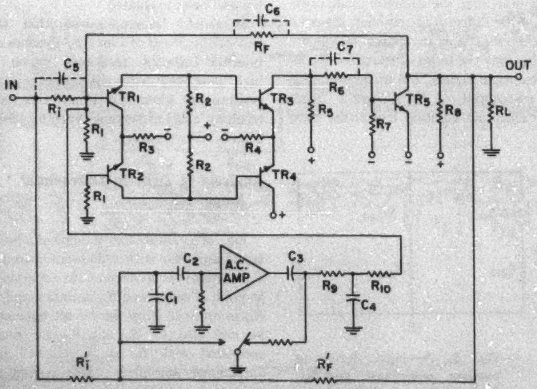

Fig. 7. Chopper stabilized operational transistor amplifier with differential input stages

For unequal I_{co} changes with temperature, the equation is

$$E_{L2}=-\left(\frac{\Delta I_{co1}}{\alpha_1}-\frac{\Delta I_{co2}}{\alpha_2}\right)R_f \tag{30}$$

where E_{L1} and E_{L2} are the output potentials due to V_{be} and I_{co} drifts respectively. These output drifts can be referred to the input by dividing by the closed loop voltage gain given by $-R_f/R_t$, and they become

$$E_{d1}=\frac{\Delta V_{be1}-\Delta_{be2}}{R_{e12}+\dfrac{R_{e12}R_e}{R_{e12}+R_e}}R_t \tag{31}$$

and

$$E_{d2}=\left(\frac{\Delta I_{co1}}{\alpha_1}-\frac{\Delta I_{co2}}{\alpha_2}\right)R_t \tag{32}$$

where E_{d1} and E_{d2} are the voltage drifts due to V_{be} and I_{co} effects respectively, both being referred to the input.

In a typical example, $\Delta V_{be1}-\Delta V_{be2}=17$ maximum millivolts (for a sample of 29 type *2N479*) over a temperature range of 70 to 150 F, $R_{e12}=10$ kilohms, $R_e=29$ kilohms, $R_t=100$ kilohms, $E_{d1}\doteq 100$ millivolts. This can be reduced by chopper stabilization to 0.5 millivolt if drift reduction is 200; see equation 10.

For silicon transistors type *2N479*, $(\Delta I_{co1}-\Delta I_{co2})=0.01$ microampere maximum (for a sample of ten units), and this corresponds to an $E_{d2}=1$ millivolt, which is negligible when reduced by a factor of 200. However, the same theory will result in low drifts if germanium differential stages are used.

Practical Differential Amplifiers

The Slaughter amplifier is a differential amplifier with feedback, and it incorporates all the advantages of this type of operation. However, it requires that the output be single-ended and that it be in phase with the input. Fig. 6 illustrates a differential amplifier with feedback that allows for a single-ended output of either phase, or a differential output. The input can be single- or double-ended; in the former case the other input is grounded through an impedance equal to the source impedance. The input impedance is made high by feedback operation. The gain of this amplifier is the reciprocal of the feedback β ($A_v=(2R_f+R_1)/R_1$, double-ended output) if the open-loop gain times the feedback β is much greater than unity. These results are standard for feedback amplifiers except that the feedback β is the resistor ratio given above; it does not depend on the impedance seen looking back into the first emitter. This rather surprising result has been confirmed by analysis. Incidentally, the analysis applies to a single-ended amplifier in which the feedback is introduced at the first-stage emitter in grounded emitter operation.

An amplifier was constructed according to Fig. 6 and performed as expected. The balance, gain, and level controls behave as they would in an equivalent tube-type amplifier. The gain control is optional but it is useful practically to stop oscillations if the open-loop gain is too high for the phase shifts introduced by the transistors. A gain of 10 was achieved with 30-db (decibel) feedback without frequency compensation with *2N479* silicon transistors. The divider network between the second and third stage is required to bring the output to zero d-c volts and is an ideal place to introduce frequency compensation if the transistor phase shifts cause oscillations. (The details of frequency stabilization are discussed in a later section.) The drift was, of course, a function of the difference in drift characteristics of the first-stage transistors.

To take advantage of chopper stabilization and differential stage drift reduction, an operational amplifier can be used with a differential input and a single-ended output. The chopper stabilization is effective, however, only for a single-ended input signal; Fig. 7 illustrates this type of amplifier. The gain is given by the ratio of R_f to R_i, the input impedance is the parallel combination of R_1 and R_i', and the drift reduction is equal to R_i'/R_i times the net current gain of the a-c amplifier.

The a-c amplifier has a net phase reversal so that the single-pole double-throw chopping yields no net phase reversal for the direct current. It is possible to feed the output of the chopper amplifier into the base of TR_2 if the a-c amplifier and chopper have a net d-c phase reversal.

The important features in the design of this type of amplifier are summarized as follows:

D-C DESIGN

The first and second stages are the differential type, and to determine their operating points the collector current is first specified. Since the emitter potentials are very close to the base, the common emitter resistor is calculated to have twice the individual collector currents flowing when it is operating between the base potential and the negative supply.

R_3 and R_4 are chosen high for good common mode rejection (see equation 26 for the common mode rejection formula) and this determines their negative return potential.

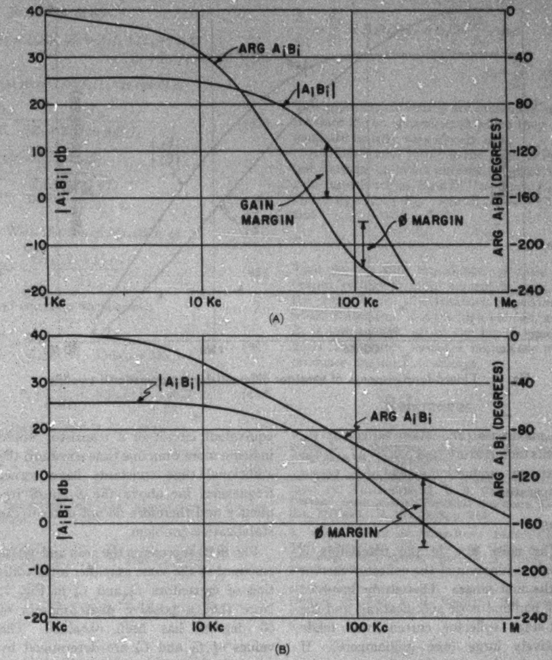

Fig. 8. A—Open-loop gain and phase response of transistor differential input operational amplifier with no frequency compensation. B—After stabilization to self-oscillation

The collector load resistance can then be selected so that it will be high (perhaps ten times as high) compared to the input impedance of the following stage. This is required since, ideally, all of the signal current should flow into the next stage. The collector supply can then be chosen large enough to allow for the signal swing, with the low value of a-c load of the next stage taken into account. For quiescent d-c conditions the small value of base bias current of the next stage can usually be neglected. The collector load of TR_4 is omitted so that it is actually an emitter follower. Since this stage is a double-ended to single-ended converter, it is not necessary, and the design is still the same since the collectors can usually be considered as current sources of high impedance.

R_6 and R_7 constitute a divider network to allow the output to be at zero d-c potential. Knowing the collector potential of TR_3 and realizing that the base of TR_5 is essentially at emitter supply potential, lead to the choice of R_5, R_6, and R_7, so that the base current of TR_5 is at the desired quiescent value. R_6 and R_5 divide the signal current so as to reduce the gain, and it is therefore desirable to keep R_6 at a minimum. However, this demands a maximum of bleeder current through R_5, R_6, and R_7 and a compromise is necessary. R_7 is made much higher than the input impedance of TR_5 in order not to divert a lot of signal current, and this usually requires its negative return supply to be rather high negatively.

It is possible to use an opposite semiconductor material for the middle stage and eliminate the divider loss; however, R_6 is an ideal location to shunt a capacitor to form a lead network for frequency stabilization. This will be discussed later.

DRIFT DESIGN

Equations 31 and 32 yield the drift referred to the input where $R_{e12}=R_1$, R_i is the same, $R_i>>R_1$, $\Delta V_{be1}-\Delta V_{be2}$ is

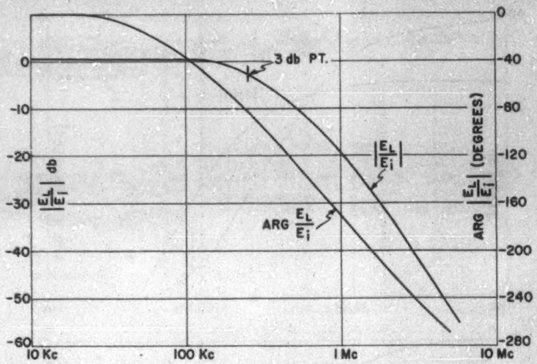

Fig. 9. Closed-loop response of transistor differential input operational amplifier

the maximum production spread of V_{be} versus temperature, and $\Delta I_{co1}-\Delta I_{co2}$ is the maximum production spread of I_{co} versus temperature.

Noise

The noise due to the transistors is mainly a function of the collector current in the first stage. This study involved very nominal noise specifications and the first-stage collector current was made relatively large (one milliampere). If this value is reduced to decrease noise effects, care must be taken to ensure that the transistor does not drift out of its active region with temperature. The small common mode gain of the differential amplifier is a distinct advantage in this respect compared with a single-ended type of amplifier.

A-C Design

If a large dynamic range is required, the d-c design must allow for the specified swing without saturating or cutting off. Again, the differential amplifier, due to its low common mode gain, helps maintain the room temperature operating conditions when the temperature varies.

To a first approximation, each transistor stage introduces a 6 db per octave slope with a corner frequency equal to the β cutoff frequency. Fig. 8(A) is a typical open-loop gain and phase response for a 3-stage amplifier shown in Fig. 7. Since there are three time constants involved, self-oscillations are possible, and indeed Fig. 7 indicates a negative gain and phase margin. Note that the gain drops off at a rate of 18 db per octave, indicating that the three β cutoff corner frequencies are close to each other. Note also that although the high-frequency equivalent circuit of a transistor would indicate more than one time constant, the additional time constants have corner frequencies far above the β cutoff frequency and therefore do not enter in the stabilization problem.

Fig. 8(B) represents the gain and phase response of the same amplifier after addition of capacitors C_2 and C_8 in Fig. 7. Note that a positive phase margin of 60 degrees has been obtained. The values of C_7 and C_8 are determined by standard techniques and will not be discussed here. There are many stabilization networks available; the two chosen are typical. Note that the use of the bleeder network R_5, R_6, and R_7 allow C_2 to form a simple cascade lead network.

Fig. 9 represents the closed loop (output divided by input) of the amplifier in Fig. 8(A) when the open-loop gain and phase were adjusted as in Fig. 8(B). The half-power point is at 250 kc. This could be raised by adjusting C_2 and C_8 in order to have a peaking in the closed loop response, but Fig. 9 represents the maximum response without peaking. Of course, peaking would reduce the phase margin of 60 degrees, but this is more than adequate to ensure against self-oscillation.

The capacitor C_8 of Fig. 7, can be used to shape the closed loop response without affecting the open-loop response of the amplifier. The reason for this is that the low input impedance at the base of TR_1 effectively short-circuits R_1 and C_8. The combination of R_1, C_8, and the input impedance of TR_1 form a lead network which which will introduce a rising 6 db per octave slope in the closed loop response, permitting a greater bandwidth than shown in Fig. 9.

Chopper Amplifier and Filter

The a-c amplifier shown in Fig. 7 represents a fairly simple design since it must amplify only the chopper frequency. A 3-stage common emitter germanium transistor amplifier was used with large emitter resistances to ensure a low stability factor. These resistors are heavily by-passed so they do not reduce the gain at the chopper frequency. The combination of net phase reversal in the chopper amplifier and the single-pole double-throw chopping contacts yield a zero net phase shift for d-c signals. The d-c output is fed back to the base of the first transistor. If other combinations of a-c amplifier phase reversal and chopping contacts yield a net d-c phase reversal, the output can be fed into the base of TR_3 in Fig. 7.

C_1 together with R_4' form a filter to prevent chopping frequency signals to be fed back to the input, and C_2 and C_3 are blocking capacitors. R_9, C_4, and R_{10} are the output filter. To reduce the chopping frequency ripple to a negligible amount, the band pass of the entire chopper amplifier is reduced to a few cps (cycles per second). This is sufficient for correcting d-c drifts but it should be noted that a more complex filter will provide additional advantages. If the filter were designed to have a flat band pass close to the chopping frequency and the fall rapidly to give the desired attenuation at the chopping frequency, stabilization could be obtained over a reasonably wide bandwidth, one example might be to use a 400-cps chopping frequency, and a filter which was flat out to > 120 cps. This combination would allow simple power supplies to be used since the 60- to 120- cps ripple introduced by such supplies would be attenuated sharply by the chopper stabilization technique. The analysis of such stabilization would be similar to that already shown.

Appendix

The current operational amplifier of Fig. 2(B) can be analyzed assuming $-A_i$ is the open-loop current gain which in general is a function of Z_L and Z_f.

From Fig. 2(B):

$$I_1=I_i+I_f=\frac{I_L+I_f}{-A_i} \tag{33}$$

Define

$$\beta_i=\frac{I_f}{I_R} \tag{34}$$

Equation 33 becomes

$$I_i+\beta_i I_L=\frac{I_L+\beta_i I_L}{-A_i}$$

$$\frac{I_L}{I_t}=\frac{-A_t}{(1+\beta_t+A_t\beta_t)}=\frac{-A_t}{1+\beta_t(1+A_t)} \tag{35}$$

From Fig. 2(B):

$$E_L=I_LZ_L=I_fZ_f+(I_t+I_f)Z_1 \tag{36}$$

where Z_1 is the input impedance of the current amplifier; from equation 33

$$I_t=-\frac{I_f(A_t+1)+I_L}{A_t}$$

Putting this into equation 36 results in

$$\frac{I_f}{I_L}\equiv\beta_t=\frac{Z_LA_t+Z_1}{A_tZ_f-(A_t+1)Z_1+Z_1A_t}$$

Dividing by A_t, and simplifying yields

$$\frac{I_f}{I_L}\equiv\beta_t=\frac{Z_L+\dfrac{Z_1}{A_t}}{Z_f-\dfrac{Z_1}{A_t}} \tag{37}$$

If, as is usually the case,

$$Z_L\gg\frac{Z_1}{A_t};\ Z_f\gg\frac{Z_1}{A_t}$$

$$\beta_t\doteq\frac{Z_L}{Z_f} \tag{38}$$

From equations 35 and 37

$$\frac{I_L}{I_f}=-\frac{(A_tZ_f-Z_1)}{Z_f+Z_1+Z_L(1+A_t)} \tag{39}$$

$$\doteq-\frac{Z_f}{Z_L}\text{ if }Z_f\gg\frac{Z_1}{A_t},\ Z_L\gg\frac{Z_f+Z_1}{1+A_t} \tag{40}$$

From Fig. 2(B)

$$E_L=I_LZ_L,\ E_t=Z_tI_t+(I_t+I_f)Z_1 \\ =(Z_t+Z_1)I_t+Z_1I_f \tag{41}$$

and since $I_f\equiv\beta_tI_L$, the result is

$$\frac{E_L}{E_t}=\frac{Z_LI_L}{(Z_t+Z_1)I_t+\beta_tZ_1I_L} \tag{42}$$

from equation 33

$$I_t=-\frac{I_f(A_t+1)+I_L}{A_t}$$

With the use of equation 34

$$I_t=-\frac{\beta_tI_L(A_t+1)+I_L}{A_t} \tag{43}$$

and equation 43 becomes

$$\frac{E_L}{E_t}=\frac{-A_tZ_L}{Z_t[\beta_t(A_t+1)+1]+2Z_t} \tag{44}$$

$$\doteq-\frac{Z_L}{Z_t\beta_t}\text{ if }A_t\beta_t\gg1,\ A_t\beta_t\gg\frac{2Z_t}{Z_t} \tag{45}$$

If, further, $\beta_t\doteq Z_L/Z_f$, then

$$\frac{E_L}{E_t}\doteq\frac{Z_f}{Z_s} \tag{46}$$

Summing up the approximate results yields

$$\frac{I_L}{I_t}\doteq-\frac{Z_f}{Z_L}\text{ if }Z_f\gg\frac{Z_1}{A_t}\text{ and }Z_L\gg\frac{Z_f+Z_1}{1+A_t}$$

$$\beta_t\equiv\frac{I_f}{I_L}\doteq\frac{Z_L}{Z_f}\text{ if }Z_L\gg\frac{Z_1}{A_t}\text{ and }Z_f\gg\frac{Z_1}{A_t}$$

$$\frac{E_L}{E_t}\doteq\frac{Z_f}{Z_t}\text{ if }A_t\beta_t\gg1,\ A_t\beta_t\gg\frac{2Z_1}{Z_t},\text{ and}$$

$$\beta_t\doteq\frac{Z_L}{Z_f} \tag{47}$$

The approximate results are extremely useful since the conditions upon which they depend are usually very closely met.

Another useful result is the ratio of output voltage to input current. Define the gain impedance as $Z_g\equiv E_L/I_t$. Since $E_L=I_LZ_L$, $Z_g=I_L/I_t\ Z_L$. But $I_L/I_t\doteq-Z_f/Z_L$ and

$$Z_g\doteq-Z_f \tag{48}$$

That is, the gain impedance, or ratio of output voltage to input current is equal to the negative of the feedback impedance, which states that if A_t is high enough, and Z_1 is low enough, all of the input current flows through the feedback impedance and produces the output voltage.

Instabilities of Push-Pull Magnetic Amplifiers Feeding the Field of an Electric Machine

H. F. STORM
MEMBER AIEE

THE CAUSES of instability of inductively loaded, center-tap magnetic amplifiers, and the remedies for this instability are well known.[1-4] If such a stabilized magnetic amplifier is used to energize the field of an electric machine, such as the shunt field of a d-c generator, the armature voltage of this machine will increase or decrease smoothly with the control voltage of the magnetic amplifier. Since the load current of the magnetic amplifier is unidirectional, the armature voltage of the d-c generator will also be unidirectional. However, in many closed-loop control systems it is necessary to obtain duodirectional output of the d-c geneator. In this case the d-c generator will be equipped with two shunt fields; each shunt field is connected to a magnetic amplifier with such polarity that the magnetomotive forces produced by the two shunt fields are subtractive. Then, if the first magnetic amplifier is controlled "full on" and the second magnetic amplifier is controlled "full off," the armature of the d-c generator develops a voltage of one polarity, and if the control to the magnetic amplifiers is reversed, the armature voltage of the d-c generator is also reversed. One may expect, furthermore, that if each magnetic amplifier is turned "one half on," the net magnetomotive force will be zero, and, hence, that the armature voltage of the d-c generator will also be zero; one may also expect that for a gradual increase of control current of one amplifier, and a similar gradual decrease of control current of the other amplifier, the armature voltage of the d-c generator will show a gradual change. The last two expectations, however, are not likely to be fulfilled. Instead, a minute change of the magnetic amplifier control currents will cause a sudden jump of armature voltage from perhaps +50% to −50% (or vice versa) of rated d-c generator armature voltage, and intermediate values of armature voltage will not be obtainable. This instability renders almost useless this otherwise inviting control scheme. It is suspected

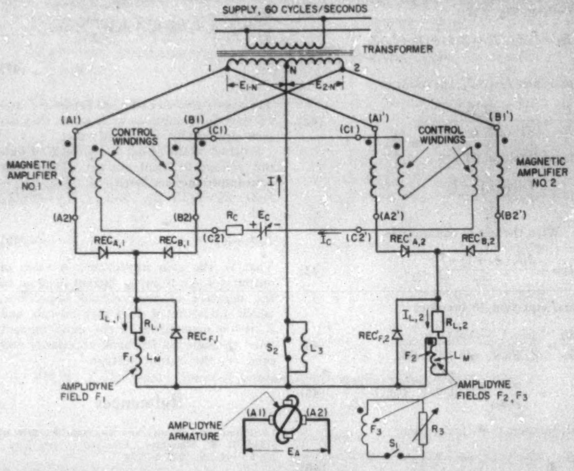

Fig. 1. Magnetic amplifiers 1 and 2, providing push-pull control for amplidyne control fields F_1 and F_2

immediately that magnetic amplifiers are prone to produce instabilities when feeding inductive loads, such as the field of the d-c generator. However, as soon as one of the two magnetic amplifiers is disconnected from its generator field, the other will produce perfect (unidirectional) control of the d-c generator, and vice versa. Hence the instability is of a different nature than suspected.

Origin of the Instability

The circuit under study is shown in Fig. 1. The d-c generator to be controlled by magnetic amplifiers 1 and 2 is of the amplidyne type. The amplidyne control fields F_1, and F_2 are connected to the magnetic amplifiers with opposite polarities, as previously described. Two rectifiers, $REC_{F,1}$ and $REC_{F,2}$ are connected across the fields of the amplidyne in accordance with standard practice, in order to remove the instabilities of the individual magnetic amplifiers when they are feeding inductive loads.

The control windings of the magnetic amplifiers are connected with opposing polarities; thus a change in the common control current I_C will increase the load current of one magnetic amplifier and decrease the load current of the other. The bias windings of the magnetic amplifiers (not shown in Fig. 1) may be energized by a constant direct current, whose value has no first-order significance for the problem under discussion; more information regarding the magnetic amplifiers and the amplidyne are found in the Appendix.

By varying the magnitude and polarity of the magnetic amplifier control voltage E_C (Fig. 1), the magnetic amplifier control current I_C is varied, and the amplidyne armature voltage E_A is expected to conform to the typical push-pull characteristic of Fig. 2(A). Instead, one will discover with considerable dismay that the actual characteristic, shown in Fig. 2(B), is quite different. If the amplifier system is operating at point A, Fig. 2(B), and the control current I_C is decreased, the amplidyne armature voltage E will decrease slowly until point B is reached. Any further decrease in amplistat control current I_C causes the amplidyne armature voltage E_A to snap from the positive value at B to the negative value at C. Similarly, if the control current I_C is increased, starting from D, the armature voltage E_A will vary along the curve D-C until point E is reached, at which point snap action will again occur. Experiments indicate that each amplistat is, by itself, well behaved, and hence one concludes that the instability, called snap action, is caused by the interaction of the two magnetic amplifiers.

Interaction between the two magnetic amplifiers can occur along two channels: 1. the common control circuit, and 2. the common amplidyne control flux. During steady-state operation, interaction through the two channels can be accomplished only by a-c components; experimentation supports the theory that those a-c components contain only harmonics of even order. It is beyond the scope of this paper, however, to discuss in greater detail the mechanics of even-harmonic generation.

Remedies for Instabilities

The evidence thus far discussed leads to the following remedies.

1. Increase of Control-Circuit External Impedance

Increasing the external impedance of the control circuit may be achieved by

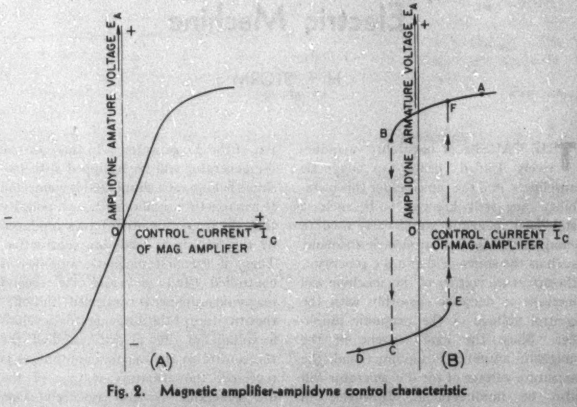

Fig. 2. Magnetic amplifier-amplidyne control characteristic

A—Expected control characteristic
B—Actual control characteristic, exhibiting instability, or snap action

Vol.
Pt. 1
196

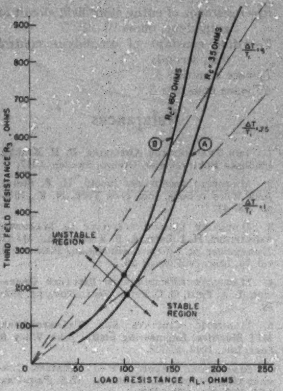

Fig. 3. Relation between R_L and R_3 to eliminate instability, and per-unit increase $\Delta T/T_1$ of time constant of amplidyne control flux

increasing the external control circuit resistance R_C, or by inserting a reactor into the external control circuit.

Two experimental characteristics which form the boundary between stable and unstable operation are shown in Fig. 3. One characteristic has been taken with a total control circuit resistance $R_C=35$ ohms, the other with $R_C=160$ ohms. The space between the curves is indicative for unstable operation with $R_C=35$ ohms, but stable operation with $R_C=160$ ohms.

2. Transformation Attenuation

To attenuate the transformation of alternating voltages from one amplidyne control field to the other, several methods are suggested which will be explained by means of the equivalent circuit diagram for a-c components in the amplidyne fields; see Fig. 4. This diagram has been derived from the equivalent transformer circuit; it neglects leakage reactances and core loss.[5] It will be seen that interaction can be combatted by the following means:

Increasing Load Resistances $R_{L,1}$, $R_{L,2}$ of Magnetic Amplifiers. For a fixed control circuit resistance R_C, and a fixed third field resistance R_3, discussed below, an increase of load resistance R_L leads in the direction of increased stability, as evidenced in Fig. 3. It should be pointed out, however, that with a given capacity of the magnetic amplifiers there is a limit as to the maximum amount of load resistance that can be afforded.

Inserting Reactors in Series with Load Resistors $R_{L,1}$, $R_{L,2}$. Some further thought will indicate that the same effect can be obtained by a single reactor L_3 in the lead to the neutral N, with switch S_2 open; see Fig. 1. The physical size of such a reactor is usually quite small. A reactor of a type size of only $2\pi f L_3 I^2 =$ 200 volt-amperes will effectively reduce the snap action tendency of a large 25-kw output unit.

Increasing Admittance Across Terminals of Magnetizing Inductance $L_{L,1}=L_{L,2}=L_M$. The most obvious solution is to connect resistors in parallel to the amplidyne fields F_1 and F_2. While this method is effective in removing the instability, the additional power consumed by these resistors calls for an undesirable increase in magnetic-amplifier capacity. The same salutary effect, however, can be achieved without an increase in magnetic-amplifier capacity by using a third field F_3 of the amplidyne.[6] This field F_3 is connected to an external resistor R_3 by switch S_1, which is now considered as closed; the power dissipated in resistor R_3 is usually only a fraction of one watt; see Fig. 1.

The effectiveness of the last-mentioned method can be gaged by an inspection of Fig. 3; the degree of amplidyne armature loading has no measurable effect on the stability of the control. Stable operation of the amplifier system is obtained for the regions to the right of and below the curves. One might conclude from curves A and B that the best design will result if R_3 is made as low as possible; this however is not necessarily so, for the following reason.

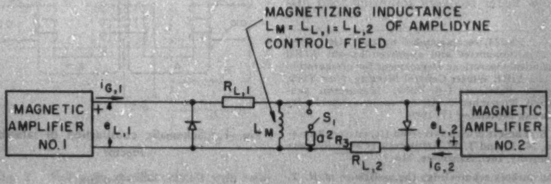

Fig. 4. Simplified equivalent a-c circuit of amplidyne fields

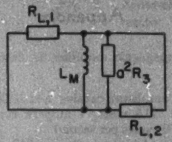

Fig. 5. Equivalent circuit for determining the time constant of amplidyne control flux

The flux time constant of a field having several windings terminated into purely resistive circuits, is equal to the sum of the time constants of the several windings.[7] Hence, the time constant T_C of the amplidyne flux is from Fig. 5:

$$T_C=\frac{L_M}{R_{L,1}}+\frac{L_M}{R_{L,2}}+\frac{L_M}{a^2R_3} \tag{1}$$

For

$$R_{L,1}=R_{L,2}=R_L \tag{2}$$

one obtains

$$T_C=T_1+\Delta T \tag{3}$$

where T_1 is

$$T_1=\frac{L_M}{R_L/2} \tag{4}$$

and ΔT is the time constant which is contributed by the presence of a finite R_3

$$\Delta T=\frac{L_M}{a^2R_3} \tag{5}$$

The per-unit increase of the amplidyne time constant $\Delta T/T_1$, due to the presence of R_3, follows from equations 4 and 5:

$$\frac{\Delta T}{T_1}=\frac{R_L/2}{a^2R_3} \tag{6}$$

One concludes that, while an increase of R_L/R_3 has the agreeable effect of counteracting the instability shown in Fig. 3, it also has the disagreeable effect of increasing the time constant T_C of the amplidyne control field. To facilitate the proper selection of R_L/R_3, the loci for various ratios of $\Delta T/T_1$ have been added to Fig. 3.

Conclusions

The various remedies for instability, listed in the previous paragraphs, are often used most effectively in combination. After the instability has been removed, the system functions according to the expectations illustrated in Fig. 2 (A). Many such magnetic-amplifier-amplidyne combinations are in use in industry and in utility fields. While this paper presents several methods of combating instability, it should not be inferred that no other methods exist.

Appendix

The magnetic amplifier is described as follows:

Type: amplistat catalog no. *101D511-G1*.
Rating: 115 volts, 1 ampere continuous, 60 cycles per second.
Control and bias windings: 250 turns, 4.9 ohms.
Gate winding: 1,000 turns, 9 ohms.
Core material: grain-oriented silicon-iron.

The amplidyne is described as follows:

Serial no. *5AM79A8324*.
Rating: 250 volts, 1.5 kw, 1,725 rpm.
Control fields F_1 and F_2: 205 turns per pole, 45 ohms.
Third field F_3: 400 turns per pole, 55 ohms.
Fourth field (not used): 330 turns per pole, 116 ohms.
Control field inductance for 1,000 turns per pole: 50 henrys.
Control ampere-turns per pole for 200-volt armature voltage: 40.
Control ampere-turns per pole for 250-volt armature voltage: 80.

Nomenclature

$a = N_C/N_3$
E_C = control voltage for magnetic amplifiers, volts, average
E_A = amplidyne armature voltage, volts, average
f = frequency of supply voltage
I = current in neutral of supply transformer, amperes, average
I_C = control current for magnetic amplifiers, amperes, average
L_3 = inductance, henrys
N_C = number of turns of amplidyne control winding F_1 or F_2
N_3 = number of turns of third amplidyne control winding F_3
L_M = magnetizing inductance of amplidyne control field F_1 or F_2, henrys
R_C = control circuit resistance of amplistat circuit, ohms
R_L = load resistance of magnetic amplifier, including amplidyne field resistance, ohms
R_3 = resistance of entire third field circuit of amplidyne, ohms
T_C = time constant of amplidyne control flux, seconds
T_1 = see equation 4
ΔT = see equation 5

Saturable-Reactor Control of Full-Wave and Biphase Rectifiers

J. B. THOMAS
MEMBER AIEE

J. W. DRENNING
MEMBER AIEE

IN MANY rectifier applications means must be provided to vary the output voltage. In some cases discrete control is permissible while in others the output must be continuously variable. A common method of providing the latter is to employ a saturable-core reactor in series with the primary of the rectifier transformer.

This paper treats certain problems peculiar to the design of rectifiers with saturable-reactor controls. One of the principal factors to be considered is the abnormally high voltage which may exist at various points in the circuit. This condition may become particularly acute in biphase and half-wave connections.

Operation of Saturable-Core Reactors

The impedance of a saturable-core reactor is made variable by means of a control winding in which a direct current flows and determines the saturation level in the iron core. As a rectifier control, this device is conventionally connected in series with the a-c lines supplying the rectifier transformer. Voltage supplied to the rectifier is therefore determined by the instantaneous difference between line and saturable-reactor voltages, the latter being variable by means of the control winding previously mentioned.

A saturable-core reactor is shown schematically in Fig. 1. The a-c coils of the reactor may be connected in parallel or in series.[1,2] Most of the "stock" saturable reactors are parallel-connected since the a-c components induced in the d-c winding of the series-connected reactor are frequently objectionable. However, series-connected reactors have an inherently faster response time; hence they are used in such applications as electrostatic precipitator power supplies to allow faster recovery following load disturbances. For brevity, only the series-connected reactor will be considered in the following discussion, although essentially the same problems exist with the parallel-connected reactor.

In the series-connected reactor (terminals *2* and *3* connected in Fig. 1), the same current flows through each a-c coil. If this current is given by

$$i_n = I_n \sin (n\omega t + \phi_n) \tag{1}$$

then reactor voltage e_{14} may be expressed as a sum of the fundamental and odd harmonics:

$$e_{14} = e_n = \sum_k E_{kn} \sin (kn\omega t + \phi_{kn}) \qquad k = 1, 3, 5, \ldots \tag{2}$$

Operation of the reactor cores over the nonlinear portion of the magnetization curve generates the harmonics and symmetry dictates that they be odd.

The relationships in equations 1 and 2 are shown graphically in Fig. 2 for a given d-c saturation level chosen so that the first and third harmonics predominate in

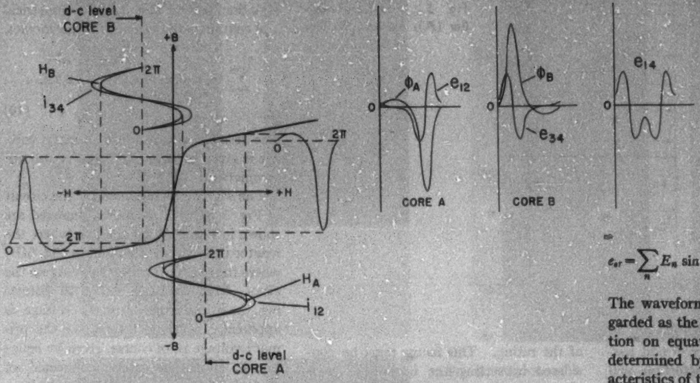

Fig. 2. Series-connected reactor

the reactor voltage e_{14}. This particular case was selected because it illustrates the actual waveforms encountered in the reactors used in this study and discussed later. In Fig. 2 the phase shift due to hysteresis has been ignored in the interest of simplicity.

As far as this discussion is concerned two cases may be distinguished. The first case is the full-wave rectifier where the reactor current is mirror-symmetrical (henceforth called symmetrical) and therefore contains only odd harmonics.[3] The second case is the unsymmetrically loaded biphase rectifier or the half-wave rectifier where the reactor current is unsymmetrical and therefore contains even and odd harmonics.[3]

Full-Wave Rectifier

Fig. 3 shows a schematic diagram of a full-wave bridge rectifier using a series-connected saturable reactor as the primary control device. An *R-C* load is shown since this is frequently encountered in practice and poses a more difficult problem than a purely resistive load. The transformer *T* isolates the load from the line or provides a change in voltage or both.

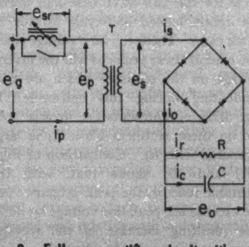

Fig. 3. Full-wave rectifier circuit with saturable-reactor control

As previously stated the reactor current i_p is symmetrical since the secondary current i_s is symmetrical. In general, therefore, the reactor current i_p, although not sinusoidal, can be expressed as the Fourier series:[3]

$$i_p=\sum_n I_n \sin(n\omega t+\phi_n) \quad n=1,3,5,\ldots \qquad (3)$$

As shown in equations 1 and 2, the voltage drop across the reactor for a sinusoidal current flow therein can be expressed as a sum of the fundamental and odd harmonics. Although the reactor is not linear and superposition does not hold, the net voltage drop across it due to the current of equation 3 is still a sum of the fundamental and odd harmonics, i.e.,

$$e_{sr}=\sum_n E_n \sin(n\omega t+\theta_n) \quad n=1,3,5,\ldots \qquad (4)$$

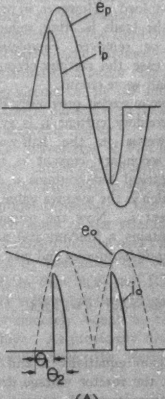
The waveform of equation 4 can be regarded as the result of a nonlinear operation on equation 3, the operator being determined by the magnetization characteristics of the saturable reactor and by the d-c saturation level. Consequently the reactor drop e_{sr} will still be symmetrical but the relative amount of the higher order harmonics will have been increased.

The resulting transformer primary voltage will be:

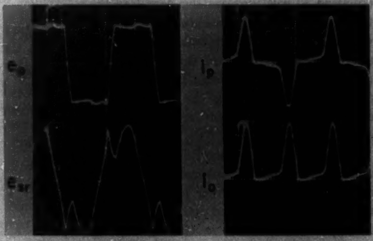
$$e_p=e_g-e_{sr} \qquad (5)$$

Thus the presence of the reactor has created a nonsinusoidal transformer-exciting voltage which is, however, symmetrical.

The effects just discussed are illustrated and compared in Figs. 4(A) and (B). In Fig. 4(A) the waveforms for the full-wave rectifier of Fig. 3 are shown for the case where the saturable reactor is short-circuited and hence the transformer exciting voltage is sinusoidal.[4] In Fig. 4(B) the waveforms for the circuit of Fig. 3 are shown for the case where the saturable reactor is not short-circuited. The effect of the reactor in distorting the transformer primary voltage is easily seen. The waveform is almost rectan-



(A)



(B)

Fig. 4. Waveforms in a full-wave rectifier

A—R-C load
B—Saturable-reactor control

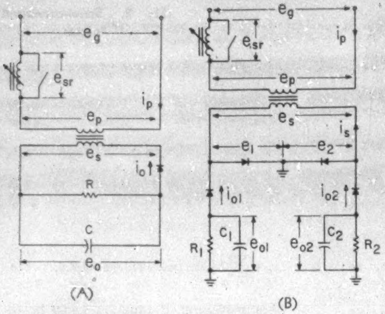


Fig. 5. Half-wave rectifier (A), biphase rectifier (B)

gular indicating the presence of odd harmonics. The degree of distortion will vary, of course, depending on the circuit parameters, but some typical values of transformer primary voltage are given in the following. Without reactor:

$$e_p = e_g = E_g \sin \omega t \tag{6}$$

With reactor:

$$e_p = E_{p1} \sin (\omega t + \psi_1) + 0.39 E_{p1} \sin (3\omega t + \psi_3) + 0.22 E_{p1} \sin (5\omega t + \psi_5) + 0.07 E_{p1} \sin (7\omega t + \psi_7) + \dots \tag{7}$$

Equation 7 was obtained experimentally with a wave analyzer using narrow-band filters.

Fig. 4(B) also shows the waveform of the saturable-reactor voltage. This waveform exhibits the characteristic "double hump" distortion shown in Fig. 2. Analysis of this voltage yields the following expression:

$$e_{sr} = E_{sr1} \sin (\omega t + \theta_1) + 0.33 E_{sr1} \sin (3\omega t + \theta_3) + 0.21 E_{sr1} \sin (5\omega t + \theta_5) + 0.17 E_{sr1} \sin (7\omega t + \theta_7) + 0.07 E_{sr1} \sin (9\omega t + \theta_9) + 0.06 E_{sr1} \sin (11\omega t + \theta_{11}) + \dots \tag{8}$$

The presence of the harmonics in the transformer primary voltage, as shown in equation 7, will increase the core loss in the transformer. In addition the peak value of this voltage will be less than that of a sinusoidal voltage of the same effective value. This fact must be taken into account in determining the transformer turns ratio required for a given peak output voltage.

The reactor, even when fully saturated, will prevent full-line voltage from being applied to the transformer primary, particularly at high load currents. The transformer, therefore, must be rated at some lower voltage. However, should the secondary be open-circuited or the load appreciably reduced, the reactor drop may not be sufficient to prevent transformer primary voltages in excess of the rating. This factor must be considered in setting the insulation levels of the transformer and the inverse voltage rating of the rectifier elements. It is particularly important in high-voltage designs.

Biphase and Half-Wave Rectifiers

Two types of half-wave rectifier circuits are shown in Fig. 5. The conventional half-wave circuit of Fig. 5(A) is often employed in electronic systems where current requirements are low and simplicity is important. The circuit of Fig. 5(B) is actually a special case of the full-wave rectifier and is often called a biphase or double-half-wave circuit. This circuit is well known in the electostatic precipitator industry where it is used to obtain the advantages of half-wave energization without the disadvantages of the half-wave circuit. Two separate half-wave *R-C* loads are supplied alternately every one-half cycle, thereby causing the rectifier to operate as though it were supplying a single full-wave load. However, in practice, one of the loads is often reduced substantially or removed completely. In the latter case the rectifier becomes essentially a half-wave circuit.

In the full-wave circuit previously discussed the secondary current i_s is symmetrical. However in the half-wave rectifier, the secondary current is not only unsymmetrical but contains a d-c component which is the average value of the load current i_o. Now the primary current i_p contains a fundamental and both even and odd harmonics and may be written as[4]

$$i_p = \sum_n I_n \sin (n\omega t + \phi_n) \quad n = 1,2,3,4,\dots \tag{9}$$

Considering again equations 1 and 2, it follows that the reactor voltage drop due to the unsymmetrical current of equation 9 will also be unsymmetrical and contain both even and odd harmonics, i.e.,

$$e_{sr} = \sum_n E_n \sin (n\omega t + \theta_n) \quad n = 1,2,3,4,\dots \tag{10}$$

The resulting transformer primary voltage is given by equation 5 and is also unsymmetrical.

The waveforms obtained for the circuit of Fig. 5(B) with R_2 and C_2 removed are shown in Fig. 6(A) for the case where the reactor is short-circuited and in Fig. 6(B) where the reactor is operating. Again the effect of the saturable reactor in distorting the transformer primary voltage is apparent. Without the reactor the primary voltage is, of course, given by equation 6. With the reactor connected an analysis of the primary voltage yields:

$$e_p = E_{p1} \sin (\omega t + \psi_1) + 0.62 E_{p1} \sin (2\omega t + \psi_2) + 0.38 E_{p1} \sin (3\omega t + \psi_3) + 0.27 E_{p1} \sin (4\omega t + \psi_4) + 0.14 E_{p1} \sin (5\omega t + \psi_5) + 0.10 E_{p1} \sin (6\omega t + \psi_6) + 0.10 E_{p1} \sin (7\omega t + \psi_7) + 0.07 E_{p1} \sin (8\omega t + \psi_8) + \dots \tag{11}$$

Similarly, the saturable-reactor waveform of Fig. 6(B) may be written as:

$$e_{sr} = E_{sr1} \sin (\omega t + \theta_1) + 0.65 E_{sr1} \sin (2\omega t + \theta_2) + 0.37 E_{sr1} \sin (3\omega t + \theta_3) + 0.32 E_{sr1} \sin (4\omega t + \theta_4) + 0.15 E_{sr1} \sin (5\omega t + \theta_5) + 0.12 E_{sr_1} \sin (6\omega t + \theta_6) + 0.10 E_{sr1} \sin (7\omega t + \theta_7) + 0.07 E_{sr1} \sin (8\omega t + \theta_8) + \dots \tag{12}$$

The presence of harmonics in the primary voltage of the half-wave circuit or the unsymmetrically loaded biphase circuit requires consideration of the same factors previously discussed for the full-wave case. In addition, another important factor exists which is peculiar to these circuits. For certain d-c saturation levels in the reactor, the instantaneous reactor and line voltages e_{sr} and e_g may combine to produce a peak voltage e_p on the transformer primary which appreciably exceeds that of the line. This condition will exist during the nonconducting half-cycle for the half-wave case and during the lightly loaded half-cycle for the biphase case. The secondary voltage e_s will also exhibit these peaks as will the inverse voltage on the rectifiers which are nonconducting during this half-cycle. In Fig. 5(B), e_2 represents the inverse voltage on these rectifiers when R_2 is large compared with R_1. Comparison of Figs. 6(A) and (B) shows that, with the saturable reactor, the peak primary voltage exceeds the peak line voltage by 30%. The resulting increase in the rectifier inverse voltage e_2 is also shown.

These excessive voltages are likely to

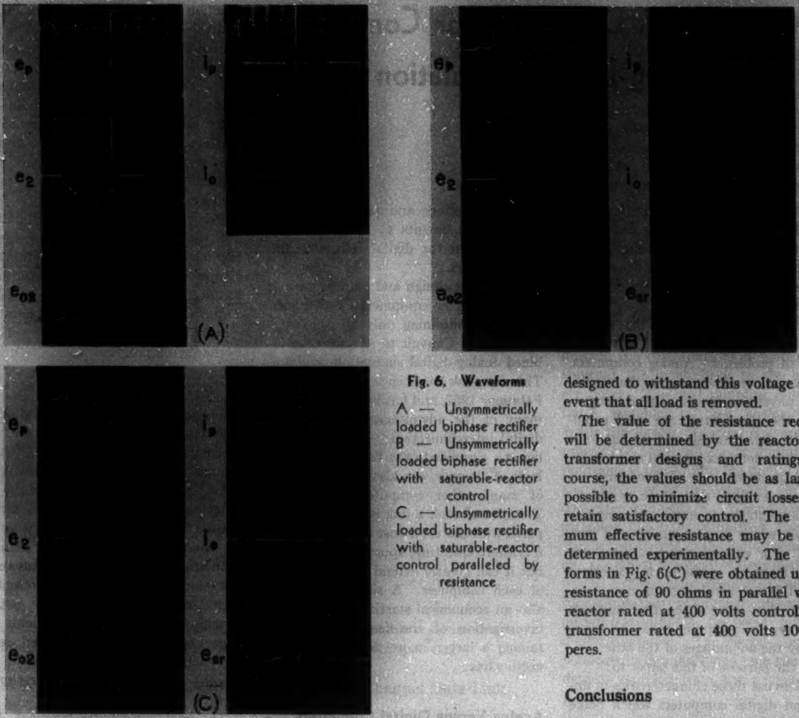

Fig. 6. Waveforms

A — Unsymmetrically loaded biphase rectifier
B — Unsymmetrically loaded biphase rectifier with saturable-reactor control
C — Unsymmetrically loaded biphase rectifier with saturable-reactor control paralleled by resistance

exceed the limits of safe operation for both the rectifier elements and the transformer unless precautionary measures are taken to prevent unbalanced loading of the circuit, unless additional safety factor is provided in the circuit components, or unless means are provided to limit the voltage stresses. A system of interlocked switchgear is one method which can be employed to reduce the probability of operation with one side of the biphase rectifier unloaded. This may not be completely effective, however, since most practical interlock systems can be bypassed and it does not apply to the half-wave case. The second approach to the problem, providing additional safety factor in both the rectifier inverse-voltage rating and the transformer insulation level, can be completely effective. This method is currently being applied successfully to power supplies using vacuum tubes or mechanical rectification where higher inverse-voltage ratings may be obtained with relative ease and reasonable expense. Recently there has been a trend toward the use of the more efficient silicon diodes as rectifier elements. These diodes are appreciably more sensitive to inverse voltage than vacuum tubes and mechanical rectifiers. In addition, larger inverse-voltage ratings cannot be provided as economically. The third method, that of limiting voltage stresses, may be implemented by a minor change in the primary circuit, i.e., by the addition of a resistance in parallel with the a-c winding of the saturable reactor.

The waveforms of Fig. 6(C) were recorded under conditions identical to those of Fig. 6(B) except that the aforementioned resistance was added. The effectiveness of the resistor in reducing the primary voltage peaks may be recognized by comparing the two waveforms of e_p in Figs. 6(B) and (C). Peak primary voltage has been reduced to a value approximately equal to the peak line voltage. As previously discussed in the full-wave case, the rectifiers must be designed to withstand this voltage in the event that all load is removed.

The value of the resistance required will be determined by the reactor and transformer designs and ratings. Of course, the values should be as large as possible to minimize circuit losses and retain satisfactory control. The maximum effective resistance may be easily determined experimentally. The waveforms in Fig. 6(C) were obtained using a resistance of 90 ohms in parallel with a reactor rated at 400 volts controlling a transformer rated at 400 volts 100 amperes.

Conclusions

Care must be exercised in the design of rectifiers using saturable-reactor controls in the primary circuit, particularly if the rectifier circuit and load are such that unsymmetrical currents exist. The resulting excessive voltages can be minimized by paralleling the reactor with a dissipative element. The additional losses introduced are usually small. If they can be tolerated, this method provides a practical alternative to increasing transformer insulation levels and rectifier peak-inverse ratings.

A 2-Channel Data Link for Combined Analog-Digital Simulation

J. GREENSTEIN
ASSOCIATE MEMBER AIEE

THE NUMBER of computing laboratories using both analog and digital computers is greatly increasing. Each type of computer is normally operated independently of the other, receiving the computing task for which it is better suited. It is generally agreed that neither type of computer is ideal for solving all classes of problems. Analog computers, for example, are widely used for the simulation of physical systems; digital computers, on the other hand, are used extensively for data analysis and for the solution of very complex physical and mathematical problems. It is becoming increasingly evident that there would be many advantages to having a computer available which is part analog and part digital. For example, such a computer would make it possible to simulate sampled-data control systems more realistically. Also some of the disadvantages of one type of computer could be overcome by the advantages of the other.

It is the purpose of this paper to:

1. Discuss those characteristics of analog and digital computers which make it desirable to combine them.
2. Describe the 2-channel link which was constructed at Convair for the purpose of interconnecting its analog and digital computers.
3. Illustrate the function of the data link in a real-time analog-digital simulation.
4. Indicate some of the additional advantages of combining an analog and a digital computer.

The Addaverter System

Convair, in order to interconnect its *550* operational amplifier analog computer with its Sperry-Rand *ERA 1103* digital computer, ordered a special high-speed 25-channel data link from Epsco Inc., Boston, Mass. This data link was installed at Convair in June 1957. It is primarily being used to help simulate the flight performance of the Atlas Intercontinental Ballistic Missile. This data link, called the Addaverter system (a contraction of analog to digital and digital to analog converter system), contains 15 analog to digital converters, 10 digital to analog converters, and gating and channel selection circuits to transfer binary data between the digital computer and the converters.

During the design and manufacture of this Addaverter equipment, a simplified data link containing only two channels was built at Convair to initiate its combined analog-digital simulation program. This data link has been in operation since February 1957, and has by its use proved many of the advantages of an analog-digital interconnection. The author believes a simplified data link, such as was built at Convair, can also meet the needs of many other computer laboratories. The cost of such a link is very low compared with the total cost of the computer it is interconnecting, approximately 0.1%, but it can greatly extend the application of each computer. A simple system is also an economical starting point for the investigation of the feasibility of obtaining a larger, more flexible interconnecting link.

Analog Versus Digital Computers

DIGITAL COMPUTER ADVANTAGES

One of the most important advantages of a digital computer is its ability to compute with essentially unlimited accuracy. On an analog computer it is difficult to limit errors to less than a few per cent and, unfortunately, the accuracy tends to drop as the problem complexity increases. Another important advantage of a digital computer is its high operating reliability. Since a digital computer generally consists of switch-type electronic circuits requiring only a yes-no response, its reliability can be much greater than high-gain analog circuits requiring operation over a wide range of input conditions.

The setup time required just prior to running a digital problem, once the programming has been completed, is extremely short. The complete program is usually conveniently stored on a paper or magnetic tape. All that is required to run the problem is to feed the stored program into the machine. An analog computer problem requires considerably more preparation time. Potentiometers, switches, function generators, etc., must be adjusted and then a complete check must be made for equipment troubles and setup errors. Trouble-shooting of a digital computer is often easier when equipment troubles do occur since the components of the computer and their arrangement remain essentially fixed regardless of the problem. This makes it possible to prepare a separate diagnostic program which can be used for the life of the machine.

Because of the greater dependability of a digital computer, and because less setup time is required for each run, the digital computer is more suitable than the analog computer for production-type problems. These problems involve a large number of repeated runs with essentially no changes in the digital program.

ANALOG COMPUTER ADVANTAGES

Frequently it is desirable to study the characteristics of actual equipment under realistic operating conditions. Often this is done by connecting the equipment to an analog computer and then using the computer to simulate, in real-time, some of these conditions. This fact that an analog computer can be used for real-time simulation is an important advantage. For many real-time problems, present-day digital computers are actually not fast enough. The arithmetic elements of a digital computer are time-shared, requiring each computation to wait its turn thereby introducing undesirable time delays.

The analog computer language, being in the form of a continuous voltage, is more compatible with other analog equipment. If a digital computer is used, costly analog to digital and digital to analog converting equipment is usually required, since communication with a digital computer must be in the form of a binary-coded signal appearing on a number of parallel wires. Also, digital results appear discontinuously, in a point-by-point fashion requiring special extrapolation techniques.

The analog computer's particular suitability for simulating physical systems is another important advantage. The components of an analog computer are easily programmed to operate in a manner analogous to the physical problem. These

B—Front view

computers are also often used "open shop," allowing an engineer to solve his own problem directly on the machine. Simple changes in the problem can usually be made by merely switching a few patch-cords. A larger number of steps are required to prepare a physical problem for a digital computer, thus multiplying the possibility of human errors and sometimes introducing frustrating delays. The problems must first be transformed into algebraic terms (possibly by a mathematician); then coded by a programmer to convert the problem into machine language; magnetic or paper tapes are made; finally the problem is fed into the machine by the computer operator. Changes in an existing program require almost as many time-consuming steps. At the present time, some much needed advances are being made in digital programming techniques to enable easier and quicker programming of physical problems.

In summary, it can be stated that the digital computer has an accuracy and reliability advantage and is better suited to perform production-type problems. On the other hand, the analog computer is better able to perform real-time physical simulations involving actual system hardware.

By interconnecting an analog to a digital computer, all of the foregoing advantages are available resulting in a more effective computing system.

Convair Two-Channel Data Link

Function

The simplified Convair data link contains one analog to digital converter and one digital to analog converter; the data link also contains transistor flip-flops, pulse drivers, gates, and delay circuits, to synchronize the flow of binary data between the digital computer and the converters. The complete data link is housed in a standard relay rack as shown in Figs. 1(A) and 1(B). The transistor circuitry, which uses approximately 150 transistors, shown in Fig. 1(B), is mounted in the rear of the relay rack behind the two converters, on hinged panels to enable access to the converters.

Fig. 2 illustrates the function of the link. The input analog voltage from the analog computer is sampled by the analog to digital converter and converted into binary form; the sampling time is controlled by an external sample pulse source. After the conversion is completed, the transistor data transfer circuits transfer the binary data into the digital computer. The digital computer uses this sampled data in its computations, and when it has finished the computations it prepares to transmit the result back to the analog computer. The next sampling pulse initiates sampling of new analog data. While this analog-to-digital conversion is proceeding, the result of the digital computations is placed into the digital to analog converter by the data link and then converted into voltage. When the analog sampling has been completed, this new data is transferred to the digital computer and the whole process just described is repeated. The analog computer performs its computation continuously, although its output is modified by the inputs from the digital computer. The digital computer performs its computations each time new data is sampled from the analog computer.

Digital Computer Input-Output

The digital computer connected to the data link is a Sperry Rand *ERA 1103*, also known as a Univac-Scientific. All data transfer between this computer and the data link is via the computer 36-bit input-output *B* flip-flop register (*IOB*). When "writing" into external devices, such as

the data link, the digital computer transfers the data word from a storage location in its high-speed electrostatic memory to its input-output register. Then the computer transmits a signal to the external source, indicating that a data word is available in its output register. When the external device has absorbed this data, it must transmit a "resume" signal to notify the computer to perform the next input-output instruction. When the digital computer is programmed to "read" an external device, it waits for the word to be placed into its input-output register. When the external device is ready, the device transmits the binary word to the computer by pulsing the input-output flip-flops and notifies the computer with a "read acknowledge" pulse that the word has been transmitted. The computer then transfers this word from its input-output register to a high-speed memory location and goes on to the next instruction.

The data link has a word length of 11 binary digits; therefore, only 11 of the 36 available *IOB* flip-flops are used for reading and writing. Two additional *IOB* flip-flops are used to start and stop the analog computations.

CONVERTERS

Each converter used in the data link is a standard Datrac converter built by Epsco Inc. Each converter has a binary word length of 11 bits, 10 data bits plus a sign bit. They are operated over an analog voltage range of ± 100 volts referenced to the analog computer.

Analog to digital conversion is accomplished by the ripple-down technique at an accuracy of approximately 0.1%. The converter has 11 current switches which draw current through a resistance matrix. Upon receipt of a sampling pulse from an external source, a programmer turns the current switches on in sequence, starting with the most significant bit (sign bit) and rippling down to the least significant bit (0.1 volt). As each switch is turned on, the analog voltage input is compared to the voltage output of the resistance matrix. If the voltage output of the matrix is found larger, then the current switch is turned off. Since each comparison takes approximately 2 microseconds and there are 11 current switches, complete analog to digital conversion takes approximately 22 microseconds. The binary value of the sampled analog voltage is determined by reading the binary state of the current switches. All the current switches on corresponds to +99.9 volts. All the current switches off corresponds to −99.9 volts.

By a simple modification, each analog to digital converter can be used for digital to analog conversion. Digital to analog conversion is accomplished by turning on the proper current switches. The resulting analog voltage appears at the output of the resistance matrix. Since only 2 microseconds are required for current switching and all of the current switches can be pulsed in parallel, neglecting transients on the output voltage, digital to analog conversion can be accomplished in approximately 2 microseconds. The voltage output of the converter, after several conversions, resembles a staircase function. After digital to analog conversion, the converter holds the voltage output constant until the current switches are triggered by a new data word. After triggering, the output voltage changes in one step from the old value to the new.

SYNCHRONIZING CIRCUITRY

Fig. 3 is a block diagram of the transistor synchronizing and gating circuitry. The main sampling pulses synchronize both the conversion of data and the transfer of data between the digital computer and the converters.

In a combined analog-digital computer operation, the digital computer is first allowed to perform its initial computations. When these initial computations are completed, the digital computer transmits a "start" signal from an *IOB* flip-flop and also places the first data word into the *IOB* register. The computer then waits for a "resume" signal to come from the data link.

The "start" signal from the digital computer opens the gate shown in Fig. 3, allowing the transmission of the main sampling pulses. The first main sampling pulse causes the generation of an analog start signal which places the analog amplifiers into the operate condition, thereby starting the analog computations. The second and succeeding main sampling pulses are fed to the pulse distributor.

The pulse distributor consists mainly of delay circuits which generate a sequence of delayed pulses for each main sampling pulse. The first pulse, labeled CLEAR, which is a main sampling pulse delayed only a few microseconds, clears the current switches of the D-A converter to zero. This causes the voltage output of the converter to start dropping. A "present" pulse follows the CLEAR signal by a few microseconds, and gates the waiting contents of the *IOB* register into the D-A converter current switches, thereby presenting a new voltage to the analog computer. At the same instant that the new data is presented to the analog computer, a sample pulse is fed to the analog to digital converter to initiate analog to digital conversion.

During the conversion process, a *IOB* CLEAR signal from the pulse distributor clears the *IOB* register, readying it for the new sampled data. A "resume" signal is then transmitted to the waiting digital computer, to allow it to continue to the next input-output instruction which will be an "External Read" instruction. The computer then waits for the analog computer's new data word.

When the analog to digital conversion is completed, a "read" pulse from the pulse distributor gates the binary value of the sampled voltage from the A-D converter into the *IOB* register. The data pulses are followed by a "read acknowledge" signal to the digital computer to inform the computer that the data word has been placed into the *IOB* register. The digital computer then continues its computation using the new data word.

At the end of the digital computation,

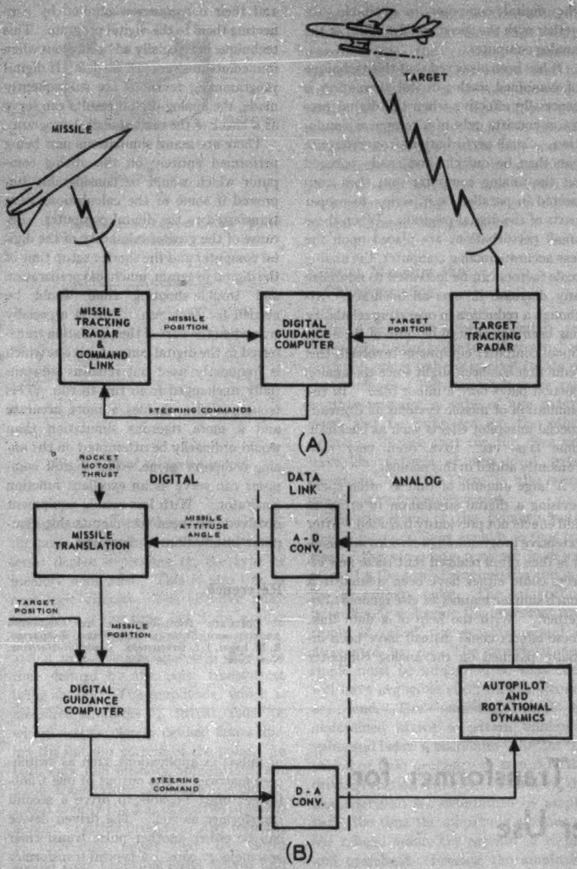

Fig. 4. Simulation of a guided missile system

A—Guided missile system. B—Combined analog/digital simulation

the new result is placed in the *IOB* register and the computer waits for the next main sampling pulse. At the next sampling pulse, new data is exchanged between the computers and the digital computations are again performed. Each digital computation must be completed before the next sampling pulse arrives or the digital computations will fall behind those performed by the analog computer.

This process is continued until the end of the combined analog-digital run. At the end of the run the digital computer places a "stop" signal on a particular output line. This signal causes a halting of the main sampling pulses and a resetting of the analog computer.

Application of the Data Link

General

The primary function of the 2-channel data link is to interconnect the analog and digital computers in order to stimulate mixed analog-digital systems. Many other useful applications exist. For example, the data link is being successfully used to sample and directly transfer to the digital computer, analog data from the analog computer and from magnetic tape units. Sampling speeds of up to 4,000 samples per second have been used. Continuous monitoring of a long digital computation is another useful application of the data link whereby digital computer results are fed to an analog recorder via the digital to analog converter.

The 2-channel data link can be extended easily into a multichannel system by time sharing the converters and the gating circuits. In this case, each separate data output from the digital to analog converter must be placed into an analog hold circuit in order to hold the voltage output constant while the converter is being switched to other channels. An analog sample and hold device may be required for those channels being multiplexed to the analog to digital converter if it is necessary to sample several analog channels at precisely the same instant. After each voltage conversion the binary result must be transferred immediately to the digital computer.

A Real-Time Simulation

Fig. 4(A) shows a somewhat hypothetical sampled-data control system which will serve as an example to illustrate the application of the Convair data link for real-time simulation. The figure shows a guided missile which has been launched for the purpose of intercepting and destroying an enemy aircraft. It is necessary that this missile be guided with extreme accuracy to its manuevering target. Assume that separate radar systems are continuously tracking the positions of the missile and the target. A ground-base digital computer samples the position data from the tracking radars at equal time intervals, and then calculates missile pitch and yaw correction signals. These correction signals are transmitted several times per second to an autopilot located in the missile, causing the missile to maneuver in the direction of the target.

From a realistic simulation of this system, a considerable amount of information about the missile system's performance can be obtained, and at much less expense than by the test firing of actual missiles. Fig. 4(B) shows a simplified simulation of this control system. The simulation can be divided into the three parts: missile translation, guidance computer, and autopilot and rotational dynamics. Both the translation of the missile and the guidance equations performed by the ground-based digital computer are best simulated on the more precise digital computer. A high-gain autopilot, controlling changes in missile attitude, would ordinarily have a fast response characteristic with respect to the over-all guidance loop; therefore, it can best be simulated on the analog computer. Since an actual autopilot might not function any more accurately than the analog computer, the lower accuracy of the analog computer is not necessarily a disadvantage. The separate analog and digital simulations are then joined with the help of the data link. This simulation technique allows the lower-frequency higher-accuracy portions of the system to be performed by the digital computer, while the lesser-accuracy higher-frequency portions are performed by the analog computer.

When the actual autopilot equipment becomes available for test, it may easily be placed into the control loop to replace the simulated autopilot. With the lower frequency effects restricted to the digital computer, a slower digital sampling and computation rate can be used, making it easier for the digital computer to keep up in real-time.

MORE EFFECTIVE COMPUTER USE

In the preceding example, the major function of the data link was to enable a more realistic simulation. Convair's experience with the data link also indicates that a more advantageous utilization of computers results when analog and digital computers are interconnected. For each simulation, the accuracy and reliability of the digital computer is available, together with the speed and flexibility of the analog computer.

It has been observed that this technique of combined analog-digital simulation is especially effective when the digital program consists only of a reference simulation. Small perturbations from reference can then be quickly and easily patched on the analog computer and then connected in parallel, or in series, to proper parts of the digital program. When these small perturbations are placed upon the less accurate analog computer, the analog scale factors can be increased to minimize any decrease in over-all accuracy. Although a reduction in operating reliability has been experienced because of the additional computer equipment involved, this reduction has been slight since the analog portion plays only a minor role. In the simulation of missile systems at Convair, special autopilot effects such as backlash, time lags, etc., have been very conveniently added in this manner

A large amount of time is often spent revising a digital simulation in order to add effects not previously included. After extensive programming revisions are made it is then often realized that these new effects could either have been treated in a much simpler manner or else ignored altogether. With the help of a data link, these effects could instead have been initially patched on the analog computer and their consequences studied by connecting them to the digital program. This technique is especially advantageous when immediate answers are needed. If digital programming revisions are subsequently made, the analog-digital results can serve as a check of the revised digital program.

There are many simulations now being performed entirely on the analog computer which would be considerably improved if some of the calculations were transferred to the digital computer. Because of the greater reliability of the digital computer and the shorter setup time of the digital program, much less preparation and trouble-shooting time would be needed for each run. This is especially true when the part of the simulation transferred to the digital computer is one which is frequently used but remains substantially unchanged from run to run. This technique also enables a more accurate and a more rigorous simulation than would ordinarily be attempted on the analog computer alone. The digital computer can serve as an excellent function generator. With less analog equipment involved, the need for huge analog computer installations is decreased.

Specifying a Pulse Transformer for Computer Use

R. R. BLESSING
ASSOCIATE MEMBER AIEE

THE pulse transformer described in this paper is a specialized current-driven device that functions as a precision component in large-scale ferrite-core memories, and also as a switching device in computer logic. Typical transformer characteristics do not satisfy the exacting demands of computer applications. Greater precision in specifying and measuring these components is required along with closer tolerances.

The paper will show how the specifications are arrived at, how the devices are measured, and how these characteristics are related to the application.

How the Device Functions

When used as an input device to large core memories, the transformer must respond to pulses that are trapezoidal in shape. It must faithfully reproduce this waveform at one or more secondary windings. It must also be able to respond with an output to only the first of a train of pulses in applications such as switch-core matrices. The output of one transformer must be able to drive a second transformer as well. The driven device can be either another pulse transformer or a memory core. A typical transformer and an input pulse are shown in Figs. 1 and 2.

Critical Requirements

The above describes the ideal which is difficult to achieve. The most critical requirement of this type of transformer is faithful reproduction of the input pulse at the secondary. In memory applications one is not interested in the output of the memory core when information is entered, but only in the pulse that results when the core is interrogated. The interrogating pulse must faithfully resemble the input to the switch core.

The pulse transformer response must be a true reproduction of the input only during the time the memory core is being switched.

Paper 59-119, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted November 3, 1958; made available for printing November 6, 1959.

R. R. BLESSING is with the International Business Machines Corporation, Poughkeepsie, N. Y.

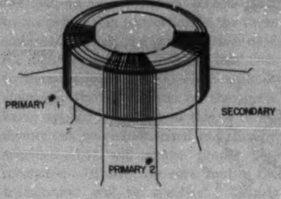

Fig. 1. Specialized current-driven pulse transformer

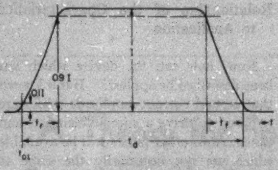

Fig. 2. Input or driving pulse

During the time information is entered, the pulse can be distorted to a greater or lesser degree depending on the type of memory core used. This is also true in core logic circuits. The effective pulse must have a rise time and shape similar to the primary pulse, negligible overshoot, and a negligible droop for a period of time defined by the pulse transformer being driven. The amplitude, which is measured in terms of current, must be within certain closely defined limits during the flat-top portion of the pulse. In both logic and memory applications, the pulse transformer secondary should respond to only the first of a series of pulses applied to either primary. Any response to succeeding pulses that does occur should have negligible effect on the unit being driven. The point of interest is the amount of energy being transmitted to the driven unit expressed in terms of the amount of flux change appearing at the secondary.

Physical Characteristics

Normally, the pulse transformers consist of two or more windings on a magnetic core of toroidal shape. The windings can be placed for maximum or minimum interaction with each other depending on the application. Because most cores are sensitive to shock, it is appropriate to encapsulate them in some plastic compound. The compound selected should be one that does not stress the core in setting. It also must protect the core and its windings from handling damage. The windings are then brought out in a manner which allows their ready insertion into the circuit. In many applications, it has been found best to wire the winding to a base assembly similar to that of the base of a 9-pin miniature tube. By so doing, it can be plugged into an appropriate tube socket. The transformers can also be assembled on a base that will allow ready insertion on a printed wiring card. Fig. 3 shows typical physical configurations.

How to Measure the Characteristics

Fig. 4 shows the actual secondary response of a loaded pulse transformer when the appropriate pulse is applied to one of the primaries. Between each pulse put on that primary, a pulse of like nature must also be impressed on the other primary. Notice that the top does not have the flatness of the ideal pulse shown in Fig. 2. There is also some overshoot and ripple present.

The rise time of the primary pulse should be made short enough so that the rise of the secondary response is determined by the core characteristics and not by the primary pulse. The flat portion immediately following the overshoot and ripple is called the amplitude and is designated by I_m. The overshoot and ripple must be minimized so that they will have negligible effect on the secondary load. This amplitude must be maintained above a certain minimum value and below a maximum value for the period of time necessary to complete the driving function required. Therefore, the characteristics are determined by amplitude, the time the amplitude remains at the critical value, the amount of ripple, and overshoot. Because the amplitude of the input pulse directly affects the switching time, the operating frequency must allow sufficient time for the switching of the core. When the time between pulses approaches the core switching time, the duration of the pulse entering information becomes critical. If the core is not completely switched, it will affect the response during the most critical pulse time.

The pulse response is directly related to the hysteresis loop of the core used. The most important characteristics of the loop are the *Br/Bs* squareness ratio, the high-permeability region, the amount of time it takes a pulse to drive through this high-permeability region, and the rate at which the permeability decreases as saturation is approached. The magnetic core characteristics can be determined by observing the secondary pulse response of the transformer. Fig. 5 shows a typical hysteresis loop. If it is assumed that the core is in the state labeled $-Br$ and a pulse is applied in the direction that tends to switch the core to $+Bs$, the rise time can be adjusted so that it occurs before the loop is traversed to the knee, designated by the numeral 1. The curve from point 1 to point 2 covers a relatively high permeability region. During this time, the shape of the top of the pulse will be governed by the permeability. If this section of the curve is vertical, a flat top response is obtained. It is apparent that the permeability decreases as it approaches saturation at $+Bs$. During this time, the pulse can be expected to droop in direct relationship to the curvature of the hysteresis loop (i.e., decrease in permeability). The period of time during which the amplitude is above a certain predetermined level can deter-

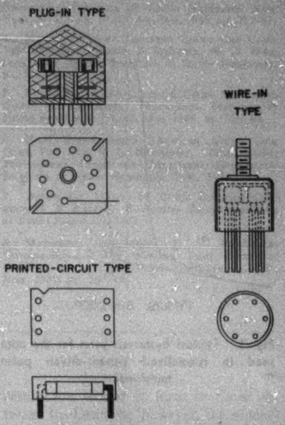

Fig. 3. Typical physical configurations of specialized current-driven pulse transformers

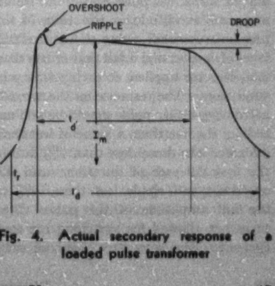

Fig. 4. Actual secondary response of a loaded pulse transformer

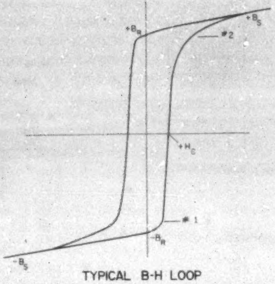

Fig. 5. Typical hysteresis loop for the core used in specialized current-driven pulse transformers

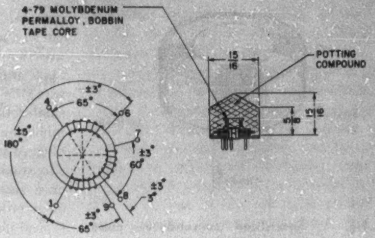

Fig. 6. Typical specialized current-driven pulse transformers

mine whether or not the permeability is satisfactory. The rate of decrease in permeability as saturation is approached can be determined by a measurement of pulse duration at a percentage of I_m.

If a pulse is applied to a primary following a similar pulse applied to the same primary, the portion of the hysteresis loop from $+Br$ to $+Bs$ is traversed. The change in flux that occurs will cause a pulse to appear on the secondary whose amplitude is inversely related to the ratio of Br to Bs. If this ratio is low, the pulse that occurs on the secondary will be large, and vice versa. Since it is desired that no signal appear on the secondary at this pulse time, the response should be small. Therefore, the ratio of residual to saturation flux, which should be kept as large as is possible, can be determined by its relation to the amplitude of this secondary response.

To illustrate further the relationship between the pulse transformer characteristics and the hysteresis loop of the magnetic element, it would be in order to describe a part for a specific application. Fig. 6 shows a drawing of such a unit. Each primary has 17 turns and the secondary 15 turns. A pulse of 400 ma (milliamperes) amplitude, a rise time of 0.2 μsec (microsecond), a duration at the 90% level of 8 μsec, and a fall time of less than 0.6 μsec, are applied at each primary in succession. The response on the secondary during either pulse should be 400 ma ±3%; the rise time, a value of less than 0.5 μsec; the droop less than 5% during the first 2.0 μsec of duration; and the overshoot and ripple less than 10% of the full amplitude of the pulse. Two turns are allowed for switching the core element. The secondary response may vary ±3% of the 400 ma. This allows a total of ±180 ma-turns variation. Therefore, the amount allowed for switching the core is 800 ±180 ma-turns, a variation of coercive force of ±22.3%. The total amount of flux change allowed is controlled by the pulse width at the 50% of full amplitude level. The requirement is that it be 3.5 ±0.4 μsec. Therefore, the core is required to be near the saturation level between 3.1 and 3.9 μsec after the start of the response. Since the total flux change can be achieved with the specified pulses in a definite period of time, the control on the pulse width controls the amount of total flux change.

The high-permeability region is specified by the droop requirement. The pulse should not droop more than 5% within the first 2 μsec after the start of the pulse. During this period of time the core is driven through the high-permeability region of its hysteresis loop and does not start to approach the curvature leading to saturation until after 2 μsec of the pulse have passed.

If only one winding is pulsed successively and the response observed on the secondary, a relatively high voltage response occurs. If this response is integrated, the amount of flux change can be determined which is caused by this pulse traversing the loop from a residual state to its same saturation state. The flux change is related to the amount of energy available for work at the load. By establishing a maximum limit on the integrated response, the Br/Bs squareness ratio is defined. In summary:

1. The amplitude allowed determines the coercive force of the core.
2. The pulse width determines the amount of saturation flux density.
3. The amount of droop determines the permeability of the core in the critical region.
4. The measurement of the flux change from a residual state to the same saturation state determines the squareness of the core.

Relationship of the Characteristics to Application

Now, how can the device which has been described be applied? If it is known that certain current-amplitude pulses are required to drive a specific element, and that certain other pulses will be available which are not necessarily the same as those required for driving this element, a pulse transformer can be devised and specified to meet the application. By requiring a certain pulse amplitude for a specific time the coercive force and the high-permeability region of the core to be used are determined. The pulse width specifies the amount of saturation flux, and the amount of energy the unit being driven can withstand before reacting to it determines the squareness ratio. When the core characteristics are known and are described through the desired characteristics of the pulse transformer, then the special type can readily be specified: the specialized current-driven pulse transformer.

Conclusions

The previous discussion of methods of characterizing specialized current-driven pulse transformers is intended to describe exactly how it is possible to specify the requirements for an application of this component. The method is primarily concerned with the electromagnetic characteristics of the pulse transformer. It has not been pointed out that in conjunction with the characterization that the mechanical and electrical properties are also considered. For instance, insulation resistance, winding resistance, dielectric strength, and the mechanical stability of the unit are determined.

Although the problems involved in characterizing pulse transformers have not been discussed, it might be pointed out that the primary problem is that of achieving the required drive pulse. This is especially difficult if the transformer is a current step-up device. In such cases, the load on the secondary reflects back to the primary in proportion to the turns ratio. Therefore, the current driver used for input would have to stand load fluctuations as great as 500 ohms without changing the amplitude of the pulse being applied. In spite of this, a transformer can be characterized and thereby specified that will assure proper performance. In turn, the core used in the transformer will be specified. This is done without requiring tests of the magnetic characteristics of the core except, indirectly, for its Br to Bs squareness ratio.

It has been found that this procedure is quite satisfactory and that pulse transformers of this nature can be readily described through specification after characterization in this manner.

A Theory for Space-Charge-Limited Currents with Application to Electrical Precipitation

P. COOPERMAN
NONMEMBER AIEE

THE FLOW of steady electric currents in the interior of any medium is governed by three laws 1. Poisson's law which essentially relates space charge to potential. 2. Conservation of charge. 3. A law of the type of Ohm's law connecting current flow and potential gradient. In most solid and liquid conductors of technical interest, Poisson's law can be satisfactorily approximated by the simpler equation of Laplace, and Ohm's law applies with the conductivity taken as constant. In gases, however, these simplifications cannot be made and hence the problem of calculating such electrical parameters as the current-voltage relationship, field strength, and charge density is much more difficult.

The approximate calculation of these parameters for a corona discharge in coaxial cylinder geometry was done by by Thomson and Townsend.[1,2] Experimental verification of the theoretical formulas has been provided by other investigators.[3,4] However, this geometry is an especially simple one for the reason that all the electrical quantities are functions of the radial distance from the axis and of no other geometrical factor. Where the geometry is essentially 2-dimensional as in electric precipitators of the "duct" type, the methods used in solving the problem for coaxial cylinders do not apply except for rather crude approximations.[5] A very sophisticated attempt to obtain formulas of use in duct-type precipitators was made by Deutsch;[6–7] however, his work was shown to have been in error both by experiment and by theory.[8–10]

The object of this paper is to present a new method for the calculation of the electrical parameters of space-charge-limited currents in gases, and to apply the method to two geometries of interest in electrical precipitation, namely, coaxial cylinder and duct geometry. The results of this work will be good approximations for low current densities and applied voltages not too far removed from the starting voltages. These conditions are, however, typical ones in electrical precipitation. For cylindrical geometry, the results are exactly the classical ones given by Thomson and Townsend. For duct geometry, i.e., a grating of equally spaced wires centered between parallel plates, the results are similar in form to those obtained by Deutsch; however, the numerical coefficients in the formulas are considerably different and, as a result, different conclusions are drawn.

Physical Basis of the Method

A distinguishing feature of electrical conduction in gases is that the electric field which moves the charge also creates it. Thus, when the applied voltage is increased beyond a certain minimum, i.e., the starting voltage, not only does the already existing charge move more rapidly, but also new ions are created at a higher rate. This contrasts strongly with the situation in most solids and liquids where the strength of the applied field acts on ions whose rate of generation is independent of the field. A second characteristic of conduction in gases is that the charge between the electrodes, i.e., the space charge of the moving ions, is comparable in magnitude to the electrostatic charge on the surface of the electrodes. This means that the ions distort the field which both produces and moves them. In solids and liquids, the space charge is usually very small compared with the electrostatic charge and hence the space charge field has a negligible effect on the ions. These features of conduction in gases produce a strong interaction between electric field and space charge which makes it impossible to calculate these two parameters independently of each other. Mathematically, the same difficulty exhibits itself in that the differential equations which govern the phenomena are highly nonlinear.

The basic idea which this paper presents is that the difficulties discussed can be overcome by treating the problem as if no interaction exists but subsequently

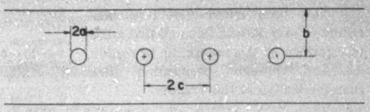

Fig. 2. Cross section of a duct precipitator

making corrections in a suitable fashion. Thus, first it is assumed that there is no space charge but that the entire field is electrostatic in origin, i.e., the field is that of surface charges on the electrodes. With this as a given field, the distribution of the space charge for a given flow of current is calculated. With this distribution of space charge known, calculations can be made to determine how the original electric field has been altered by the presence of space charge. Now this process of changing the field and the space charge alternately is simply repeated. If it could be shown that each repetition brought the results closer to the exact results, one would have a mathematically valid method of solving the appropriate differential equations by an iterative scheme. The proof of this fact is, however, quite complex and hence will be published later in a mathematical journal. In this paper, the reasoning will be on a physical rather than a mathematical basis.

Actually, it will not be necessary to prove the validity of the method in general since only one iteration will be shown here. It will begin with the electrostatic field, then the space-charge distribution corresponding to this field will be calculated, and then the potential corresponding to the space charge recalculated. It is clear that if the curent density is low, the effect of the alteration in the field on the space charge will be small and a second iteration will not be needed. With this restriction, a valid result is obtained. For many situations in electrical precipitation, the limitation is not severe.

Application of the Method

By the mathematical theory given in the Appendix, the potential function $u(r)$ for coaxial cylinder geometry is given by

$$u(r)=\frac{V_0 \log b/r}{\log b/a}+\frac{I \log b/a}{2kV}(b^2-r^2)$$

Notice that the first term is the purely electrostatic potential existing at the starting voltage while the second term gives the change stemming from the space charge. Since at the high-tension electrode $r=a$ (see Fig. 1), the potential must equal the applied voltage V, this equation gives for the current-voltage characteristic

$$I=\frac{2k}{b^2 \log b/a}V(V-V_0)$$

This is the classical formula originally obtained by Townsend. It has been found here again by a much more complicated method, but one which can be extended to the duct precipitator.

Let the dimensions of a duct precipitator be indicated as in Fig. 2. In terms of these parameters, a constant d can be defined as follows:

$$q_1=e^{-2\pi b/c}$$

$$k_1=\left[\frac{2q_1{}^{1/4}\sum_{n=1}^{\infty} q_1{}^{n(n-1)}}{1+2\sum_{n=1}^{\infty} 1^{n^2}}\right]^2$$

$$K_1=\int_0^{\pi/2}(1-k_1{}^2\sin^2\varphi)\,d\varphi$$

$$d=c/k_1{}^{1/2}\,K_1$$

Notice that since k_1 and K_1 are dimensionless, d has the dimensions of length. With this notation, and with the use of the electrostatic potential for a duct given in reference 11, the following is obtained for the modified formula

$$u=-\frac{V_0}{\log(d/a)}\log\left[k_1{}^{1/2}\left|\operatorname{sn}\left(\frac{K_1Z}{c},k_1\right)\right|\right] \tag{1}$$
$$+\frac{\log(d/a)\,I}{kV}(b^2-y^2)$$

where $\operatorname{sn}(K_1Z/c, k_1)$ is a Jacobian elliptic function. From this, the current-voltage characteristic for a duct can be derived as

$$I=\frac{k}{b^2\log(d/a)}V(V-V_0) \tag{2}$$

This formula requires that one be able to compute the constant d, a somewhat formidable task. However, this difficulty can be avoided for it can be shown that the following approximations are valid to within 1% under the conditions indicated

$$\text{for } b/c \leqq 0.6 \qquad d=4b/\pi \tag{3}$$

$$\text{for } b/c \geqq 2.0 \qquad d=c/\pi\, e^{\pi b/2c} \tag{4}$$

For b/c in the range 0.6–2.0, the values of d/c are plotted in Fig. 3. However, if somewhat larger inaccuracies can be tolerated, the value of d given by equation 3 can be used up to $b/c=2.0$. The error caused by this procedure is shown in Table I.

The following results have now been obtained. In a duct precipitator, the current-voltage characteristic is given by equation 2 where the constant d is given by equations 3 and 4 and Fig. 3. The starting voltage, V_0, is given by

$$V_0=aE_0\log(d/a) \tag{5}$$

where E_0 is the "critical" field strength.[12]

Conclusions

Equation 3 states that the length d is independent of the wire-to-wire spacing when b/c is less than 0.6. For a fixed wire-to plate spacing, this means that the current per foot of wire, I, does not depend on the wire-to-wire spacing until the wires approach each other very closely. For example, when b is 4 inches, the current per foot of wire remains constant to within 1% for wire-to-wire spacings up to 13 inches and remains constant up to 15%, for wire-to-wire spacings as close as 4.5 inches. Since there is a normal day-to-day fluctuation in most precipitators of this order of magnitude, it is clear that for practical purposes the current per foot of wire is constant up to the point

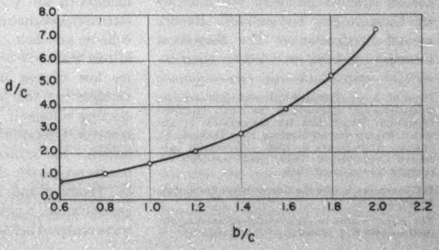

Fig. 3. Calculated values of d/c versus b/c

Table I. Error Made in Calculated Current by Use of Equation 3

b/c	c	log 4b/πa	log d/a	Per-Cent Error
0.8	5.00	4.65	4.70	1.06
1.0	4.00	4.65	4.80	3.12
1.2	3.33	4.65	4.95	6.65
1.4	2.85	4.65	5.10	8.83
1.6	2.50	4.65	5.29	12.1
1.8	2.22	4.65	5.48	15.1
2.0	2.00	4.65	5.69	16.5

where the wire-to-wire spacing approaches the wire-to-plate spacing. This point has been verified experimentally (as described in the author's unpublished company report no. *46*).

Now consider the situation as a and b are held constant while c becomes small (but remains larger than a). Under these circumstances, equation 4 applies. The logarithm in the denominator of equation 4 will usually be small compared with the second term. For example, with $a=0.05$ inch, $b=4.0$ inches, and $c=0.5$ inch,

$$\log(c/\pi a)\cong 1.16$$

$$\pi b/_2c\cong 12.56$$

For these conditions, equation 2 reads

$$I/c=\frac{2k}{\pi b^3}V(V-V_0) \qquad (6)$$

I/c is proportional to the current density at the collecting plate. In fact, if i is the current density at the plate surface, then

$$i=I/4c \qquad (7)$$

and by equation 6,

$$i=\frac{k}{2\pi b^3}V(V-V_0) \qquad (8)$$

This shows that, except for effects due to changes in the starting voltage, close spacing of the wires leads to a constant current density. Beyond a certain point, the total current can no longer be increased by the addition of more wires. In fact, the current will start to decrease as c gets smaller because V_0 will increase. The reason is that for a given configuration, V_0 depends on the field-strength required to initiate a self-sustaining discharge; d changes inversely as c, hence as c decreases, V_0 must increase in order to attain the critical field strength.

Because the current is influenced in opposite directions by the changes in d and V_0 caused by changes in c, it follows that there is a value of c for which the total current is maximum. For $a=0.05$ inch, $b=4.0$ inches, and $E_0=180$ electrostatic units, the current density i is given in Table II. These calculations indicate that the maximum current is obtained for a wire-to-wire spacing of approximately 5.7 inches.

Table II. Current Density as a Function of Wire-to-Wire Spacing

c	i
2.00	172
2.22	197
2.50	208
2.85	213
3.33	204
4.00	194
5.00	170

Note: $k=600$ electrostatic units; $V=150$ electrostatic units.

The wire radius a affects the current voltage ratio primarily through its action on V_0 as shown by equation 5. The effect of the logarithm term in equation 2 is relatively small. Thus, when V is *very* close to V_0, changes in a are very important, but as V increases, these diminish in significance.

For c relatively large, equation 2 indicates that the current varies inversely as $l^2 \log 4\,b/\pi$, whereas for c relatively small, the current is inversely proportional to b^3. Thus, in general, it may be said that if all other dimensions are kept constant, the current varies inversely as b^n where n lies between 2 and 3.

Summary

A new method of deriving theoretical current-voltage relationships and other electrical parameters for single-carrier-current flows in gases has been presented. This method has been applied to corona discharge in precipitators. For coaxial cylinder geometry, the well-known formula of J. S. Townsend was obtained. For duct geometry, essentially new results were obtained. The following conclusions were drawn:

1. For large wire-to-wire spacing, the current per unit length of wire tends to be constant.
2. Except for the effect of the starting voltage, the current density tends to become constant and large for small wire-to-wire spacing.
3. Decreasing the wire-to-wire spacing increases the starting voltage whose effect is to lower the current.
4. Because of the above, there is a value of the wire-to-wire spacing for which the total current is maximum.
5. The wire radius is most important at very low voltages but becomes less significant at higher voltages.
6. The current depends on wire-to-plate spacing inversely as a power lying between 2 and 3.

Appendix

The boundaries of the electric fields to be considered are made up of high-tension electrodes, grounded electrodes, and certain lines of force which are characterized by being also lines of geometric symmetry. These portions of the boundaries will be denoted by B_1, B_2, and B_3, respectively, and the region enclosed by them will be called D. The three laws governing conduction in a gas are

$$\nabla^2 u=-4\pi\rho \qquad (9)$$

$$\nabla\cdot \mathbf{j}=0 \qquad (10)$$

$$\mathbf{j}=-k\rho\,\nabla u \qquad (11)$$

where

$u(x,y)$ = potential function
$\rho(x,y)$ = space charge density
$\mathbf{j}(x,y)$ = vector current density
k = mobility

$\Delta=i\partial/\partial x+j\partial/\partial y$ = vector differential operator with i, j unit vectors in x, y directions respectively. The units are electrostatic.

Equations 1–3 do not have a unique solution unless certain conditions on the boundaries are specified. These are

$$u=V_0 \quad \text{on } B_1 \qquad (12)$$

$$u=0 \quad \text{on } B_2 \qquad (13)$$

$$\partial u/\partial n=0 \quad \text{on } B_3 \qquad (14)$$

where $\partial u/\partial n$ is the derivative of u in the direction of the normal to B_3. In addition to these conditions, the following must be added

$$\rho=f(E) \qquad (15)$$

where E is the magnitude of the field strength i.e.,

$$E=|\nabla u| \qquad (16)$$

The nature of the function f is outside the scope of this theory but can be obtained in other ways. However, in electrical precipitation, it is not necessary to know f since the high-tension electrodes are very small and hence E is practically constant on their surfaces. It follows that equation 7 can be replaced by

$$\rho=\rho_0 \text{ on } B_1 \qquad (17)$$

where ρ_0 is a constant.

The problem above can be broken up into two parts by assumption. Let

$$u=u_e+u_c \qquad (18)$$

where u_e is the electrostatic part of the potential and u_c is the part due to space charge. Then, $u_e(x,y)$ must be the solution of the following equations:

$$\nabla^2 u_e=0 \quad \text{in } D \qquad (19)$$

$$u_e=V \quad \text{on } B_1 \qquad (20)$$

$$u_e=0 \quad \text{on } B_2 \qquad (21)$$

$$\partial u_e/\partial n=0 \quad \text{on } B_3 \qquad (22)$$

Similarly, because of equations 9 and 12–

14, the following conditions must be satisfied for u_c:

$$\Delta_2 u_c = -4\pi\rho \text{ in } D \tag{23}$$

$$u_c = V' \quad \text{on } B_1 \tag{24}$$

$$u_c = 0 \quad \text{on } B_2 \tag{25}$$

$$\partial u_c/\partial n = 0 \quad \text{on } B_3 \tag{26}$$

where V' is some constant. The constants V and V' are to be related to each other by the requirement that for $\rho=0$, $V=V_0$, and $V'=0$ where V_0 is the "starting" voltage of the discharge.

Equations 19–22 are the mathematical form of a perfectly determinate problem, and it is known that there is one, and only one, potential u_e satisfying these conditions. However, equations 23–26 do not determine the potential u_c because the space charge density, ρ, is unknown. The space charge density can be found by combining equations 9–11 with the result

$$\nabla\cdot(\rho\nabla u)=0 \tag{27}$$

At this point, assumption is used and Δu is replaced by Δu_e. With the help of equation 19, this leads to

$$\nabla\rho\cdot\nabla u_e=0 \tag{28}$$

For the 2-dimensional case, $u_e\ (x,y)$ is the real part of an analytic function of a complex variable. Let $v\ (x,y)$ be the imaginary part. Then, it is well-known that

$$\nabla v\cdot\nabla u_e=0 \tag{29}$$

By comparison of equations 28 and 29, it is seen that the general solution for the space charge density is given by

$$\rho=g(v) \tag{30}$$

where g represents an arbitrary function.

The equation of a line of force is $v(x,y)=$ constant, and each line of force corresponds to a different value of the constant. Equation 30 states that ρ is constant along a line of force. Suppose now that ρ is known along a curve which intersects every line of force as, for example, is done by equipotential lines. Then, at any point in the field, one can follow the line of force through the point back to the given line. The value of ρ at the intersection of the line of force and the given line is, by the constancy of ρ, also the value of ρ at the point.

Equation 17 states that ρ is constant along a closed equipotential line. It follows that ρ is constant and the *same* constant on every line of force. By the use of equation 17, therefore,

$$\rho=\rho_0 \text{ in } D \tag{31}$$

Equation 31 makes it possible to find u_c, for equations 23–26 now can be solved without any greater difficulty in principle than offered by the problem of finding u_e. From a practical viewpoint, the usefulness of this method will depend very largely on the ease with which the functions u_e and u_c can be obtained. However, for the two geometries of interest in electrical precipitation, the function $u_e\ (x,y)$ can be found in almost any textbook on the theory of the potential. Furthermore, $u_c\ (x,y)$ can be represented in the form satisfying equation 23

$$u_c(x,y)=\alpha\, u_e(x,y)-2\pi\,\rho_0[Ax^2+(1-A)\,y^2+Bxy+Cx+Dy+E] \tag{32}$$

where α, and A-E are arbitrary constants. It is not generally the case that these constants can be adjusted so as to make $u_c\ (x,y)$ satisfy equations 24–26; however, for cylindrical and duct geometries, this adjustment will be possible, at least approximately.

An Investigation of the Dynamic Switching Properties of 4-Layer Diodes

G. E. McDUFFIE, JR.
NONMEMBER AIEE

W. L. CHADWELL
NONMEMBER AIEE

THE VOLTAGE-CURRENT relation for 4-layer diodes has been described in the literature and is characterized by regions of high and low positive resistance separated by a region of negative resistance.[1,2] The transition between high positive resistance and negative resistance occurs at a potential designated as the breakover or firing potential, V_b. This breakover potential is normally specified in terms of static (d-c) or low-frequency sinusoidal measurements but is, however, a variable dependent on the waveform of the applied voltage. The purpose of this paper is to present experimental data on the variation of breakover potential for various types of applied voltage waveforms, and to give a qualitative explanation of this variation in terms of the breakover process of the 4-layer diode.

Low-Frequency Operation

An idealized voltage-current characteristic of a 4-layer diode is shown in Fig. 1. Although this idealized characteristic does not show the details of the transition from the low-current region to the high-current region, it is closely approximated by the actual device when the characteristic is measured by d-c or low-frequency sinusoidal technique. The slope of the curve of Fig. 1 in the low-current region is of the order of 10^9 ohms and, in the high-current region, is of the order of 10 ohms. The static breakover potential V_{bdc} can be made to vary from 10 to 100 volts by proper physical design. The diodes to be described in this paper have static breakover potentials between 25 and 40 volts.

Moll, Tanenbaum, Goldey, and Holonyak[3] have described the current characteristic of Fig. 1 by the expression

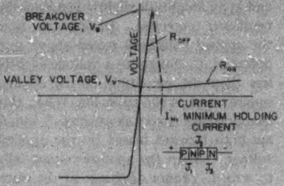

Fig. 1. Static characteristics

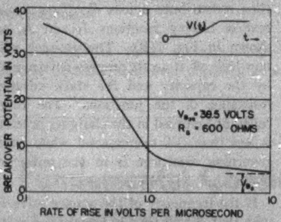

Fig. 2. Variation of breakover potential with the rate of rise of applied voltage

$$I = \frac{I_{co}}{1-(M_p\alpha_1 + M_n\alpha_2)} \tag{1}$$

where M_p and M_n are the hole and electron multiplication factors caused by an avalanche process at the center junction J_2, α_1 and α_2 are the current gain factors of the p-n-p and n-p-n sections of the 4-layer diode, and I_{co} is the current which would flow if there were no avalanche or transistor action. McKay[4] has shown that the avalanche multiplication factors in a single silicon junction diode are approximately equal and a function of the junction potential. Assuming that M_p and M_n are equal, the multiplication factors of equation 1 can be expressed by

$$M_{p,n} = \frac{1}{1-(V_{J2}/V_a)^\beta} \tag{2}$$

where V_{J2} is the potential across J_2, V_a is the avalanche breakover potential of J_2, and β is a constant dependent on V_a. It is also well known that the current gain factor of a silicon transistor increases with increasing current.[5-6] Thus increasing the applied voltage across the 4-layer diode increases both the M's and α's and at the device breakover potential V_b, the quantity $M_p\alpha_1 + M_n\alpha_2$ of equation 1 approaches unity. Under static conditions the current gain factors in the low-current region are small except in the neighborhood of V_b, and the device breakover potential is approximately equal to V_a. If it is assumed that V_{J2} is equal to the applied voltage, equations 1 and 2 may be solved for the breakover potential V_b. However, in considering the dynamic behavior of V_b for various applied waveforms it is more convenient to examine the variations of the M's and α's separately.

Single Transient Breakover

If the breakover potential of the 4-layer diode is measured using waveforms other than low-frequency sinusoids or slowly varying d-c potentials, a wide variation in the breakover potential is observed. Fig. 2 shows the variations of V_b when a variable rise-time ramp function is applied to the diode. Experimentally the ramp function was obtained by using a variable rise-time square-wave voltage source operating at a repetition rate of approximately 1 cps (cycle per second). Because of the low repetition rate and the fact that the switching of the 4-layer diode occurs in a time equal to or less than the shortest rise-time shown in Fig. 2, the voltage waveform initiating breakover can be assumed to be a ramp function. At low rates of rise V_b is approximately equal to the $V_{b_{dc}}$ shown on the static characteristic curve. As the rate of rise increases the breakover potential decreases until a minimum breakover potential V_{b_0} is reached.

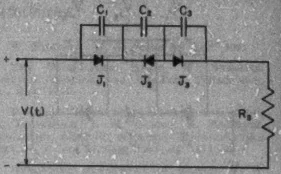

Fig. 3. Descriptive equivalent circuit

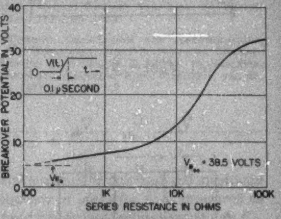

Fig. 4. Variation of breakover potential with series resistance

The behavior of V_b with rate of rise of the ramp function is best understood in terms of the descriptive circuit shown in

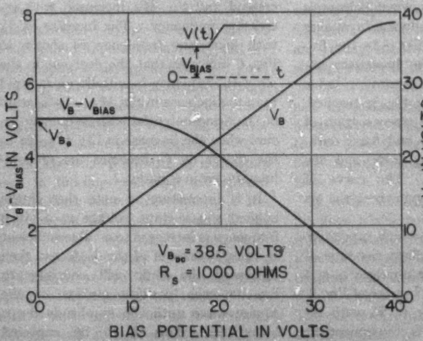

Fig. 5. Variation of breakover potential with d-c bias

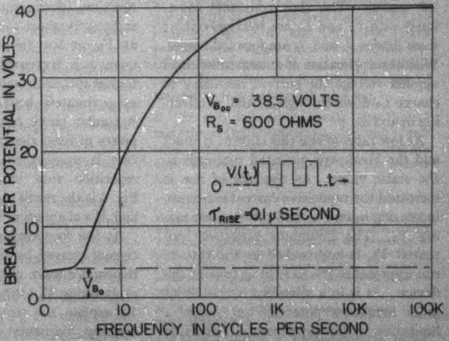

Fig. 6. Variation of breakover potential with frequency of applied square wave

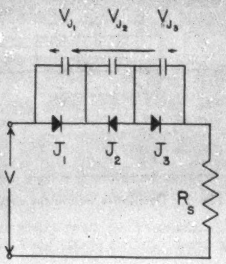
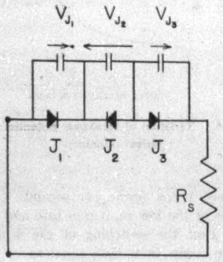


(A) V(t) = V



(B) V(t) = O

Fig. 7. Descriptive equivalent circuit for an applied square-wave voltage

Fig. 3. The capacitances shown in this figure represent the normal depletion layer capacitances of the junction and are of the order of 100 μμf (micromicrofarads) each. R_s is the total series resistance and includes the internal impedance of the source. The time constants associated with C_1 and C_3 are relatively short since diodes J_1 and J_3 are forward biased. With the application of a ramp function of applied voltage the current necessary to charge C_2 flows through J_1 and J_3 affecting α_1 and α_2.

At low rates of rise this current is small and the breakover potential conforms to the static value. As the rate of rise is increased the capacitive current increases, increasing α_1 and α_2 and thereby decreasing V_b. The minimum breakover potential V_{b_0} is approached as the rate of rise approaches the switching time of the device. It is in a sense not a true minimum breakover potential but rather a limitation of the experimental technique employed. If the rate of rise is increased past the maximum values shown in Fig. 2, the breakover potential will continue to fall and eventually the device will resemble a simple capacitor.

Fig. 4 shows the variation of V_b with series resistance; this curve was measured using a ramp function of fixed slope corresponding to the rate of rise producing the minimum breakover of Fig. 2 and at a 2-cps repetition rate. The increase shown in V_b with increasing R_s is also explained in terms of the capacitive current varying α_1 and α_2 as in the preceding argument, with R_s now controlling the magnitude of the capacitive current.

D-c Bias Breakover

When a d-c bias is applied to the diode, and the breakover potential measured using a ramp function of applied voltage with a fixed rate of rise, the breakover potential varies as shown in Fig. 5. The rate of rise of the ramp used for this plot again corresponds to that causing the minimum V_{b_0} in Fig. 2. Since the d-c bias has been applied to the diode at a rate sufficiently slow to preclude breakover by the bias, V_b increases with increasing bias voltage. The curve of $V_b - V_{bias}$ in Fig. 5 shows the effect of the bias potential on M_1 and M_2. As the bias is increased the M's increase as indicated in equation 2, and the increase in α_1 and α_2 by capacitive current necessary to cause breakover is decreased.

Square-Wave Breakover

The applied voltages of the preceding sections have been essentially single transient voltages because of the low repetition rate used. When a square-wave voltage of fixed rise-time is applied to the diode a variation of V_b with frequency results, as shown in Fig. 6. The rise-time of the square-wave voltage is sufficiently short to produce a breakover at V_{b_0} at low frequencies. As the frequency is increased the breakover potential increases until a saturation value approximately equal to $V_{b_{dc}}$ is reached. A similar curve results when a train of pulses of fixed rise-time and fixed duration is applied to the diode and the repetition rate varied. The curve of Fig. 6 is the result of varying both the α's and M's of equation 1.

At low frequencies the high capacitive current caused by the short rise-time of the square-wave voltage increases α_1 and α_2, lowering V_b to the V^*_0 value of Fig. 2. To explain the increase in V_b with increasing frequency it is convenient to examine as a function of time the voltages across the junctions at a fixed frequency and at an amplitude slightly less than the breakover potential. During the time the applied voltage is raised above zero potential, C_2 charges to a voltage slightly less than the amplitude of the applied square wave as shown in Fig. 7(A); this charging time is very short since J_1 and J_3 are both forward biased by the applied voltage. When the applied voltage falls to zero, C_2 cannot discharge at the same rate as the charging rate since J_1 and J_3 are reverse biased in respect to the discharge current. The charge on C_2 must then redistribute across C_1, C_2, and C_3, reverse biasing junctions J_1 and J_3, as shown in Fig. 7(B). The charges will now leak off at a rate roughly determined by the capacity and the static reverse resistance of the junctions. The time constant involved in the charging process is less than 0.1 microsecond while that governing discharge is in the order of several hundred milliseconds.

If the frequency of the square wave is such that the off-time of the applied voltage is less than the discharge time of the junction capacities both the M's and the α's are affected. The charge on C_2 will raise the values of the M's in a fashion similar to that of the d-c bias previously discussed. The charge on C_1 and C_3 will lower the values of the α's in that the initial capacitive current occurring when the square wave rises from zero to the applied amplitude will no longer be a current injected into the base regions of the p-n-p and n-p-n sections of the diode but rather a current which discharges C_1 and C_3. Thus the initial capacitive current does not tend to raise the α's as is the case when C_1, C_2, and C_3 are completely discharged.

Increasing the frequency allows less time for the junction capacitances to discharge; thus the α's are effectively decreased and the M's increased with increasing frequency. The increase in V_b with increasing frequency as shown in Fig. 6 indicates that the decrease in the α's with frequency is initially more rapid than the increase in the M's. Saturation of the firing potential with frequency occurs when the increase in the M's due to the charge on C_2 becomes the predominant factor in equation 1.

It is interesting to note that if the applied square-wave voltage at a given frequency is increased to a value sufficient to cause breakover of the diode and then decreased, the diode will continue to fire on each positive portion of the square wave until the amplitude drops below V_{b_0}. This is to be expected since, when the diode conducts, the voltage across it drops to a very low value;

the major part of the applied voltage is dropped across the series resistance, and C_2 no longer charges to the amplitude of the applied voltage. Each positive going portion of the square wave is now independent of the previous positive portion and the firing potential behaves as if the frequency had been reduced to a very low value. The dashed curve of Fig. 6 shows the variation of V_b with frequency for the case of a conducting diode.

Conclusions

The results of these measurements indicate that the breakover potential of a 4-layer diode is dynamic in nature and dependent upon the applied waveform. Under dynamic conditions, the capacitive current plays a considerable role in determining the potential at which transition between low and high current occurs, and under certain conditions the voltage existing across the center junction prior to the application of the terminal voltage affects the breakover potential.

The curves which have been presented in this paper are typical of the commercial, low-power 4-layer diodes tested although the sensitivity of V_b to the various parameters discussed can be varied to some extent in the design of the device.

Fundamental Considerations of Power Dissipation Limits in Some Bistable Transistor Pulse Circuits

H. RAILLARD
NONMEMBER AIEE

THE PROBLEM of determining the minimum power that has to be dissipated by a transistor flip-flop covering a set of given specifications is one of general interest. Among the various significant considerations which determine the power level are: output power requirements, stability, temperature variations, and required speed of operation. The following considerations deal mainly with the problems of speed limitations at various power dissipation levels. The investigated circuits employ silicon devices to insure good temperature stability and are based upon a design which offers good stability and a constant output voltage. The required increase in power level which is necessary for a desired increase in output voltage is also discussed.

Two essential properties of transistors used in flip-flop operation are current amplification and cut-off frequency. If a single figure of merit is wanted, the product of the two, viz., the gain-bandwidth product, may be used. For applications at low power levels, both current amplification and cut-off frequency have to hold up at low emitter currents and at low collector voltages. The collector saturation resistance indicates how well the gain holds up at low collector voltages and must be as low as possible.

The design procedures discussed here deal exclusively with nonsaturating circuits in order to eliminate the transient delay variations caused by saturation. This is desirable because a wide range of pulse repetition frequencies will be used, including frequencies where saturation delay is significant and where it is not. This paper deals with the nonsaturating emitter-coupled and base-return configurations shown in Figs. 1 and 2, which are widely used. A constant collector voltage swing of 2 volts is assumed as a practical minimum value. For reliable and nonsaturating operation the minimum collector supply voltage E_{cc} is found to be 6 volts for emitter-coupled flip-flops and 4.5 volts for base-return flip-flops.

In order to investigate a number of flip-flops whose power dissipation varies from less than 1 mw (milliwatts) to more than 100 mw, flip-flops of both the emitter coupled and base-return types are designed with various load current swings. The power dissipation P_d is found to be approximately 15 mw per milliampere load current swing.

Each flip-flop is triggered through a suitable gating circuit and the maximum frequency of operation f_m is measured as a function of the coupling capacitance C_K. The results are plotted and shown in Fig. 3(A) for the emitter-coupled circuits and in Fig. 3(B) for base-return flip-flops, with the power dissipation P_d of each flip-flop as a parameter.

The curves shown in Figs. 3(A) and (B) permit the following conclusions:

1. For a given power level the maximum frequency of operation f_m peaks at a frequency f_{mm}. At this frequency C_K is approximately $C_{K\min}$, the minimum operational coupling capacitance, below which the flip-flop does not operate.

2. For a given power level and for $C_K \gg C_{K\min}$ the maximum frequency f_m is inversely proportional to C_K. In this region of C_K values, f_m is determined by the discharge time constant of C_K only.

3. For a given fixed capacitance $C_K \gg C_{K\min}$ the maximum frequency of operation f_m is approximately proportional to the power level of the flip-flop.

4. The locus of the peak maximum frequencies for each power level form the dotted lines of Figs. 3(A) and (B). For larger power levels (larger than 80 mw), f_{mm} becomes independent of increases in circuit power dissipation and is only a function of transistor gain-bandwidth, $\omega_{\alpha B}\,\alpha_B$.

5. At very low power levels (less than 5 mw) the peak frequencies f_{mm} for each power level occur at the same value of C_K and are approximately proportional to the power level of the flip-flop.

Paper 60-20, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted August 24, 1959; made available for printing November 20, 1959.

H. RAILLARD is with the General Electric Company, Syracuse, N. Y.

The author wishes to acknowledge the helpful discussions with Mr. J. J. Suran, Mr. B. K. Eriksen, and Mr. E. A. Fisch, of the General Electric Electronics Laboratory.

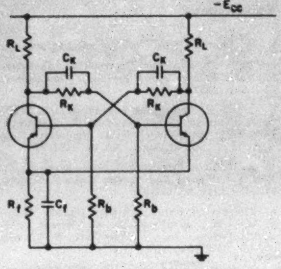

Fig. 1. **Emitter-coupled flip-flop**

An analytical approach to determine the maximum operating frequency f_m of the flip-flop is made as follows.

The time constant T_f of the exponential collector response is

$$T_f=(1+\omega_{\alpha E}\alpha_E R_L C_c)/\omega_{\alpha E} \qquad (1)$$

where

α_E = current amplification (common-emitter)
$\omega_{\alpha E}=\alpha_E$—cutoff frequency
R_L = collector load impedance
C_c = collector capacitance

Also the coupling network time constant T_K can be computed from

$$T_K=C_K R_K R_b/(R_K+R_b) \qquad (2)$$

Equations 1 and 2 are consolidated into a tentative formula for maximum theoretical frequency of operation

$$f_m=1/(T_f+R_K) \qquad (3)$$

The frequency f_m in equation 3 is calculated for all the flip-flops and plotted next to the measured curves of Figs. 3(A) and (B). The correspondence between experiment and theory is in general very good.

From a comparison of the calculations of maximum frequencies f_m described before with the experimental curves f_m in Figs. 3(A) and (B), it is found that the curves peak consistently at a point where

$$T_K/T_f \cong 0.4 \qquad (4)$$

This point, experimentally, is always close to the point where regeneration is lost completely. When the quotient (T_K/T_f) becomes smaller, too little of the collector pulse is transmitted through the coupling capacitor C_K and regeneration is lost. Equation 4 indicates the minimum tolerable value of (T_K/T_f) for regeneration.

The dotted curves in Figs. 3(A) and (B) show a breakover between a region where the peak maximum frequency f_{mm} is approximately proportional to power level P_d, at low power levels, and a region, where f_{mm} is a constant, independent of power level.

By taking the set of equations 1, 3, and 4, and eliminating both T_K and T_f a theoretical value for the peak maximum requency f_{mm} is obtained

$$f_{mm}=4.4 f_{\alpha E}/(1+\omega_{\alpha E}\alpha_E C_c R_L) \qquad (5)$$

in which the denominator consists of two terms, namely, the constant 1 and a term which is inversely proportional to power level. At very low power levels (less than 5 mw) the second term in the denominator is of dominant significance, therefore f_{mm} is proportional to power level in this region. At large power levels (more than 80 mw) the first denominator term dominates so that f_{mm} is independent of power level in this region.

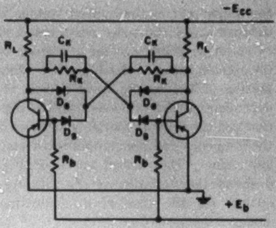

Fig. 2. **Base-return flip-flop**

Breakover between the two regions occurs when the two terms are equal, that is,

$$\omega_{\alpha E}\alpha_E R_L C_c=1 \qquad (6)$$

which happens at a power level of approximately 15 mw.

The measurements and calculations discussed show that in general the following circuit parameters are of influence on the maximum frequency of operation f_m:

1. The current amplification α_E of the transistor.
2. Parasitic transistor parameters, that is collector capacitance C_c in conjunction with circuit load impedance R_L.
3. Cross-coupling elements: R_K, C_K.
4. The gain-bandwidth product of the transistor $\omega_{E\alpha}\,\alpha_E$.

The peak maximum frequency f_{mm} for a certain power level P_d is determined by the following parameters, whereby the numbers presented here are valid for nonsaturating flip-flops of the emitter- and base-return type, with a fixed voltage swing of 2 volts using silicon transistors.

1. $P_d<0.5$ mw. In this region the current

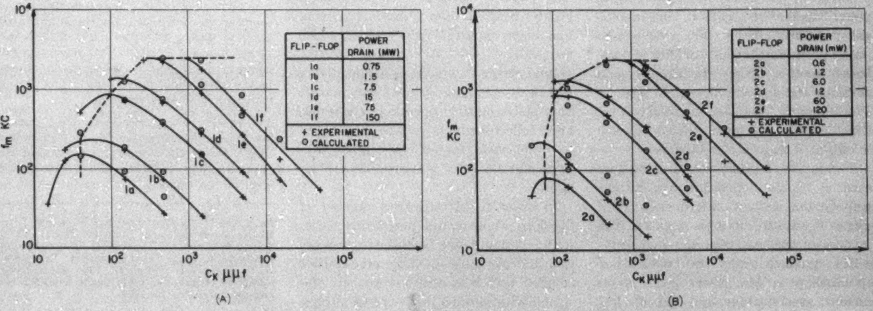

Fig. 3. **Maximum operating frequency f_m versus coupling capacitance C_k for**

A—Emitter-coupled flip-flops 1a–f. $E_{cc}=6$ volts, $\Delta V=2$ volts
B—Base-return flip-flops 2a–f. $E_{cc}=4.5$ volts, $\Delta V_e=2$ volts, $E_b=0$

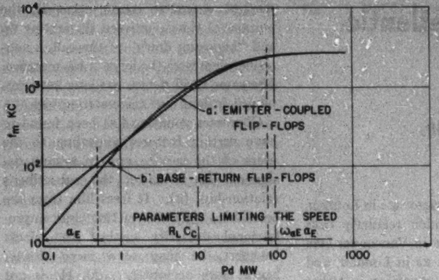

Fig. 4. Peak maximum operating frequency f_m versus power dissipation P_d for emitter-coupled and base-return flip-flops, $\Delta V_c = 2$ volts

amplification α_E decreases rapidly with decreasing power level and limits the frequency range.

2. $0.5\text{ mw} < P_d < 80\text{ mw}$. In this region the frequency range is limited by the collector capacitance-load impedance product R_L C_c.

3. $P_d > 80$ mw. For large power levels the frequency range becomes independent of all stray and circuit parameters and depends only on the gain-bandwidth product ($\omega_{E\alpha E}$) of the transistor.

The peak maximum frequency of operation f_{mm} is plotted in Fig. 4. These curves indicate the various parameters that limit the frequency of the flip-flops.

In a practical case one may want to increase the collector voltage swing to some value larger than 2 volts. For the same load current swing, the supply voltage, the resistance value of the circuit, and the total power dissipation increase proportionally to the voltage swing.

The very low power region discussed before, where the flip-flop speed is limited by the decreasing current amplification α_E, is determined by the emitter current, thus the power dissipation limit of this region will increase proportionally with voltage swing.

The large power region where the flip-flop speed limit becomes independent of circuit parameters is determined by the load impedance level. Therefore the value of power dissipation limiting this region will increase proportionally to the square of the voltage swing.

A Character-Metered Transatlantic Switching System

I. S. COGGESHALL
FELLOW AIEE

P. HOLCOMB, JR.
MEMBER AIEE

IN ADDITION to offering public telegram services over transatlantic facilities, cable and radio carriers today offer various forms of temporary, switched teleprinter interconnections between correspondents, upon request of a calling party, in a manner and through means characteristic of long-distance telephone calls. Regardless of forms of the national teleprinter exchanges involved, the international portion of the haul is usually between manual boards at central offices. The placement of a specific call over a particular idle two-way trunk among those at the moment available is controlled by concerted action of the two operators guided by information exchanged over a parallel order circuit or "bid channel" connecting them.

These operators reach their respective calling and called subscribers through tie lines terminating in the jacks of manual switchboards or "turrets." Connection of the tie lines with an overseas trunk is accomplished by inserting, into the jacks, plugs led to the trunks by "cords" into the circuits of which all manner of signaling, ringing, and supervisory controls may be built. These controls may contain as many automatic features as desired, such as for testing the tie line for continuity and "line-busy," or for clocking and recording the call. Owing to differences between the engineering problems presented by the typed and spoken word, an extraordinary amount of automation is included in the cord-plug-jack circuits of the telegraph system described.

System Aspects

INTERNATIONAL METERED COMMUNICATIONS

The IMCO (International Metered Communications) system departs operationally from telephone practice in the following particulars which specify the designs:

1. Any one patron in New York (for example) does not require random interconnection with all patrons in London (and vice versa); rather, subscribers pair themselves off for contract service. Hence, when MA in New York signals for service it is almost invariably for connection to joint contractor MA in London. Similarly, MB in London regularly calls MB in New York; RF in Vancouver (via New York) deals with RF in London, and so on. The typical connection in either direction may therefore be completely described by 2-letter calls, like MA, MB, RF; a circumstance of which full advantage is taken in design.

There is an exception, however. MA New York can be connected to MB London through an operation called "cross bidding." For the present, cross bidding may be ignored.

2. The relative absence of cross bidding results in the constant availability of far-end tie lines to callers. If MA New York is not sending to MA London, probably no one is. The important circumstance that there are virtually no tie-line busy conditions encountered on the IMCO system substantially improves the speed of service. Means are incorporated in the system to handle counter bids in the event that MA New York and MA London happen to call each other at the same instant.

3. All initiated calls are one-way (not back-and-forth) calls. A reply to a query (if a reply in the opposite direction is called for) or an acknowledgment of receipt is separately initiated as a call upon termination of the query. Transatlantic messages on IMCO, it has been found, like those sent over duplexed private-wire networks in the United States, are one-way communications rather than the question-and-answer type. By virtue of this fact, not only is the trunk load factor improved by eliminating entirely the idle half of a duplexed setup for every call, but also it is made possible to utilize the benefits of reperforator storage at central office transmitting points without the usual mutual interference encountered from opposite ends of a half-duplexed reperforator facility. Keeping trunks fully loaded is, of course, of economic benefit to all concerned.

4. In contrast with widespread teleprinter switching practices in Europe and the United States of charging by the minute or of measuring service by the nickel, both of which are based on clocked time, IMCO charges are based upon straight character count; that is, the number of times, between the setting up and "knocking down" of the call, a subscriber depresses the keys of his machine. The same tariff device has long been employed in land-line telemeter service.

Character counting has been found to have certain features appealing to the users of the service and to system designers. In terms of the subscriber's relationship: (*a*). It frees him from the economic whip of pitting his unprofessional dexterity against the clock. Inexpert, he may send more slowly, hence more accurately. (*b*). He is not required to pay for "units or a fraction thereof," but only for the service used. He may send messages as short and as often as he wishes at no greater cost than if he accumulates them to send in batches with less frequent calls. Coded messages of half a dozen characters or less are not unusual. The letter R followed by a terminating signal suffices to acknowledge receipt of a message.

In terms of telegraph system design, character counting contributes to the designer's freedom to utilize the trunk efficiency inherent in a reperforator storage system; and since it is unnecessary to have a calling party hold the line until a through end-to-end circuit can be established, he is enabled to afford each calling customer an instantaneous start or "go-ahead."

5. It is necessary to cater to the relative incapabilities of people who attempt to operate customers' teleprinters. The best of them are experts, but even they, after special training and practice, must exercise care in transmitting (along with the text of messages, which is comparatively simple) the information which identifies a message in its sequence, in time and date, and in other respects covered by the preamble, or "heading," of a telegram. In the IMCO apparatus as much as possible of such information is generated electromechanically at the central office and transmitted to the

---

Paper 58-1143, recommended by the AIEE Telegraph Systems Committee, and approved by the AIEE Technical Operations Department for presentation at the AIEE-IRE Second National Symposium on Communication Systems, St. Petersburg Beach, Fla., December 3–5, 1958. Manuscript submitted September 29, 1958; made available for printing June 25, 1959.

I. S. COGGESHALL is with AIEE Headquarters and P. HOLCOMB, JR., is with The Western Union Telegraph Company, New York, N. Y.

The authors thank their associates, A. W. Dickey, H. F. Krantz, G. T. Fontaine, E. A. Wold, R. I. Mills, and J. H. Browne, for assistance in the development of the equipment and circuits and in the preparation of the paper. The apparatus was engineered and manufactured by the Taller & Cooper Division of American Electronics from functional designs and specifications prepared by Western Union.

customer right on his tie line as the lead-off of, and in a manner of speaking, an advance receipt for, his message. The advantages of having an automatic machine intervene in the preparation of this difficult and necessary but purely routine information are obvious: it can be prepared more rapidly and accurately than any introduced manually, and it can be made constantly and instantaneously available.

6. Complete automatization was to be avoided because of the expense of duplicating automatically the discretionary functions of the assigned operators, particularly in the switching of inbound trunks to tie lines. However, in the design of the turrets and the cord-transfer system, every effort was made to make the operators' jobs easy, straightforward, and devoid of fatigue. It is believed that it has been made impossible for them, without being "defeated" by interlocks, to insert a right or wrong plug in a wrong or right jack. Automation that is included sounds alarms and blocks faulty manipulation and switching failures of trunks, tie lines, and equipment. The accuracy of all plugged-in connections is checked by machine before trunk transmission is permitted to begin. Customers' calls appear twice in succession to guard against the cardinal fault of sending a message into the wrong tie line.

7. For special reasons having to do with cost and time limitations, only standard communication apparatus was to be used. There are therefore no units of equipment requiring description in this paper.

Operational Environment

Following is a brief résumé of operational routines and physical equipment layouts.

PLACING AND CONFIRMATION OF BIDS

New York subscriber MA wishes to place a call to his London correspondent MA. His printer is not yet running. He pushes a button which energizes a signal light over the MA jack in the New York cable-office turret. The turret is shown in Fig. 1.

The IMCO operator selects an idle sending cord, say R, and plugs in.

At once, the calling customer gets his cue to begin sending; his printer motor starts, and within 6 seconds the heading of his message is automatically typed on his printer: RFH526MAMA. This sequence uniquely identifies the message he is about to send from all others which will pass through the IMCO system. He and his London correspondent may use it for reference and service purposes.

Fig. 1. IMCO turret, jack field, and cords

With the heading now on his blank, the customer may begin typing his message at his leisure. The heading and text are simultaneously being stored temporarily at New York cable office in a standard *FRXD* type of reperforator transmitter.

At the end of the text the patron depresses the FIG and J keys (bell signal) to terminate the call. His part is finished.

Meanwhile, at the central office, the mechanism which generated the message heading for the customer also passed it over the transatlantic bid channel for the London IMCO operator to act upon, but in the abbreviated form RMA. The London operator, seeing this notation on his inbound bid printer, inserts his receiving cord R in the MA jack as directed.

This accomplishes several things at once: 1. It tests the London MA tie line for continuity and starts the subscriber's printer. 2. It establishes a through message facility from the New York reperforator to the London customer's printer. 3. It sends the combination RMA back to New York, where an automatic comparator checks it for accuracy against the RMA sent from there. If anything in the mean time has gone wrong (wrong cord, wrong jack, call garbled going through to London or returning) the bid will be rejected and have to be remade from New York. 4. It makes a heading appear on the London customer's receiving blank, reading slightly different from that now in storage in New York, viz: RFH53-MAMA.

Meanwhile, normal operation of the comparator at New York will have released the heading and text of the message temporarily stored in the reperforator there and it will begin to run over the R transatlantic message trunk (not the bid trunk) into the London subscriber's printer. The original New York heading will appear right below the London-generated heading, thus:

RFH53-MAMA
RFH526MAMA

and the subscriber, once having been initiated, can trace from these notations the genesis of the call and by accurate record its transit time. The second notation is still the one used for reference.

Following the text, when the New York sender's terminating bell signal reaches the New York and London operators in succession, the customers' printer motors will be stopped, the operators pull down the cords, and the call is complete.

As soon as the customer's printer has stopped, he may initiate a new call by pressing his calling button even though the operators have not yet unplugged the call just completed.

TIE-LINE TERMINATIONS

The subscribers' teleprinters are standard type *15s* in consoles, with a-c motors started and stopped by relays controlled from the central offices. The tie lines themselves are operated on a single-line-to-ground basis. Tie-line power comes from the central office. Termination there is in the IMCO jack turret, which has been made an adjunct to a standard plan *2* concentrator already

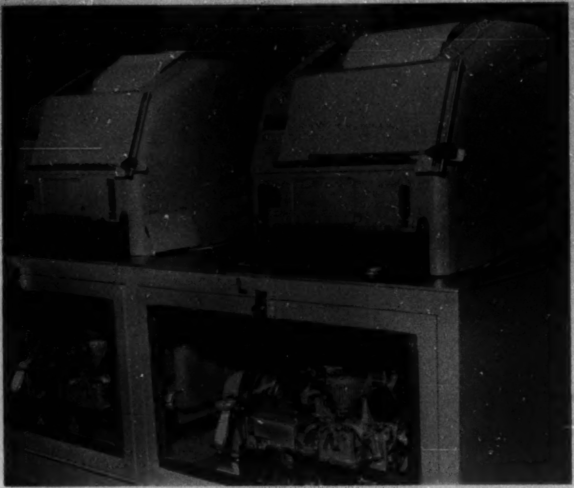

Fig. 2. Monitor cabinet, FRXDs, printers, and tape reels

described in the literature.[1] The concentrator contains signal circuit relays responsive to a push button in the subscriber's office, a busy-test feature, test for open line, and control of the printer motor, as stated. In teleprinter practice, as distinguished from telephony, the starting, stopping, and testing of the subscriber's printer is important to the dependability of the service.

A westbound call cannot be "sent to the wind" in New York if the called party's tie line or printer relay stands open or busy because of safeguards built into the plan *2* tie-line concentrator used.

A further safeguard has been tried out and is under consideration for automatically pretesting an unattended receiving printer for full operational capabilities at the instant the tie-line connection is made. Due to time-zone differences, unattended operation is frequently encountered in transatlantic practice. This test would consist in detecting, at the moment of plugging in at the central office, the customer's printer's response to a specially transmitted bell signal, FIGS J. The FIGS character would be transmitted with a spacing bias, the J with a marking bias, both within the range tolerances of a properly adjusted printer. If the line and equipment added bias to one side or the other, the tolerance for safe operation would be exceeded and the test would be negative. If the test proved positive, the bell lever system in the printer would trip a line-opening contact. This responsive momentary open-line condition immediately after transmission of the FIGS J combination is the positive test sought and detected at the central office to denote a properly operative printer.

If the printer did not respond satisfactorily to this test, because its motor was not running at proper speed, range, and synchronism, a bid could not be confirmed and the message could not be sent. This test has been found experimentally to be good irrespective of the length of the tie line or the number of repeaters in it. When applied to IMCO, it is expected to be more stringent and quicker than the test given printers by means of the "who are you" key-and-cam test used on Telex machines in Europe. The revelation of printer identity is, of course, made superfluous by the precautions taken in IMCO to check the identity of the tie line in which the sole printer operates.

CENTRAL OFFICE LAYOUT

At the central cable office the IMCO turret with its jack field of 200-tie-line capacity, its shelf equipped with a double row of 20 sending and 20 receiving cords, and the position occupied by the IMCO operator with his bid and monitor printers, dominate the installation. Surrounding this group as its physical core are 20 monitorial cabinets in which are mounted 20 inbound monitor printers and 20 outbound *FRXD* reperforating monitor units, connected with the respective cords (see Fig. 2). Automatic tape winders make it possible to refer to any transmission in either direction.

In an inconspicuous position is mounted the IMCO control rack, the heart and brains of the installation, containing the character generators, the program switch, time and date group generators, the comparator unit, an *FRXD* collector unit, relays, and miscellaneous equipment, all included in Fig. 3.

Character Generating and Programming

In order that an intelligible sequence of Baudot character signals may be presented as needed to the tie lines and reperforators as message headings, to the bid trunks and printers as bids, and so on, a multipoint stepper-type rotary[2] machine switch is employed which is called the program switch. This switch is stepped by a character generator[3,4] in such a way that the program switch stops on each of its step points just long enough to pick up in rapid succession the seven units of the Baudot start-stop teleprinter code presented on that point during that particular sweep of the switch.

The presentation of an appropriate generated character to each successive switch point at any given sweep of the switch is the function of other machine switch and relay circuits, among which are the cord-designating contacts, the date-and-time generating assembly, the message-sequence designator, and the call-letter designator.

These controllers of generated characters are shown in the lower part of Fig. 3 and will be described. Meanwhile, their relation to the typical message heading already referred to: RFH526MAMA, may profitably be considered. R designates the cord plugged up by the IMCO operator; F designates the day of the week (SMTWHFA); H is the hour (*A* to *Z; I* and *O* omitted), and *52* the minutes, of the time of day. The figure *6* is the sequence designator, the system message serial number associated with the designated time of day. MA is the designation of the calling and called parties; it is repeated for safety as MAMA.

It will be obvious to those familiar with printer functions that any such succession of printed characters has to be supported by accompanying printer "stunt" functions. In this case they are: LTRS CR LF RFH FIGS 526 LTRS MAMA CR LF.

To meet all needs, the entire alphabet of 32 characters is continually produced

by the character generator; this includes the 26 letters, the figures, FIGS and LTRS for carriage shift and unshift, the carriage return CR and line feed LF signals, word-space SP, and the 5-spacing blank signal BK.

Like many rotary switches, the program switch has independent levels which are swept simultaneously and which are used to send different character sequences into different circuits at the same time, as required by the correlation of the entire operation. The switch arms on all levels start together and end simultaneously at a home position, regardless of length of the sequences transmitted on the various levels.

Character Generator

The character generator is a single, constantly rotating, standard 7-unit stop-start distributor whose segments are applied to seven busbars in rotation (see Fig. 3). These busses are overlaid, grid-fashion, by 32 code busses representing the 32 Baudot characters. Diodes applied at the appropriate intersections of the grid collect marking battery at properly spaced time intervals and hence generate simultaneously 32 different characters in the code busses each time the distributor brush sweeps its seven segments.

The character generator, then, is a constant source of all 32 Baudot signals, each of which can be conveyed continuously, or distributed as called for, to any switch point on any level of the program switch.

Pulses *3*, *4*, and *5* are properly phased with respect to the generated characters to actuate the program switch, advancing it one step per completed revolution of the character generator's driving distributor.

Program Switch

The single program switch is a multipoint multilevel rotary switch. The New York and London program switches will be wired identically when installations are completed and are so described.

The program switch at either office is used by the operator as required to handle eastbound or westbound calls indiscriminately, in the fortuitous order of their being placed by patrons, and only one call at a time. Fig. 3 shows the program switch connections for a sending cord. Receiving cords have an auxiliary setup relay at point *Y*, which transforms sending cord combinations into those appropriate for receiving cords.

To aid in straightforward cord manipulation and to prevent mix-ups, the sequence of completing calls at the distant central office is always the same as the transmitting sequence at the home end.

The New York program switch, in transmitting bids over the bid trunk into the London operator's printer, does so over an exclusive eastbound bid trunk which is not joined electrically or mechanically to London's program switch. Hence the two program switches rotate independently, each under the operators' local control, though used functionally to bid and acknowledge the same calls.

Fig. 3 shows six levels on the program switch and the character transmitting sequences of level *1-s*. The switch points are numbered *1* to *25*. The switch homes on point *1*. On some of the switch points, characters picked up from the character generator are never changed by secondary switching. Other points pick up generated characters which are permuted by the secondary control circuits of the cords and of the calendar, clock, and sequence units.[5]

An unpaid-for authentic date-time-sequence group used for message identification has been found superior to a serial number in that it "places" a message in the flow of timed transactions in the originating business office and cannot be errored, altered, faked, or omitted by anyone handling the message.

Traffic load studies, ordinarily made by special live-traffic observations at extra expense when messages are serially numbered, are easily made through the time-group and sequence-number notations on the IMCO monitor record.

Automatic Call Identification

The 200 tie-line jacks in the IMCO turret are arranged in 10 horizontal rows labelled *A* to *K*, and in 20 vertical columns labelled *A* to *Z*, with omissions. The intersection of column *M* and row *A* will be the locus of tie-line MA at New York. The London board is arranged in the same way; normal service is that called for, in one direction or the other, between these identical jacks (see Fig. 3).

The jacks are wired to receive tip-ring-sleeve plugs, of which the tip only is involved in the tie-line connection through the plan *2* concentrator already referred to. The ring and sleeve are used automatically to place the tie-line designation on points *14-15* and *16-17* of the program switch; that is, these points are furnished generated characters corresponding to the co-ordinates of the jack plugged into. The sleeve of the plug picks up the letter locked to that particular column of sleeves, and the ring picks up the letter locked to that particular row of rings. Together, the adjacent switch points signal the 2-letter tie-line designator. The call is repeated, as an accuracy check, on points *16-17*.

SHAKE RELAY

As to any single jack or any group of jacks within the turret jack field, additional information may be made accessible through the ring and sleeve grid by the use of shake relays. During such times as the program switch does not require call letters, multipoint 2-position shake relays may divert the ring sleeves from revealing office calls to passing other bits of information about the calling party obtainable from auxiliary storage devices and subprogram switches.[6,7] In this way the name of the city of origin may be identified and inserted in the transmission; the standard time zone at origin may be included if desired, or Eastern Standard Time translated into the time in the zone of origin; priorities may be inserted in messages where authorized, as in the case of government tie lines; or serial-numbering[8] machines may be introduced, or special tests may be applied to particular tie lines. In Fig. 3 a shake relay is shown as a means of simplifying circuitry, avoiding a multiplicity of vacuum tubes or the overloading of diodes.

COMPARATOR FRXD

Level *4* is used to set up in a comparator *FRXD* the combination: LTRS RMA, to await the bid confirmation.

The arrival of London's switching apostrophe on the bid channel westbound causes contacts on upper-case S of the bid printer to close, starting stepping pulses to the comparator *FRXD* transmitter. The previously stored LTRS RMA combination from level *4* will be stepped in unison. If the two sequences test for identity, the eastbound message reperforator, containing by now the original heading and part of the text, will be unlocked and will begin transmitting on the overseas trunk. If the identity test fails, the operator is called in on alarm to initiate a rebid (compare reference 9).

DOVETAIL BIDDING

Since the character generator spins at 390 rpm, it puts the program switch through its 25 steps in only 4 seconds. Nevertheless, when bidding is heavy, the program switches will not be developing their capabilities for handling calls at full effectiveness unless means are provided for an operator to set up a second call during the 4-second interval the program switch is preoccupied with the first. This is done by rendering a cord associated with a second call, inactive, even though plugged up, until the program switch is on its home position. With such overlapping, full capacity of the program switch may be realized during peaks.

Overseas Trunk Facilities

BID CHANNEL

The bid channel is a duplexed varioplex channel, equipped with teleprinters for each direction and at each end, kept at priority disposition of bids and confirmations but automatically available for supervisory wires and service conversations at other times.

TYPES OF CABLE FACILITIES

Although the sending cords, upon being plugged into jacks, automatically cause the program switches to function as described, their main function is to join the tie lines, through reperforation, to an appropriate transatlantic one-way message trunk (see Fig. 4). As fitted, New York's 20 sending (eastbound or outbound) and 20 receiving (westbound or inbound) cords, associated with their opposites in London, will join 40 one-way transoceanic facilities for independent communication to subscribers.

A switch on each cord permits its equipment to be moved from a varioplex to a multiplex channel or vice versa. Both types of facility employ 5-unit transmission on the main trunk lines of cable which operate near the ceiling of capacity. Both also are joined to 7-unit start-stop teleprinters on the tie lines.

UTILITY OF VARIOPLEX FOR IMCO SERVICE

The steady capacity of both the multiplex channels and varioplex subchannels under normal total system loading is in excess of the output of the average customer's operator using an on-line start-stop keyboard. Manipulation of varioplex and multiplex capacity preserves this desirable relationship.

However, the following advantages of the varioplex[10-12] over the multiplex make it the preferred facility for IMCO service (the multiplex handles the overflow and fall-back):

1. Ten times as many customers can simultaneously be given direct connections.
2. Whenever a customer's call is acknowledged by allocation of a cord and he is given the automatic heading as a signal to go ahead, transmission on the message trunk begins from the reperforator immediately and results in the two subscribers working directly together. Only the varioplex utilization of full trunk capacity permits the economical assignment of direct connections indiscriminately to slow or deliberate senders. Under single-channel or multiplex reperforation, trunk transmission cannot economically be permitted to begin until the customer has completely prepared his entire message and signed off, thus subjecting it to initial delay as well as to cumulative delays behind other customers' unitized messages.
3. Messages originating over each particular tie line arrive at their destinations via varioplex in the same sequence that they start, whereas a succession of reperforator-switched messages handled over several multiplex trunks may arrive out of turn if delay on all trunks is not equal or if expensive oldest-call-first devices are not used. Maintenance of sequence is essential in dealing with buy-and-sell market transactions.
4. Since the varioplex will not work unless duplexed, and since its chain circuits and subchannels contain means of efficiently employing reverse-direction interlocks, it is adapted to automatic checking of the accuracy of switching in the manner already described.
5. Since the varioplex incorporates automatic machine switching of multiple subchannels among fewer available multiplex channels, its use promotes maximum trunk utilization for switched services. This is an advantage where facilities are limited and other services have to be maintained.
6. The pattern stop built into the varioplex, tests for and recognizes line trouble and abruptly stops transmission in both directions, constituting a main-line transmission error-detecting device which multiplex does not possess.
7. Because a varioplex subchannel preoccupies no line time while it is inactive, lightly loaded bid channels are feasible.

MULTIPLEX OPERATION

In the cable plant, multiplexes predominate, so the IMCO design contemplates their auxiliary use to greatest advantage. If no more varioplex trunk sending cords are available, the IMCO operator uses a "multiplex" switch to modify one of the sending cords, say cord S. Unlike cord R in varioplex, heretofore considered, modified cord S conditions the release of the stored message upon receipt of the knockdown bell marking its completion. The message is then handled cross-office as a unit. An IMCO heading is furnished the sending tie line automatically.

Each of the overflow multiplex sending channels contains an *FRXD* and a collector switch with seeker and sender levels. When clear of the last message sent, the seeker will look for a "live" message, cross-office, stored in a monitor *FRXD* whose associated knockdown relay has been actuated. The sending level will complete the circuit between the two reperforators cross-office, and the message will start flowing over the outbound trunk.

At the receiving office the switching sequences dictated by fortuitously arriving unit messages over the several channels are funneled into one page printer for operating convenience. Successive messages are identified by the usual sending headings. To facilitate switching them at the IMCO turret, the receiving IMCO operator has a prefix-storing *FRXD*, emptying prefixes (only) into his inbound bid printer (see Fig. 4).

Imagine the system to be operating at London. When an inbound overflow cord is unplugged from its circuit-completing "home" jack, or from a receiving IMCO customer's tie line in response to a disconnect signal, the prefix-storing *FRXD* is thrown into temporary association with the bid printer, permitting the prefix (only) of the next message to be displayed there for switching purposes (but without sacrificing it). The cord which the operator has just unplugged is thereupon placed in the new jack so indicated. The second message then proceeds into the tie line. The operator thus plugs up new connections for the entire multiplex channel group into the tie-line turret at the continuing instruction of his single-bid printer, without having to identify the channels he is switching. This is believed to be a novel way safely to switch to tie lines a volume of messages pouring in over a trunk group.

Character Counting and Billing

A number of years' experience has been had with character counting and automatic meter reading, on-line and off-line. Either method provides the carrier with an accurate character count automatically and immediately upon knockdown; if on-line, the information may, if desired, be communicated into the tie lines.

A point in favor of off-line counting, that is, saving reperforated tape and running it later through high-speed local printers, is that copy so prepared can be tailor-made to the bookkeeping and billing operation. For example, short uniformly-sized tapes, consisting of preamble and a fixed amount of reperforated text in the form of a toll ticket, can thus be prepared for sorting by customers' accounts. Bills may be actually prepared on page printers, automatic totalizing being also performed in one monthly operation. On-line copy is not so readily adaptable.

As fitted to IMCO at the time of writing, an off-line printer is connected to a simple counting program switch and a pair of cross-checking 4-stage decade counters. In the home position of the switch the counters are restored to zero. The switch steps once on the FIGS combination of the prefix and a second time on LF. It then releases the character counters but continues to step until a fixed quota of LFS has been received. When FIGS J goes through the transmitter, the switch supplies any extra LFS that may be needed to form a blank of manageable size, then prints the independent but coinciding readings of the two counters for cross checking. Other precautions are taken to afford a fourfold daily verification of loads and charges.

Extended Services

Conversational Use of IMCO Tie Lines

Normally no conversation takes place between a subscriber and his IMCO operator, in completing a call, at either end of the circuit. In fact, were it not for built-in switching disabling means, it would be impossible for a subscriber to ask questions or converse locally with his operator.

The means adopted involves a slow-acting relay[13] which interposes an interval of $1^{1}/_{2}$ seconds between the instant the IMCO operator plugs in and the moment the program switch begins its sweep (see Fig. 3). It will be recalled that in placing a call the subscriber pushes a calling button. His printer motor does not start until the IMCO operator plugs in. Thereafter, for a period of $1^{1}/_{2}$ seconds, the customer is afforded an opportunity to freeze the program switch, simply by touching any key on his keyboard. He may then converse with the IMCO operator at will. Since the program switch has not operated it is not a chargeable call, no bid has been made to London, no trunk has been occupied.

In the reverse sense, the IMCO operator can plug in any sending or receiving cord or his test-printer cord in a tie-line jack and raise the subscriber by bell signals. In this case the regular functions of a plugged-in sending or receiving cord are automatically disabled by a talk-freeze relay (Fig. 3).

Cross Bidding

Cross bidding, in the nature of an extension to usual IMCO connections of the MAMA type described, is provided for in the equipment. By its use, MA New York could ask for occasional connections to MB, QC, or PD London. By adaptation to cross bidding, the IMCO service, in fact, would become a general teleprinter exchange service, because it is in the nature of transatlantic telegraph communication for a customer to call regularly one principal correspondent and others only occasionally.

Cross bids may be placed during the $1^{1}/_{2}$ second interval mentioned, during which the customer may freeze the program switch. If MA wishes to be connected to PD, his "conversation" with the operator consists merely in saying, "PD PLS." The operator pushes his cross-bid key; the program switch steps to point *13;* PDPD is then inserted and the cross-bid key touched again to complete the bid (Fig. 3).

When the cross bid arrives in London, the operator there proceeds exactly as though it were a PD bid, and when he inserts the plug in the PD jack, the usual information is sent back to New York for automatic checking. Thus, cross bids are checked on the overseas bid trunks with the same accuracy as are regular bids.

IMCO Call Simulation

The constant availability of two switching operators with the versatile low-cost reperforator equipment described lends itself to utility uses whether connected or not with IMCO. The overseas trunks assigned to the switched service may be adjusted in number to suit the varying needs of the dispatcher. If their use in non-IMCO service is to be temporary, for example, to set up an overflow circuit to relieve congestion or provide a direct press channel, there is a gain in leaving it in IMCO in order to take advantage of its simple switching facility.

It is obvious that any stop-start termination can be made to simulate an IMCO tie line, be it an operating position in the central office, in a branch office, or on a trunk extension of any length beyond London or New York; and a number of corresponding jacks in the New York and London turrets may be reserved for the making of non-IMCO utility or regular pairings instead of the constant ones under IMCO contract. Of course the traffic so handled would come under appropriate non-IMCO tariffs, and any character counts automatically supplied between the establishment and knockdown of the non-IMCO service would be meaningless for charging purposes.

Non-IMCO Tie-Line Message Switching

A rather large number of non-IMCO tie lines in New York are used for mixed business, domestic and cable, and of the

Vol.
Pt. 1
196

cable usage, a high percentage is for London destination. There is an obvious speed and economic advantage in having such New York–London messages switched direct from the New York customer to a London (rather than a New York) receiving cable operator, and vice versa. Provision is made in the IMCO designs for making such switching transfers.

Such mixed tie lines are multipled into an assigned section of the IMCO turret on jacks identified as to tie-line call letters but unmatched with a calling signal light. When the service is operating, the IMCO operator's attention will be called to the call, by a printer to which the call letters are relayed by one of the regular plan *2* concentrator tie-line operators, on a house pony wire.

Mixed tie lines of this type have double identities. For their domestic and non-London cable business, they use their regular 3-letter tie-line calls and deal with a New York operator. When they want the London operator, they say to the answering tie-line operator: VA PLS, VA being their assigned call for use with London. The tie-line operator removes his plug from the plan *2* concentrator jack, stopping the customer's printer, plugs into the house pony (which contains interference prevention arrangements) and says "VA." The IMCO operator, in response, plugs into the VA multiple and handles the transferred call the same as any other IMCO call, the London-end "subscriber" being the London cable operator. The usual message heading is the calling party's receipt for his transferred London connection. All circuit elements are subject to the IMCO tests for integrity and the IMCO records protect the service.

Such service is also open to cross bidding, in which event all printer services converging in the London office are available for intercommunication to all points served by teleprinter which can be brought into the New York IMCO turret. When this is done a relatively inexpensive general reperforator system is created, having in it only one *FRXD* reperforator, the transmitting feature of which becomes operative before a completed message is in storage. This may be compared with ordinary private-wire reperforator systems, which also connect switching turrets (with their operators) in two cities but which require cross-office transmission with two reperforators at city of origin, a third reperforator at city of destination, and a completed-message requirement on all three reperforators.

Cord Circuit Detail

The foregoing explanations are probably necessary to an understanding of the built-in features of the sending cord circuits of Fig. 3, showing an R cord in the MA jack at New York, connected to send on a varioplex subchannel to London through the *FRXD* reperforator. When plug R is inserted in jack MA, the tie-line circuit from ground is completed through operate relay, connect relay, and setup relay to a vacuum-tube circuit through plan *2* concentrator for a busy test. If clear, negative battery completes the circuit to tie line; tie line closes to marking, applying ground to the connect relay through operate relay contacts to negative at monitor table power relay, starting *FRXD* and operating the connect relay.

The connect relay locks up through setup relay to positive battery: 1. removing busy test; 2. transferring local ground to the *FRXD* transmitting relay; 3. energizing the "go-ahead" point from the program switch preparing it to close the operate relay after the message heading has been run; 4. connecting outbound bid printer into circuit; and 5. operating the release relay.

The setup relay: 1. operates the shake relay to permit the rings of the turret jacks to place call letters on the program switch; and 2. releases the slow-release relay.

After $1^1/_2$ seconds, back contacts of the slow-release relay apply a stepping pulse through the back contacts of the break relay to the stepping magnet of the program switch. The sequence then follows level *1-s*.

After the message heading has been sent, the operate relay receives its pulse from the program switch, which: 1. disconnects the connect relay; 2. locks itself up, maintaining power on the monitor table; 3. applies a locking circuit to the release relay; 4. transfers the coil of the *FRXD* reperforator to marking contact of tie-line relay; and 5. transfers the tie line from the apparatus common to all cords to battery unique to the cord in use.

The customer is now sending, and his tape is being stored. The release relay blocks off the transmitting portion of the *FRXD*. London's confirmation of the bid through the comparator contact puts opposing currents through differential coils. The release relay falls back, removing the block against *FRXD* transmission. The message now goes to London on a varioplex trunk.

The customer's knockdown bell signal on the tie line closes a contact in the *FRXD* receiving element, operating the disconnect relay. The disconnect relay: 1. locks itself up; 2. short-circuits the operate relay and restores it to normal; 3. maintains power on the monitor table to handle any tape remaining in *FRXD;* 4. opens the customer's tie line, shutting down his printer; 5. lights the disconnect signal; and 6. puts ground on *FRXD* to prevent making any false letters when unplugged.

The operator responds to the disconnect signal as soon as the neon light stops flashing showing transmission is ended. The operator unplugs, breaking the circuit through disconnect relay and restoring normality.

If tie-line relay is opened (by the customer) during the interval before the slow-release relay has closed to start the program switch, the break relay operates and locks, preventing the stepping of the program switch.

If a cross bid is made by the customer, the operator throws the cross-bid key momentarily to the nonlocking "down" position, letting the program switch rotate and stop on point *13*. He inserts the cross-bid PDPD on his bid printer and contact *13*. He again throws the cross-bid key down momentarily allowing the complete cross bid to go through. The top (locking) position of the cross-bid switch is used to permit conversation between the operator and the customer on the tie line when the program switch is on point *13*.

The talk-freeze relay works in concert with the tie-line relay as long as the customer does not interrupt the tie line during the interval between plug-up and the time the program switch reaches point *13*. If the customer does interrupt, the talk-freeze relay passes an operating current to the break relay preventing the program switch from starting, or, having started, from going beyond point *13*. This permits the customer to stop or modify a bid.

◆

Discussion

Austin G. Cooley (Times Facsimile Corporation, New York, N.Y.): This switching system offers many very desirable operating features not found in other arrangements and accomplished with simple standard equipment. The designs take full advantage of the fact that the majority of the connections are established between the same offices.

When other than routine connections are required the switching is accomplished manually. The switching operators can make rapid connections with "insurance" against mistakes, as ingenious safeguards are provided against switching error or connection to an inoperative tie line or called printer. This[9] supervisory method is extremely simple and effective, being of course partly based on the fact that customer *A* in New York normally calls only customer *A* in London, *B* in New York, only *B* in Paris, etc. But provision is made for occasional *A–B* or *B–A* connections by special calling and switching procedure.

Functions are performed automatically on the customer's behalf which usually require him to make accurate and most exacting keyboard manipulation, such as numbering his messages, indicating on the message "origin" and "destination," adding "time" and "date," etc. These functions are performed by automatic equipment (which also includes the testing devices for insuring correct selection of an operative-called station).

While automatic switching gear might be employed, the cost and complexity of such gear is avoided by using a manual cord-type switchboard with automatic alarms and controls to guard against wrong connections. A single "common" control equipment is automatically associated with each cord during the time a connection is being set up and then released for another call.

The day-to-day operation of the Western Union IMCO system affords ample evidence of the value and importance of this development.

Radio-Frequency Interference Considerations in the TD-2 Radio Relay System

H. E. CURTIS
NONMEMBER AIEE

THE NUMBER of microwave systems that may be used on a particular frequency assignment in a given area is determined by the mutual interference between the systems. The Bell System is particularly conscious of this problem because of its extensive use of broadband microwave systems.

At the end of 1958 the Bell System had in operation approximately 215,000 one-way broadband channel miles of microwave systems in the United States, corresponding to approximately 7,000 transmitters and an equal number of receivers. A large portion of this extensive network makes use of the *TD-2* radio relay system[1,2] operating in the 3,700–4,200-mc (megacycles) band. The *TH* system[3] operating in the 6-kmc (kilomegacycles) range is under active development, and the *TJ* system operating in the 11-kmc common carrier band (10,700–11,700 mc) is now in commercial use. Equipments made by other manufacturers also operate in the 4- and 6-kmc bands.

In spite of the highly directive antennas now in use, a certain fraction of the transmitter power from any station will be radiated in directions other than that for which it is intended, and this becomes a potential source of intrasystem interference to itself and also to other systems operating in the same frequency band.

This paper is directed specifically toward the *TD-2* system because of its extensive use and the experience gained with it. However, the philosophy developed herein may be applied directly to the study of interference arising in or from other systems.

It is sufficient for the purposes of this paper to point out that the *TD-2* system, in common with many other microwave systems, uses frequency modulation. It can provide six 2-way broadband channels. Each of these channels can handle two one-way television channels or 480 or more 2-way telephone channels.

The frequency arrangement at a repeater is shown diagrammatically in Fig. 1. The six channels in one direction operate on channel assignments whose midband frequencies are 80 mc apart. The six channels in the other direction are interlaced with the first six, and thus there are 40 mc between midband frequencies of adjacent channels in opposite directions. Thus, the potential interference from a transmitter at a tower is always separated by 40 mc or more from the closest receiving carrier frequency used at the same tower, and r-f (radio-frequency) and i-f (intermediate-frequency) filtering is sufficient to reduce such interference to a negligible magnitude.

When a 2-way channel such as that shown in Fig. 1 is extended to include three consecutive repeaters, as in Fig. 2, it will be noted that two additional types of interference are involved. Similar interferences will exist, of course, on the other five channels.

For convenience in discussing these interference paths, let each antenna involved be given a number followed by a pair of letters designating the direction of transmission and whether the antenna is transmitting or receiving. Thus the sequence from west to east is $1E(T)$ to $2W(R)$ to $2E(T)$ to $3W(R)$, etc. At any particular receiving antenna such as $2W(R)$ there will be normally two important interferences. One is from $1W(T)$ into $2W(R)$, and the second is from $3W(T)$

Paper 60-54, recommended by the AIEE Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted October 22, 1959; made available for printing November 23, 1959.

into $2W(R)$. The first, for convenience, is designated "same section," since it transverses the same repeater section as the desired carrier from $1E(T)$; the second, $3W(T)$ into $2W(R)$, may be designated "adjacent section" for obvious reasons. Each antenna is normally subject to these same two interferences.

Of particular significance is the fact that the interference has the same nominal frequency as the carrier with which it interferes, and, hence, it cannot be discriminated against by filters. Therefore, the only protection lies in making the backward response of the antennas adequately low.

The interference situation becomes increasingly complex at a point where a number of converging microwave systems operate on the same or nearly the same frequency. An extreme example of such a point is that which exists at New York, where the Bell System has two centers from which microwave systems radiate, as shown in Fig. 3. Here we have a total of five converging routes with angles ranging from 50–110 degrees, with a sixth paralleling route.

Relation Between R-F Interference and Baseband Interference

The relation between radio interference and baseband interference depends, among other things, on the kind of baseband signal being transmitted. In general, in Bell System use, this is either a video signal or a number of telephone channels arranged in frequency division. The latter case is emphasized herein, since it has been found to lead to a philosophy that provides adequate freedom from interference when either telephone or television signals are transmitted. For analytical and experimental purposes a

Fig. 2. R-f interferences on the TD-2 microwave system with typical paths as shown

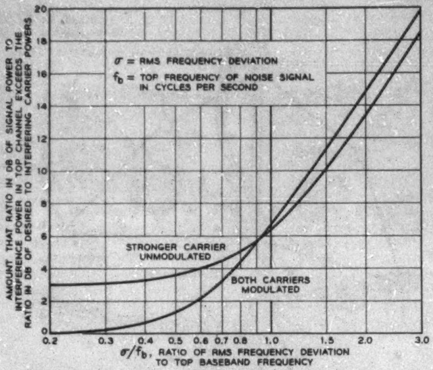

Fig. 4. Cochannel interference from a multichannel FM system modulated with flat band of noise

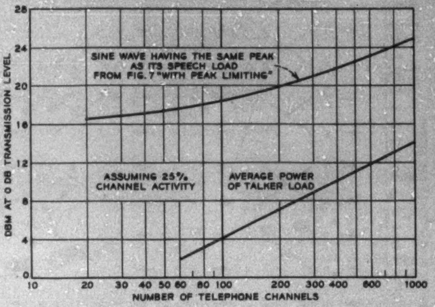

Fig. 5. Multichannel telephone load, assuming 25% channel activity

multichannel telephone signal can be adequately simulated by a band of random noise of the same average power and the same bandwidth as the multichannel signal.

The problem of intermodulation due to echoes in FM (frequency-modulation) with noise loading has been treated in a previous paper,[4] which showed that the amount of intermodulation depends, among other factors, upon the echo delay. (During the preparation of this paper, a theoretical paper[5] on the interference between noise-modulated FM carriers appeared, which gives a general expression for the interferences as a function of frequency deviation, top baseband frequency and frequency separation between carriers. The resulting equation is identical with the one from which Fig. 4 was computed.) It is of significance to the present problem that, as the echo delay becomes infinite, the correlation between the signal modulation on the echo carrier and that on the main carrier becomes zero. Hence, it may be reasoned that, in the limit, the interference problem discussed herein becomes analogous to the echo problem. An important difference is that here the carriers may be separated in frequency, whereas the echo must always have the same carrier frequency as the main wave.

This theoretical work, which is not reproduced here, leads to Fig. 4, which shows the relationship between the baseband signal-to-interference ratio and the ratio in decibels of the desired-to-interfering carriers when the latter ratio is greater than about 10 db. This depends on the FM deviation ratio, which, in this case, is specified in terms of the ratio of the rms frequency deviation to the top baseband frequency. Furthermore, the relationship depends somewhat on whether both carriers are modulated with noise or only the weaker is so modulated. In the latter case, the baseband signal to which the interference is referred is assumed to be equal in magnitude to that applied to the interfering carrier.

In addition to the interference from the modulation on the carriers evaluated in Fig. 4, there is generated a beat note having a baseband frequency equal to the difference in frequency between the desired and interfering carriers. Since the beating oscillator frequencies in the *TD-2* system are crystal-controlled, the carrier differences are held to within a few tens of kilocycles. Hence, the interferences between the carriers themselves fall below the lowest frequency used by the *TD-2* system's channelizing equipment. Experience has shown that tone interference into systems carrying television service will be adequately low if the interference requirements imposed by multichannel telephone service are met.

With speech loading, the frequency deviation is generally specified in terms of the peak value in contrast to noise loading where it is convenient to refer to it in terms of the rms frequency deviation. Fig. 5 shows the sine wave power, at a point of 0-db transmission level, which has the same peaks as a multichannel telephone system, assuming an activity factor of one-quarter. This is taken from a paper by Holbrook and Dixon.[6] Also shown in Fig. 5 is the power of a multichannel load, based on talkers whose volumes correspond to the mean power of the assumed talker distribution curve, an activity factor of one-fourth being included. This curve is derived from constants given in reference 6.

The *TD-2* system with a 480-channel load normally uses a peak deviation with speech of ±4 mc. Fig. 5 shows that for this channel load the ratio of the rms frequency deviation with equivalent full sine-wave modulation to the rms deviation with noise loading is 11.5 db. This ratio referred to peak sine-wave deviation is 3 db greater, or 14.5 db. Accordingly, the rms deviation with a

3-db beamwidth = 2.5 degrees

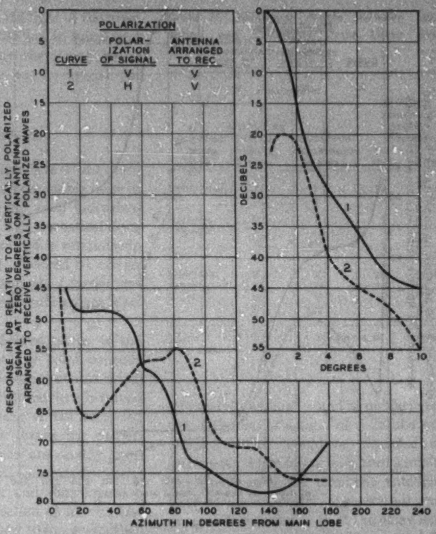

Fig. 8. Smoothed directivity in the horizontal plane for a horn-reflector antenna at 4 kmc

noise load can be seen to be 0.7 mc. Therefore, since the top baseband frequency is approximately 2 mc in the example, the ratio of rms frequency deviation to top baseband frequency would be approximately 0.35. Hence, Fig. 4 shows that, in this case, the baseband signal-to-interference ratio in a telephone channel at the top baseband frequency is 1/2 db greater than the ratio in decibels of the "desired" carrier to an interfering carrier when both carriers are modulated with noise. Thus, by rounding this value to 1 db, we may write in db

$$S_{\text{dbm}}-N_{\text{dbm}}=C-I+1 \qquad (1)$$

It has been found useful in the Bell System to express noise power in a telephone circuit in dba. (A discussion of this unit and its relation to other units of noise power is given in some detail by Franke.[7]) This implies a specific frequency weighting characteristic, and 1 milliwatt (0 dbm) of flat noise in a 3-kc band reads 82 dba. For a measurement of noise power to have meaning, it must be referred to the signal power at the same point in the circuit, or else the transmission level at which the measurement is made must be specified. Noise in dba is often specified at the 0-db transmission level, the point of reference being the toll transmitting switchboard.

Holbrook and Dixon give the power of an rms talker at a point of 0-db transmission level (0-db TLP) as −9.9 dbm. With a channel activity factor of one-quarter, the equivalent noise load per 4-kc channel is −15.9 dbm. The noise in a 3-kc band is 1.2 db less, or −17.1 dbm. This amount of noise power would measure very nearly 65 dba. From this it follows that, given a measurement of signal power and of noise power in the same narrow band, the equivalent noise in dba at a point of zero transmission level can be obtained from the following relationship:

$$N_{\text{dba}}=65-S_{\text{dbm}}+N_{\text{dbm}} \qquad (2)$$

By combining equations 1 and 2, the relationship between interference in a telephone circuit and the r-f carrier-to-interference ratio can also be obtained. Thus, for the *TD-2* system

$$N_{\text{dba}}=64-(C-I) \quad \text{in db,} \qquad (3)$$

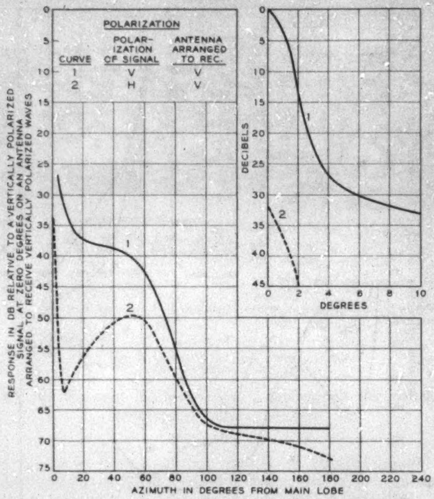
provided $C-I$ is greater than about 10 db. This relationship is plotted in Fig. 6.

Objectives

Experience has shown that long-haul telephone circuits will give excellent transmission performance if the rms noise from all sources is 38 dba or less at a point of zero transmission level (0-db TLP). On a radio relay circuit, noise in the more general sense may arise from many sources. A portion will be in the form of fluctuation noise arising in the converters; some will be intermodulation because of amplitude and phase distortion in the i-f and r-f circuits, as well as from echoes in the wave guide runs and the interconnecting i-f cables. It is necessary to divide the total permissible noise among all the known contributors, allotting to each source an objective consistent with its importance and the feasibility of meeting it. Of particular concern here is unintelligible crosstalk caused by r-f interference; a reasonable allocation for this last source of impairment is 24 dba at the 0-db TLP for a 4,000-mile system.

Provision must be made for both the interference within the main route itself and interference to the main route from other systems that converge. Of the total of 24 dba given previously, it appears reasonable to allot 22 dba to main route interference. As mentioned in the foregoing, there will be two main-route r-f interferences of major importance at each repeater: "same section" and "adjacent section" interference.

In order to arrive at a "per interference" allotment, it is necessary to discuss the antenna directivity patterns. The measured directivity pattern of an individual



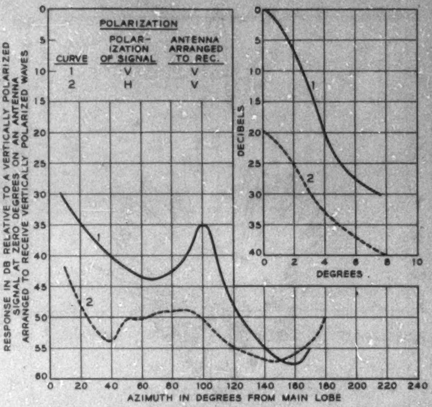


Fig. 9 (left). Smoothed directivity in the horizontal plane for a delay lens antenna at 4 kmc

Fig. 10 (above). Smoothed directivity in the horizontal plane for an 8-foot parabolic antenna at 4 kmc

sample of a given antenna at a particular frequency will exhibit numerous maxima and minima, as shown by Fig. 7. It is not practical to make use of the sharp nulls to reduce converging route interference, because their angular position varies with frequency and is apt to differ from one particular antenna to another. Also, the nulls are usually sharper than the angular stability of the tower used to support the antenna. Therefore it is desirable to use smoothed directivity patterns, as shown in Figs. 8, 9, and 10, in designing particular systems. The smoothed patterns were obtained by drawing a more or less smooth curve through the peak (or poorest) values of the measured patterns. Therefore, these effectively are "worst" values rather than "rms" values.

In a multirepeatered system where there is a sizable number of exposures involving random angles, a substantial percentage of these exposures will contribute less interference than would be indicated by the work presented here. Therefore, the total rms interference is somewhat less than would be expected by simple power addition of the individual interferences. An examination of various measured directivity patterns indicates that it is reasonable to assume that straight power addition is perhaps too conservative by about 6 db. This factor can be introduced into the allotment either by altering the antenna characteristics or by altering the allotment. Since the antenna characteristics describe what was actually measured, we have chosen not to modify them; instead, we have modified the allotment.

Furthermore, considering one exposure alone, intelligible crosstalk can appear only if the two carriers involved are within a few hundred cycles of each other; the chance of this is very small. Actually, the two carriers may be as much as several tens of kilocycles apart in frequency; hence, an observer would more probably hear crosstalk from two telephone channels simultaneously with a random amount of frequency staggering. Since the frequency differences between carriers in a large number of exposures will be quite randomly distributed about an average, the telephone interference will appear as babble and may be treated as noise. Therefore, on the basis of 140 repeaters (4,000 miles), two interferences per repeater, and a factor of 6 db as previously mentioned, the per repeater allotment in dba for either the same section or the adjacent-section interference is

$+22-10\log 280+6$
or approximately $+4$ dba at 0-db TLP

Since this allotment is slightly below that for first circuit noise, the sideband power cycle of allowable r-f interference is slightly below the fluctuation noise per cycle in the receiver converter in which the r-f interference falls.

It is evident then that during a fade of the desired carrier entering any particular receiver converter, the converter noise and the r-f interference contributions, as observed in any telephone channel at the terminal of the system, will rise together and always stay in balance. Obviously, if the interfering carrier fades, it becomes increasingly weaker than the fluctuation noise, and the effect then becomes entirely negligible.

Pertinent features of a long main route such as may extend across the continent are the spurs by means of which television and telephone channels are brought to cities situated off the main route.

At each point where a spur joins a main route four r-f interferences will occur, as shown in Fig. 2. Two of these will appear finally as telephone channel babble at the west end of the backbone route, and similarly two will appear at the east end. Thus, assuming 64 spurs per 4,000 miles, there will be a maximum of 128 such interferences at either end.

However, the angles of the spurs may be expected to be distributed at random, with presumably no angle less than a value consistent with the objectives developed below. Hence, many interferences may be expected to contribute substantially less baseband noise than the alloted value. In view of this it is probably not unreasonable to assume that only one-half of these interferences will contribute significantly to the total.

The maximum amount of baseband noise each of these r-f interferences may be

Table I. Minimum Angle Between Disturbed and Disturbing Paths for Cochannel Interference

	H	V	110
	V	H	X

* X indicates that the objective cannot be met at any angle with these conditions.

permitted to contribute can then be obtained by using the same line of reasoning as was followed above. Thus, assuming 64 spurs per 4000 miles, the per spur allotment is

$$+20-10\log 64+6$$
or $+8$ dba at 0-db TLP

It is recognized that the foregoing, at best, can be only a guide, since any tentative layout may call for spur angles ranging from zero (which may introduce excessive interference) to 180 degrees. Hence, each specific spur contribution must be examined in the light of the overall spur allotment, bearing in mind that cases will arise where there may be no practical alternative but to exceed the pro-rated allotment.

Systems Application

The previous sections have 1. set down objectives in terms of permissible noise in a telephone channel for each individual r-f interference on a hypothetical long system, and 2. developed a relationship between the ratio of a desired r-f carrier to an interfering cochannel r-f carrier and the telephone channel interference that results therefrom.

The ratio of the desired carrier to the interfering carrier at any point depends on the transmitted powers, antenna gains, path losses of the two carriers involved and the discrimination of the receiving antenna against the interfering carrier. The first three factors are readily computed and need not be elaborated on here. The antenna's gain and discrimination are, of course, a function of its size and design. Figs. 8, 9, and 10 show smoothed discrimination curves for the antennas normally used in the *TD-2* system: the horn-reflector antenna, the delay lens antenna and a simple 8-foot parabolic antenna.

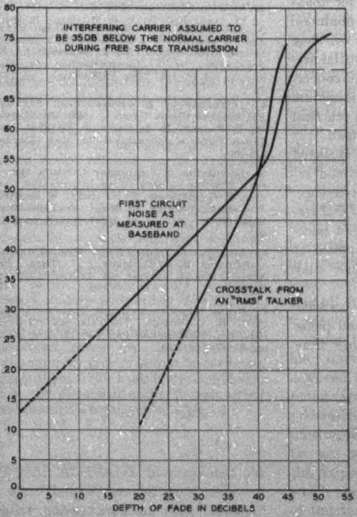

Fig. 11. First circuit noise and adjacent channel crosstalk with interfering carrier assumed to be 35 db below the normal carrier during free-space transmission

	H	H	20	7.2
	H	V	5	1.8
	V	H	8	4.9

* Less than 2 degrees; a minimum of 2 degrees is suggested.

Since the response of the 8-foot parabolic antenna to a signal from the rear is only 45 db below the main lobe response, both the "adjacent section" and "same section interference" would be on the average +19 dba, or a total of +22 dba per repeater. This would be regarded as intolerably high for a long-haul circuit. For this reason, the parabolic antennas have been used mostly on short-haul spur or secondary routes. Both the delay lens and horn-reflector provide in excess of 65 db discrimination in the rearward direction, which is entirely adequate even for systems of 4,000 miles in length.

The minimum angle between a spur route and a main route on the basis of a given permissible interference is determined by the discrimination of the antennas involved. This, for a given pair of antennas, depends on whether the interference is polarized similarly or at right angles to the plane of polarization of the desired carrier.

Table I gives the minimum angle between the disturbed and disturbing paths based on the interference into the receiving antennas at the point of convergence, with the inherent assumption that the disturbed and disturbing signals are equal in strength; i.e., they originate from similar equipments and traverse paths of equal length.

In general, the Bell System does not operate separate microwave routes in close enough proximity for mutual interference to become a consideration. However, where it is suspected, the baseband interference can be computed on the basis of the principles laid down above. In general, disturbing transmitters and the disturbed receivers on separate routes do not point at one another, and the discrimination advantage of both antennas is obtained. The combinations and possibilities are so great for such cases that generalization becomes useless and each case should be treated individually.

In the standard frequency arrangement

for the *TD-2* system, transmitting and receiving carriers are separated by 40 mc. Ahead of the receiver converter, r-f filters provide 20 db of discrimination to the transmitter. This and the i-f selectivity are more than adequate to eliminate interference between transmitters and receivers at the same site.

It is possible under certain conditions to operate channels in the 20-mc slots between an adjacent transmitter and receiver in the standard frequency arrangement. These interstitial or so-called "slot" channels are used at converging points or spurs where co-channel interference considerations would limit the minimum angle of convergence to an undesirably large angle. (Developments subsequent to the preparation of this paper indicate that additional discrimination applied at each repeater at the intermediate frequency of 70 mc reduces the crosstalk from the adjacent microwave channels 20 mc offside so as to allow the minimum angle between converging routes to become zero degrees. This is equivalent to saying that six interstitial 2-way microwave channels can also be operated in the 3700- to 4200-mc band, making a total of 12 broadband channels. The technical problems relating to the possible use of these six additional 2-way channels are now being studied at Bell Telephone Laboratories.)

When interstitial frequencies are used each channel may have interferences separated only 20 mc from the normal carrier frequency, i.e., at 50 mc and 90 mc in the i-f band. This separation is not sufficient to provide any appreciable suppression of the interfering carriers by r-f filtering. Furthermore, the i-f discrimination to such interferences is only of the order of 5–10 db.

If the FM receiver could be assumed to consist of a perfect limiter and a perfect demodulator, FM theory would indicate that the resulting interference at baseband frequencies would be infinitesimal in magnitude in the frequency range occupied by the normal signal. Furthermore, any such interference would be incoherent with the modulating signal on the disturbing channel. Actually, experiment has shown that the signal on the weaker carrier is transferred to the stronger carrier. The crosstalk increases 2 db as the ratio between the desired carrier and the interfering carrier decreases 1 db, provided that the interferring carrier is weaker than the desired carrier; beyond this point, the baseband interference rises still more rapidly. No completely satisfactory explanation has been advanced, other than the generalized one that physical amplifiers, limiters, and discriminators are frequently not ideal devices.

From a systems engineering viewpoint, when interstitial frequencies are used the interfering carrier must be sufficiently weaker than the desired carrier during free space transmission that, when the desired carrier fades, the crosstalk remains below the fluctuation noise as long as the circuit is useful.

Fig. 11 shows how the fluctuation noise theoretically increases with depth of fade on a single typical repeater section. Also in Fig. 11 is a curve showing how the crosstalk from an interstitial channel increases with a fade, assuming that the interfering carrier is 35 db weaker than the interfered-with carrier during periods of free space transmission. It is assumed, in this case, that the interfering channel is modulated with average power talkers.

This figure indicates that, with a carrier ratio of 35 db, the crosstalk remains below the noise for fades up to about 35 db. Arrangements are provided automatically to switch the faded channel to a protection channel when the depth of fade exceeds 35 db.

Since this carrier ratio is about 20 db less than the requirement for tolerable cochannel interference, the minimum angle at which two routes may converge is greatly reduced when interstitial frequencies are used at the point of convergence. Table II illustrates the minimum angles of convergence that are practical when interstitial frequencies are used.

In a linear system it would be expected that additional i-f selectivity would reduce the effect of interstitial interference. Experiment has shown that the *TD-2* system is so nonlinear that added i-f selectivity is effective only when applied at each repeater where interference may enter the system.

For this purpose i-f filters are available that have no appreciable loss and phase distortion in the frequency range from about 60–80 mc and about 30 db loss in the frequency regions of 50 and 90 mc. When these filters are used in a *TD-2* system using an interstitial frequency plan, the angles between converging routes need be such as to provide an antenna discrimination of only 25 db during periods of free-space transmission. Table II gives the minimum angles necessary for adequate protection from interference when i-f filters are used.

When the suggested minimum angles are very small, as when filters are used, allowance must be made for the mechanical stability of the towers and for the precision to which the antennas can be oriented. The former depends on the design of the tower structure and on the loads to which it is subjected. The latter depends on the method and skill used in orienting the antennas. No safety factors for these considerations have been included in the suggested minimum angles.

Also for these same reasons, with the delay lens antenna and a crosspolarized interfering carrier, it is suggested that the minimum permissible angle between converging routes be 2 degrees rather than 0 degrees as would be indicated by the discrimination pattern for the delay lens antenna.

Optimum Design Considerations for Radio Relays Utilizing the Tropospheric Scatter Mode of Propagation

CHARLES A. PARRY
MEMBER AIEE

Synopsis: There are many areas of the world where the service which can be provided by the scatter link is needed, but cannot be justified economically. One approach toward reducing costs, suggested here, is to investigate the improvements achieved through optimizing system-design parameters.

It is shown that the nonlinear noise introduced by truncating the bandwidth may be used as a basic tool in this analysis. It is found that the signal-to-thermal-noise ratio may then be expressed purely as a function of traffic volume and noise bandwidth. Data are given relating this to such factors as trunk occupancy, speech volumes, grade of service offered by trunks, and the percentage of time during the busy hour for which the given performance is offered.

This approach leads to a minimum permissible noise bandwidth B given by $B = 15.2\ N$ kc, where N is the number of contiguous 4-kc channels extending from zero frequency. General expressions for the optimum bandwidth as a function of signal-to-noise ratio and traffic loading are also developed. From these expressions it is possible to derive the minimum permissible transmitter power for the optimized system. When related to performance over a smooth spherical earth, it is concluded there is a wide field of application for 100- and 250-watt installations. It is suggested that the optimum design (propagation) reliability should be established from the slope of the bivariate probability distribution for instantaneous fading; this leads to a limiting value of 99.9% on a yearly basis.

Expressions for minimum power also leads a design efficiency factor, expressed as the ratio of optimal power to actual power. In addition, an economic index is discussed; this permits a comparison between various links carrying different numbers of channels and with different grades of service and reliability. Methods of reducing transmitter power by stabilizing some of the parameters are reviewed; a new technique is described in which the bandwidth is controlled by traffic volume, and it is shown that further reductions in transmitter power are thereby possible. A means for the greater utilization of circuits carrying light traffic loads is also considered. From the discussion outlined, commercial breakthrough is considered feasible.

IT HAS ALREADY been pointed out that the commercial application of scatter poses something of a paradox.[1] The physical conditions which tend to lead to the use of scatter, in themselves, imply a social independence between the connected groups which precludes economic justification for the link. Even in strategic applications where normal economic evaluation cannot be applied, the scope of services which can be provided must conform to national budgetary allocations. Under these circumstances even strategic planners must carefully evaluate a communication technique which may cost as high as $10,000 per route mile, and require 250-watt transmitter power per decibel (db) signal-to-noise ratio.

Some of the factors which enter into economic justification have been discussed[1] and a technique for this evaluation in specific terms has been outlined.[2,3] It is apparent that there are many factors involved beyond basic costs alone; nevertheless, any possibility of extensive commercial utilization must be approached by considering the ways in which these costs may be reduced.

Certainly there have been developments in methods of fabrication which have improved the economic picture, but despite this, over-all costs associated with the scatter system remain formidable. When assessed in terms of available revenue, there are many areas of the world where such systems are technically desirable but economically unsound.

Undoubtedly new techniques, for instance controlled carrier operation[4] and low noise preamplifiers, will prove useful in specific applications; however, in many cases, the approach toward minimal over-all cost systems tends to offset advantages so gained.

So far, little has appeared on the possible improvements which might be achieved by optimizing the normal system-design parameters. While a comprehensive analysis of all the factors which must apply to the design of the radio relay are beyond the present scope, it is the purpose of this paper to discuss those which appear most significant. Apropos of this it was pointed out in a previous discussion, that the optimum FM (frequency modulation) system would be "peak" limited; that is, one where the per-channel deviation would be established by the "overload point" of the system.[5] Although this parameter is not normally used in FM-system design, the concept will be developed in the following text.

This discussion is restricted to FM relays using FD (frequency division) channeling equipment.

Initial Approach

The basic starting point for the analysis of communication circuits is the signal-to-noise ratio obtained in the information bandwidth.[6-8] The total circuit noise in practical systems is comprised of nonlinear and thermal components. The calculation of the principal component of the thermal noise which appears in the channels of the multichannel system has been treated extensively and will not be detailed here.[9]

The signal-to-weighted-thermal-noise ratio, S_t, in the top channel of the (single-link) FM system, with the r-f (radio-frequency) signal power equal to the FM threshold, can be expressed in the following manner:

$$S_t = \frac{K'\delta B_\epsilon}{2b\ T_e}\left[\frac{\Delta}{f_m}\right]^2 \tag{1}$$

The threshold power P_t for which this applies is given by:

$$P_t = KTFB_\epsilon \tag{2}$$

The terms in these expressions are defined as follows:

K' = weighting factor. For 4-kc spacing between channels, $K' \simeq 2$.

δ = improvement due to the use of pre-emphasis and de-emphasis networks. This will depend on the particular networks employed; for typical conditions $\delta = 2$ in the top channel.[10]

B = noise bandwidth cycles. For all practical purposes this is the 3-db i-f (intermediate-frequency) bandwidth.

ϵ = minimum permissible ratio of r-f signal power to (rms) noise power in the band B and referred to receiver input. This is defined sometimes as the FM threshold factor.

b = channel spacing in cycles. It is considered to be small compared to the absolute base-band frequency corresponding to the center of the channel.

Paper 60-7, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted November 3, 1958; made available for printing December 4, 1959.

CHARLES A. PARRY is with Page Communications Engineers, Inc., Washington, D. C.

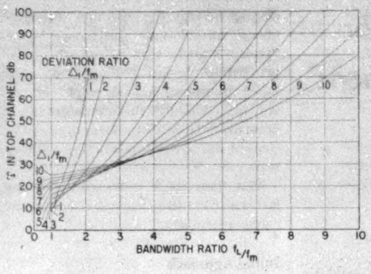

Fig. 1. Signal-to-noise ratio γ measured in top channel of system with white-noise signal extending from $0 \rightarrow f_m$. $2f_1$, truncated bandwidth, Δ_1 peak deviation

Δ = "peak" deviation obtained with a sine-wave signal having an rms power equal to that of the mean power of the multichannel signal (measured in the base band). $\Delta = 1.4 \times$ rms deviation cycles

f_m = modulating frequency for the top channel cycles.

T_c^{-1} = ratio of single-channel test-tone power to mean power of the multichannel (base-band) signal.

F = effective noise figure of receiver.

If the factors of equation 1 were unrestricted, system design would present very little problem, since Δ could be suitably increased for any finite B. However, in practice, as is well known, transmission of the complex wave comprising the multichannel signal, through distorting elements in the system, introduces nonlinear noise into the channels,[9,11,12] and this increases with Δ. A substantial part of the total nonlinear noise tends to vary inversely with B. Equation 2 indicates that for small P_t, B should also be small. Thus, the possibility of a compromise value between Δ and B is indicated. Values ascribed to Δ and B in the literature vary considerably, although the CCIR (International Radio Consultative Committee)[13] has now stipulated per-channel deviation for international circuits. As far as is known, no attempt to correlate Δ and B has been made.

Nonlinear noise associated with B arises from two principal sources. The first is due to loss of side-band energy since B is finite, and for the FM wave, a theoretically infinite bandwidth is required. This is the "truncated bandwidth" effect of Medhurst, and means for calculating this have been derived.[14] This truncated bandwidth may be taken as equal to the noise bandwidth in practical designs. The second source of noise is associated with phase nonlinearity due to the passive networks which determine B. This latter problem has been analyzed by a number of workers,[15—24] and reviews of the principal techniques used have been given by Brown,[16] and Collings and Swirzynaski.[17] Unfortunately, the assumptions which must be made to arrive at workable solutions, tend to reduce the validity of the end result. Most authors use a quasi-stationary format, and Franz indicates certain conditions under which this is valid for the dynamic condition.[18] However, while reasonable agreement can be obtained for simple circuits, there are large divergencies among authors for the general case. Brown, in fact, concludes that a satisfactory analytical solution is not possible. Collings,[17] in deriving coefficients for a typical coupling circuit, indicates that difficulties of solution limit the magnitude of the parameters which could be used for this purpose. On the basis of this work, it does not appear reasonable to derive a general relation for the nonlinear noise power in terms of bandwidth and peak deviation and the phase derivative.

When large numbers of networks in tandem are contributing more or less equally to the total distortion, the resultant bandwidth is substantially greater than that pertaining to a single network with the same total distortion. Typical interstage couplings, such as critically coupled double-tuned[19] circuits, maximally flat triples,[17] and compensated single- and double-tuned circuits,[25] can be designed with acceptable values of distortion. The noise bandwidth of typical interstages is virtually equal to the 3-db bandwidth[26] so that this single stage will also determine B.

Thus it would seem feasible to use a single stage, or at most, a minimal number of stages, in order to control B and at the same time achieve satisfactory phase linearity. The principal nonlinear noise components arising from this source vary at most as the third order of B; on the other hand, the components arising from the truncation effect will vary as the twelfth to thirtieth order.

Hence, if B is varied, this latter effect rapidly becomes controlling and is equivalent to behavior at overload in an AM (amplitude modulation) system. It is feasible to introduce the nonlinear noise from this source as a limiting factor in the design, since the system may then be regarded as "peak limited."[6] This establishes the optimum condition since it per-

mits the minimum transmitter power for a given set of performance criteria. Hitherto, this approach does not appear to have been used. It will be developed further in a later section of this paper.

Fig. 1 shows the signal-to-noise ratio γ calculated for the top channel of the multichannel system when using a white-noise test signal. This is based on Medhurst's equations 7 and 8. The transition from his "large" to "small" deviation formulas is obtained by replotting the data in the form shown in Fig. 2. In Figs. 1 and 2, Δ_1 is equal to Medhurst's term $(S/2\pi)$.

Mean Power of Multichannel Signal

Since T_c is associated with single-channel test tone, it is numerically equal to the mean power of the composite multichannel signal in dbm 0 (db referred to 1 milliwatt at a point of zero level). This is determined by the statistical properties of speech as well as the number of channels; system design is usually based on that level which will not be exceeded for more than 1% of the busiest hour. The distribution of mean power with time was originally investigated by Holbrook and Dixon,[27] later by Jacobsen[28] and several telephone administrations in various parts of the world.[29] The curve obtained by Holbrook and Dixon is shown in Fig. 3. Subrizi[30] has indicated that average talker volume has apparently decreased since this original work, particularly for short-haul toll circuits. It has been pointed out that the distribution curves derived by these authors, indicate that for many design purposes an exponential relation may be assumed between the number of channels and mean power.[5] Then the following expression may be used:

$$P=XN^{\alpha} \tag{3}$$

from which

$$T_c=XN^{\alpha} \tag{4}$$

where P is the mean power, N is the number of channels, and X and α are constants. Values for X and α are given later in this section. A curve on this basis using Subrizi's data is also shown in Fig. 3. These curves do not include the effects of carrier leaks and signaling tones. The result of including spurious signals at -20 dbm 0 per channel is also given. None of the data shown include the effects of limiting. Since this tends to reduce the mean power, the curves shown may be regarded as conservative and sufficiently well approximated by the exponential relationship.

The original data were based on an observed activity factor of 0.25. This may be defined as the fraction of time a busy channel, that is, one not available for another caller, actually carries voice energy. Although this figure has been questioned,[5,31] it is reasonable to believe that this is an average figure for a typical busy circuit.

Of more significance however, is the implication that all channels are busy regardless of the number, and this is certainly sufficiently true for medium sized groups of trunks on typical exchanges. Study of traffic data,[32–34] including the latest methods of analysis by Hettwig and Rhode,[35] indicates that this is not a reasonable assumption for small numbers of channels. Fig. 4 shows trunk occupancy derived from several sources. The Rural Electrification Administration suggests a 5% grade of service for toll-connecting trunks[32] which is a reasonable qualification for scatter-circuit service. A curve on this basis is given in Fig. 4. In most cases it can be expected that the scatter channels would be routed through a manual switchboard; accordingly a curve has also been added for a 5% probability of congestion.[33] It does not seem feasible to establish a design on worse than 5% grade of service, particularly when it is recalled that the scatter link can be engineered to provide the reliability requisite of toll circuits. By contrast the CCIF (International Telephone Consultative Committee) curve for 20% deferred calls is also shown in Fig. 4, showing virtually 100% trunk occupancy.[36] It is believed that this results in 30% lost calls, which would be totally unacceptable for normal service.

By determining the number of busy channels from the average trunk occupancy indicated in Fig. 4, it is possible to derive curves for the distribution of mean power based on a specific grade of service. This has been done in Fig. 5. It is believed these curves are more representative of mean powers likely to be realized in operational systems than those of Fig. 3. Although design is ordinarily based on the curve pertaining to the 1% of the busy-hour criterion, originally this was a somewhat arbitrary choice. It represents an unnecessarily high objective

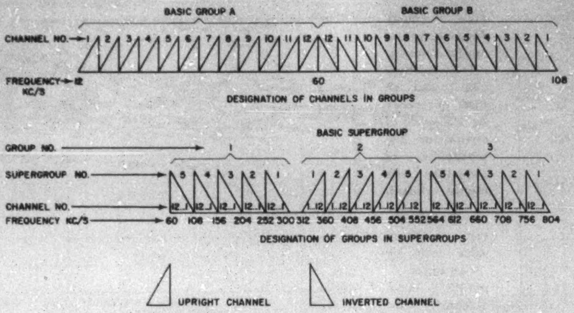

Fig. 6. CCIF channeling arrangements showing groups and super groups

for private industrial or quasi-national circuits, where somewhat reduced performance is often permissible. Accordingly, in Fig. 5, a curve for a "5% of the busy hour" criterion has been added, as a suggestion for these latter applications.

Values of the constants X and α for the various curves of Figs. 3 and 5 are shown in Table I.

Channels

In order to obtain minimum traffic capacity, it is necessary to have contiguous channels extending from $0 \rightarrow f_m$. This virtually dictates the use of CCIF frequency allocations which have tentatively been recommended for use in radio relays.[27] Channels are 4 kc wide, extending from a lowest frequency of 12 kc; see Fig. 6. Conforming equipments have been manufactured and installed in many parts of the world. When standardization, compatibility, and availability are evaluated, the use of the CCIF allocation is almost mandatory. Even when only a few channels are being considered, use of compatible equipment offers so many advantages that the value of a possible reduction in (f_m) is offset. Furthermore, the band below 12 kc is available for special purposes including service channels, so that the spectrum is normally fully utilized. Also, since this is the bottom end of the band where lower noise can be expected, it is feasible to consider as many as five additional narrow-band channels within the 12-kc limit with slightly increased transmission impairment,[29] particularly for military applications.

The system's analysis will, therefore, be based on the relation $Nb=f_m$ where N is the number of channels from $0 \rightarrow f_m$.

White Noise and Peak Deviation

The statistical characteristics of the complex signal comprising a number of voice channels are similar to those of white noise.[27] Although the relative peak-to-rms ratio increases as the number of channels is reduced, it can be shown that limiting substantially reduces this effect,[28] and the white-noise concept is suitable down to perhaps four to six channels. The nonlinear noise which results from the transmission of such a signal through distorting elements in the system has been analyzed for both FM and AM systems by many authors.[9,12,28,30] It can be shown that the nonlinear noise which falls in any channel is dependent on the rms value of the transmitted wave.[38] By using a white-noise signal with rms value equal to that anticipated in the working system, behavior under operative conditions is simulated. Preferably the white-noise test signal should extend over the entire base band, measurements being carried out in narrow band at the upper end of the spectrum. Data obtained with the so-called "50% illumination" are misleading, since the distribution of nonlinear noise over the base band is thereby altered and significant products may be lost.[9,38] The full base-band concept is used throughout this paper. The white-noise concept was probably originated by Bennett,[40] and has now received almost universal acceptance.[5,41] In addition it is a powerful analytic tool used by many workers in the field.[12,14,42]

It is customary to define the per-channel transmission level in terms of the peak power capability of the equipment and a loading factor.[27] This concept is of little value with the white-noise approach, since the "peak" characteristics of noise are uniquely defined by inherent statistical properties. Furthermore, it should be noted that only the rms value can be measured with any certainty, and data related to peak values can be quite misleading; this has also been observed Hamer and Medhurst.[43] This anomaly can be overcome by specifying equipment in terms of the rms noise-power handling capability, a rating which is now overdue in the industry.

It is to be noted that the CCIR has indicated a specific rms level for the white-noise testing of wide-band radio relays.[18] Recently it has been suggested that this should equal the mean power corresponding to the 1% of the busy-hour criterion as shown in Fig. 3.[44] With the test rms value given, the per-channel transmission level follows directly from the equivalent mean-power curve.

When the signal-to-noise ratio γ is measured in a channel by this particular method, a correction must be added to obtain the equivalent signal-to-noise ratio in the operative system.[5] This correction is obtained from the relation:

$$S_n=\frac{K'N\delta'\gamma}{T_c} \qquad (5)$$

where S_n is the signal-to-weighted nonlinear noise in the system and γ the signal-to-noise ratio measured in the white-noise test, and δ' has the same significance as δ in equation 1 and depends on the principal order of distortion. For the purposes of this discussion, $\delta'=2$, although it tends to be somewhat greater than this for second-order distortion[10] which is usually the most significant.

In the FM system the concept of peak deviation when modulating with a Gaussian spectrum is meaningless. In keeping with the previous discussion, the concept of rms value, and T_c, will be retained. For the purposes of calculation, the modulation index used (Δ/f_m of equation 1) will be derived from the peak deviation obtained with a sine-wave modulating signal having an rms value equal to that of the white noise. This peak deviation is therefore 1.4 times the rms deviation of the white noise. The per-channel deviation will therefore be $[(\Delta/(T_c)^{1/2}]$.

Optimum Utilization of Noise Bandwidth

Equation 1 may be written, after substituting for K', δ:

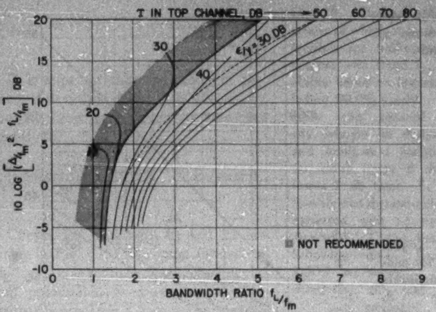

Fig. 7. The factor $[(\Delta/f_m)^2 f_l/f_m]$, in terms of bandwidth ratio and γ

$$S_t=\frac{4\epsilon f_m}{bT_c}\left[\left(\frac{\Delta}{f_m}\right)^2 f_l/f_m\right] \tag{6}$$

where $2f=B=$"truncated" bandwidth. If radian measure is used for the bracketed terms, they will be recognized as parameters in Medhurst's equations. Substituting *Nb:*

$$S_t=\frac{4\epsilon N}{T_c}\left[\left(\frac{\Delta}{f_m}\right)^2 f_l/f_m\right] \tag{7}$$

and with equations 5 and 7:

$$S_t=S_t\gamma\epsilon^{-1}\left[\left(\frac{\Delta}{f_m}\right)^2 f_l/f_m\right]^{-1} \tag{8}$$

If S_t and N are fixed, then the bracketed term of equation 7 will be fixed, so that S_n becomes a function of γ. However this is dependent on f_l/f_m. The relation between γ, f_l/f_m, and the bracketed term is shown in Fig. 7. Typical curves for S_n, derived from equations 7 and 8 and Fig. 7, are shown in Fig. 8.

A study of Fig. 7 indicates certain useful design limits. The change in direction of slope of the γ curves indicates the region in which an increase in deviation no longer produces a commensurate increase in signal-to-noise ratio; see reference 7. A smooth line has been drawn through the parameters to approximate this transition point. Values of $(\Delta/f_m)^2 f_l/f_m$ which lie above this line could not be recommended. It will be noted that this effect is less serious as γ increases, and some flexibility in the position of the nonrecommended area above $\gamma=30$ db is permissible.

A further limit is associated with the absolute value of γ. Since distortion is associated with loss of signal energy, small values of γ will be associated with noticeable level variations. Usually, small γ implies small S_t and is therefore associated with a relatively poor quality circuit, on which such variations might be acceptable. The acceptable minimum for γ is somewhat indeterminate. Taking into account the net results of this effect, the suggested minimum value of γ is 25 db, and values below 20 db could not be recommended for normal multichannel service.

In a practical design analysis, it is convenient to consider that the nonlinear noise power will be kept at some given fraction of the thermal noise power in order to examine the effect of various parameters. Accordingly,

$$S_t=yS_n \quad y<1 \tag{9}$$

It may be shown that maximum possible signal-to-total-noise ratio is obtained when the thermal and nonlinear noise powers are approximately equal (depending on the order of distortion).[8,9,13] Since nonlinear noise can be expected from several sources, the contribution of any one alone should be substantially less than the thermal noise. On the other hand, too small a value may impose unnecessarily severe restrictions on the design. It can be expected in a practical design that $0.25\geq y\geq 0.01$.

From equations 8 and 9:

$$\gamma=(\epsilon/y)\ [(\Delta/f_m)^2 f_l/f_m] \tag{10}$$

where ϵ/y is a constant for a given design decision.

The dotted curve in Fig. 7 indicates the particular relationship of equation 10 when $\epsilon/y=30$ db. Curves may be drawn in this fashion for various values of this ratio. It is found that there is a general expression for these curves, which holds very closely over the recommended area of Fig. 7. This expression is:

$$(\Delta/f_m)^2 f_l/f_m=x(f_l/f_m)^{2.5} \tag{11}$$

where x is a function of ϵ/y, and is also obtained from Fig. 7. This function is shown in Fig. 9.

The curve corresponding to the minimum permissible value of ϵ/y must not lie within the nonrecommended area of Fig. 7. This condition is satisfactorily met when $\epsilon/y=20$ db; with the previously suggested minimum for γ of 25 db, a minimum value for f_m of 5 db is obtained, yielding $f_l/f_m=1.9$. While the choice is based on a somewhat arbitrary assessment of the limits, Fig. 7 indicates that the value of 1.9 is not likely to be reduced appreciably for any reasonable re-evaluation of the limiting factors.

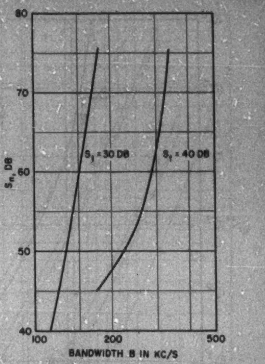

Fig. 8. S_n as function of S_t. Curves based on N=15 and curve B of Fig. 3. Effect of operating in nonrecommended region of Fig. 7 can be seen by rapid change in slope of S_t=40-db curve

When $f_l/f_m=1.9$, the minimum permissible bandwidth is obtained:

$$B=3.8\,f_m \tag{12}$$

$$B=15.2\ N\ \text{kc/second}$$

The maximum signal-to-noise ratio for this condition is obtained from equation 7 and is:

$$S_t=\frac{12.6\ \epsilon N}{T_c} \tag{13}$$

If full advantage is taken of compandors, it should be possible to reduce the ordinate of Fig. 7 to zero, yielding $(f_l/f_m)\simeq 1.5$ and giving $B=3\,f_m$. Although this is only a small reduction in bandwidth, the improvement in signal-to-noise ratio would be significant.

Values used for ϵ vary from 9 to 12 db among different authors.[45,46] As indicated by Crosby's work[47] it depends on the relative position of the channel on the base band, being greatest for the lowest channel, and Harris[48] has given a precise relation on this basis. The value determined for various multichannel systems varies very little and 10 db for the top channel is a suitable figure for design and analytical purposes. Using this, and equation 4 in equation 12:

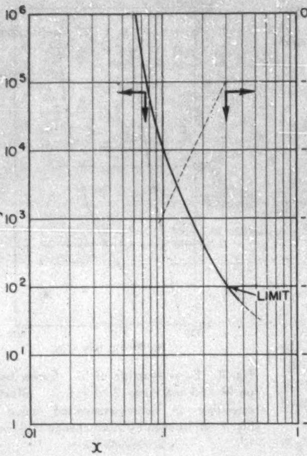

Fig. 9 (left). Relations between x, y, and ε

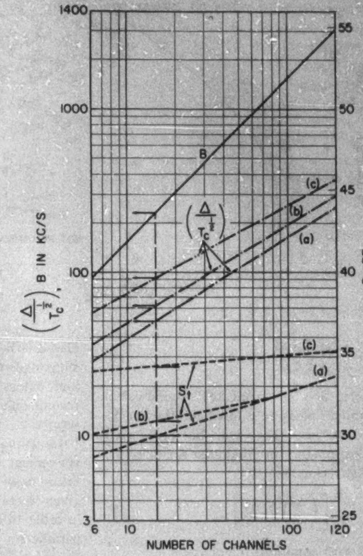

Fig. 10 (right). Relations for minimum permissible bandwidth B, which, in practical design, should be increased by at least 10% over value obtained from these curves

a—Based on curve B, Fig. 3

b—Based on Fig. 5, p=1%

c—Based on Fig. 5, p=5%

$(\Delta/T_c^{1/2})$ = per-channel deviation

$$S_t = \frac{126 N^{1-\alpha}}{X} \tag{14}$$

This indicates that compandors would be needed on minimal bandwidth systems if toll-quality circuits were required. Since ϵ/y is fixed at 20 db, then $y=0.1$ for all values of S_t. This is quite satisfactory and in keeping with stipulated limits. Also, since $f_l/f_m=1.9$, then $\Delta/f_m=1.29$.

Thus, the per-channel deviation, for maximum signal-to-noise ratio is:

$$(\Delta/T_c^{1/2}) = \frac{5.16\, N^{(1-0.5\alpha)}}{X^{0.5}} \text{ kc/second} \tag{15}$$

Equations 12, 14, and 15 are shown in Fig. 10.

It is possible to derive more general relationships for B in terms of S_t. Using equations 7 and 11:

$$S_t = \frac{4\epsilon N x}{T_c}(f_l/f_m)^{3.5} \tag{16}$$

To a close approximation, from Fig. 9,

$$y = 1.25\, x^4 \tag{17}$$

It is to be noted that if a corresponding equation is developed for the range in which $y<0.01$, even higher orders of x are indicated.

From equations 16 and 17:

$$S_t = \frac{3.78\, \epsilon^{0.75} N y^{1/4}}{T_c}(f_l/f_m)^{3.5} \tag{18}$$

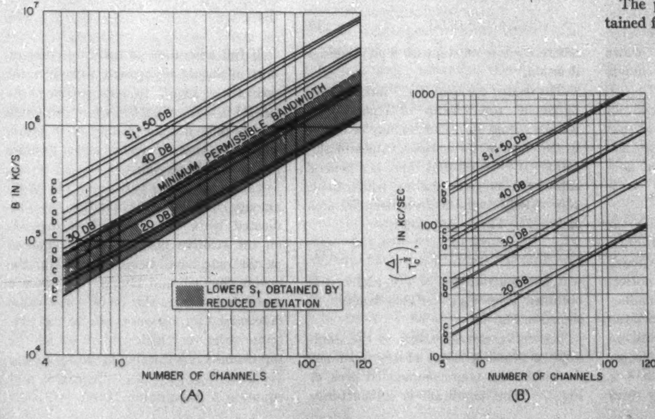
Using $\epsilon=10$ and substituting for f_l:

$$B/f_m = \frac{0.83}{y^{1/4}}\left(\frac{S_t T_c}{N}\right)^{1/3.5} \tag{19}$$

Substituting for f_m and using the values in Table I:

$$B = \frac{3.32\,(XS_t)^{1/3.5} N^{\left(\frac{\alpha+2.5}{3.5}\right)}}{y^{1/14}} \text{ kc/second} \tag{20}$$

The per-channel deviation can be obtained from equations 6 and 20 giving:



(A)

(B)

Fig. 11. Curves for equations 20 and 22. All curves based on y = 0.1

A—Relation between optimum bandwidth and signal-to-noise ratio B in kc per second

a—based on curve B, Fig. 3

b—based on Fig. 5, p=1%

c—based on Fig. 5, p=5%

B—Per-channel deviation for A

$$\frac{\Delta}{T_e^{1/2}} = 0.98(S_t^{3.5} y^{1/4} N(4.5-\alpha) X^{-1})^{1/7} \text{ kc/second} \quad (21)$$

It is apparent that the choice of per-channel deviation is but little affected by changes in y so equation 21 simplifies slightly to:

$$\frac{\Delta}{T_e^{1/2}} = 0.88(S_t^{3.5} N^{(4.5-\alpha)} X^{-1})^{1/7} \text{ kc/second} \quad (22)$$

Curves for equations 20 and 22 are given in Fig. 11. The most interesting observation is that the per-channel deviation permissible is much greater than ordinarily used, while the noise bandwidth B is narrower. This implies that much lower transmitter power is needed than presently applies. These equations and their method of derivation also indicate that by controlling bandwidth at the transmitting terminal, side-band "spread" might be reduced with consequent improvement in spectrum conservation. In view of the substantial dependence of y on B, it is suggested that minimal practical bandwidths should be at least 10% greater than obtained from equation 20 in order to provide a sensible design margin.

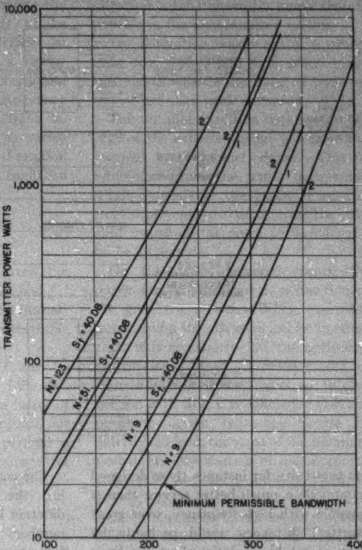


Fig. 12. Optimal transmitter power of which at least half is feasible for traffic-controlled systems with fixed f_m. Reliability based on instantaneous fading, 99.9% yearly. 1—Traffic expected for 95% of busy hour with 5% grade of service

2—Traffic expected for 99% of busy hour using curve B, Fig. 3, full trunk occupancy

Power and Reliability

It is convenient to express the required transmitter power W_t in the form:[1]

$$W_t A = P_t \quad (23)$$

where A is a factor determined by the total r-f transmission loss from transmitter output to receiver input for a given reliability and antenna configuration. The determination of A is beyond the scope of this paper but is readily obtained from established procedures.[49] Using equations 2 and 12 with $\epsilon = 10$:

$$W_t = \frac{F}{A} N \; 10^{-18.2} \text{ kw} \quad (24)$$

The general case is obtained from equation 20. It is permissible to use an average value for y since its effect is so small. Then:

$$W_t = \frac{F\,10^{-17.58}}{A}(XS_t)^{1/3.5} N^{\left(\frac{\alpha+2.5}{3.5}\right)} \text{ kw} \quad (25)$$

By choosing definite equipment configuration, A can be expressed in terms of distance over a smooth spherical earth, and the required power can then be expressed for various performance criteria. This has been shown in Fig. 12.

It has already been suggested that there is need for a 100-watt system.[1] This is substantiated by Fig. 12, and it would appear that 100-watt and 250-watt equipment should be added to the present range. It should be possible to prove in systems in this category in many parts of the world at present in need of reliable circuits.

Equation 25 provides an interesting index of system efficiency. Since W_t is a figure derived for an optimized system efficiency can be expressed in terms of W_t by the relation:

$$E_f = \frac{W_t}{\text{Transmitter power called for}}$$

The absolute value for S_t is still open to considerable discussion,[50] although acceptable values for commercial toll service have been discussed.[51] Recently it has been suggested that for the toll service, S_t should be greater than 40 db for 99% of the busy hour. A value of 35 db for 95% (radio equipment alone) is suggested for services such as private industry and utilities.[44] The curves of Fig. 12 show these two classes of service, on the basis of trunk occupancy established for 5% grade of service, as shown in Fig. 5.

The question of the figure which should be used for propagation reliability, in the design of scatter circuits, is not yet resolved, though 99.9% seems to be fairly well accepted. A considerable amount of information has been published relating to the so-called long-term and short-term effects.[52] A study of fading rates[60] indicates that, in general, the short-term effect is slower than the integration time of the ear, so that one would expect the subjective effect to be determined by the instantaneous level of noise. The instantaneous fading distribution requires the solution of a bivariate probability integral, and curves on this basis have been derived.[4] Investigation of these data leaves little doubt as to the upper design limit. The slope of these distributions increases sharply about 99.95% reliability and implies that a disproportionate increase in r-f power is required for better performance. A practical system-design limit then, is 99.9% which corresponds to an "outage" of about 8 hours per year. Fig. 12, which is based on Norton's data[49] makes use of this limit. It is doubtful if much is to be gained by reducing reliability below this figure when the period involved is taken into account. Due to the long cycle in the fading phenomena, the reliability is expressed on an annual basis. A change from 99.9% to 99% for instance, over an average path length and with a quadruple diversity system, represents a possible decrease of no more than about 6 db in power for a loss of 3 days outage, a figure which would be quite unacceptable for good quality circuits. However, low-

grade circuits, for instance those designed to provide a much better service than is possible with high frequency, over great (scatter) distances would probably be very acceptable if designed on the basis of 98%; i.e., about 1 week total outage time per year.

It is to be borne in mind that all these figures refer only to the disappearance of signal below threshold. Most circuits will "hold" down to about $\epsilon=2$, and since the design is predicted on $\epsilon=10$, the actual "lost" circuit time, even for systems designed for 98%, is likely to be less than 4 hours total.

Economic Index

Economic evaluation of the scatter circuit requires some knowledge of the price which must be paid for a given performance criterion. An indication both of capital cost and technical and logistic difficulty is obtained from a knowledge of the required power. One method which appears to be worth following is to use equations 25 and 4. It is to be recalled that W_t in equation 25 represents the minimum permissible power for specified system parameters and equipment configurations. Then:

$$\frac{(T_e\, S_t)^{1/1.8}}{N\,A}=W_t\left(\frac{y^{1/16}}{F\,10^{-15.9}}\right) \qquad (26)$$

The factors T_e, S_t, N, and A, are all related to performance criteria, while the bracketed quantity on the right-hand side is a constant. Thus the left-hand side is a measure of the technical and economic feasibility and may be referred to as an "economic index."

The concept is quite useful in comparing the proportionate economics of different links in a network when various numbers of channels and grades of performance are involved.

In addition, since A is determined by propagation reliability, the effect of changing the limit on this factor can be assessed.

Utilization of Optimal Condition

Certain techniques for the reduction of the power required for scatter circuits can be examined with the aid of the previous text. One manner of using fully a small base band is shown in Fig. 13.

Controlled Carrier Operation

A method of adjusting transmitter power by means of a pilot signal over a reciprocal path has been described.[4] The equations developed in the present paper indicate only that possibly the maximum power required for a given service may be less than that presently used. There is no indication that improvement in this technique can be effected by the concepts developed here.

Control by Noise

In equations such as 20, S_t can be replaced with $S_t'r$, where S_t' is the signal-to-noise ratio obtained when fading is taken into account, and r is the ratio of the received r-f signal during fading to threshold signal. When r is $>>1$, then $S_t'>>S_t$, and there is the possibility that the bandwidth might be reduced slightly so that the total noise (thermal plus nonlinear) remains constant.

The per-channel and resultant rms deviation are based on specific values of the system parameters, as in equation 6. The resultant nonlinear noise is then established from Fig. 7. If the design is optimized, then, as already indicated, the limiting conditions indicated by Fig. 2 are observed.

Since, from equation 10:

$$\epsilon/y=(\Delta/f_m)^2\,(f_l/f_m)$$

then reduction of bandwidth (f_l) must be accomplished by an increase in y. Since the optimized design is already based on maximum tolerable y, the method is open to serious question. Even more serious is the fact that the nonlinear noise, in the range of interest, varies with the fourteenth power of bandwidth, which can be seen both from equation 20 and from Fig. 1. Consequently, either the available control must be too small to be of use, or else y must be much too small in the initial design. It would seem, therefore, that this technique does not have anything to offer the optimized system, though it may be useful in "over-engineered" designs.

Control by R-F Signal

Since output thermal noise decreases with strong r-f signals, there is the possibility of using the received carrier to reduce bandwidth during these periods. However, the same remarks apply as for the previous paragraphs. In this case, since there is no correlation between r-f signal and traffic, any method of control is fundamentally unsound. Variations in r-f signal are most effectively utilized by means of the controlled carrier techniques mentioned earlier.

Control by Traffic

The long-term mean power of the multichannel signal is dependent on the number of simultaneously busy channels and, therefore, on traffic load. This exhibits a considerable diurnal variation[44] which may be used to advantage.

Fixed f_m

The design value of S_t is determined by affixing suitable values to the various factors of equation 6. In practice of course, Δ is a variable, determined by actual traffic. Let Δ' represent this variable in the operative system.

Equation 11 may then be rewritten in the following way:

$$\left(\frac{\Delta'}{f_m}\right)^2=(B/2f_m)^{2.5} \tag{27}$$

The variation expected in $(\Delta')^2$ can be obtained from mean power distribution curves of which Figs. 3 and 5 are an example. This variation depends on the number of channels and the residual level for spurious tones. It is quite large for systems of less than 60 channels designed on a 1% of the busy-hour basis. A "ball park" figure is 10 db, which permits B to be reduced by the factor 2.5. The net power saving is obtained by plotting the power transmitted as a function of the diurnal variation of B, based on the variation of (Δ'). Performing this for a typical system indicates that total daily transmitted power requirement is reduced to about one half of the uncontrolled value.

Of more interest, perhaps, is the improvement in reliability which can be obtained. Diurnal fading is small, so that reduction of outage obtained by reducing the bandwidth represents a commensurate improvement in reliability. Reference to traffic volumes[44] indicates that full bandwidth would be required for less than 12 hours. On this basis, the system could be designed for approximately twice the failure rate, i.e., 99.8%, with expectation that performance would be equal to that of a 99.9% uncontrolled system. This represents a permissible reduction of about 3 db in actual transmitter power for typical scatter angles.

Devices for this particular function are not yet available. They should have a fast (5 minutes) time constant to open the bandwidth and a slow one (at least 1 hour) to close it. It is of interest to observe that, if units are used at transmitter and receiver as suggested above, synchronism is not necessary.

Reduction in spurious signal (baseband) power (i.e., carrier leaks) does not achieve a great deal. The minimum permissible value for f_t/f_m is probably 1.5, when Δ' is small. With an optimized system, and for typical values of S_t, the range of bandwidth variation permissible is relatively small. Where a large range appears to be feasible, the implication is that the system is not optimized in the first place.

Controlled Channel Selection

The previous study does not take advantage of reduced trunk occupancy as traffic flow decreases. This permits the number of available channels to be reduced in accordance with traffic demand. In turn this implies a device which selects the number and position of channels, so that the lower frequency channels are utilized when the traffic demand is small. Therefore, f_m is varied in accordance with traffic. Equation 27 can be rewritten for this condition giving:

$$B=\left[\frac{2(\Delta')^2(f_m')^{1.5}}{x}\right]^{1/2.5} \tag{28}$$

As before, Δ' is determined from the diurnal variation of mean power and f_m' is a variable obtained from the (diurnal) circuit demand in accordance with traffic flow.

This concept indicates that B may be reduced even further than indicated under "Fixed f_m." A reduction factor of 10–20, depending on design, appears not unreasonable. This in turn permits a still greater reduction in transmitter power or an effective increase in propagation reliability.

LOAD MATCHING

The possibility of using units which provide a function similar to that of line concentrators has been mentioned.[1] It is possible to consider such a device in which specific entrance circuits are always routed to specific output circuits. This could increase effective channel capacity provided the minimum traffic flow did not exceed the limit for the "concentrating" circuits. This may be thought of as matching the load offered by the connected lines to the permitted capacity of the channels. Increased private-line facility would be possible, and this may have considerable advantage in many instances where there is a limited channel capacity and circuit rental is feasible. This technique also lends itself to a minimum first-cost system, with expansion predicted by demonstrated utilization. Although this concept does not seem to have yet been exploited, it is in no way restricted by the procedures of the present paper.

Conclusions

The nonlinear noise introduced by truncating the bandwidth may be used as a limiting factor in the analysis of the optimized multichannel system. The signal-to-thermal-noise ratio may then be expressed as a function of traffic volume and noise bandwidth. This leads to a minimal bandwidth criterion which permits substantially greater signal-to-noise ratio and lower transmitter power than is possible in the nonoptimized system.

The derivation makes use of a white-noise test signal, and it is pointed out that this should be expressed in terms of rms rather than peak deviation.

The optimal condition requires knowledge of the expected mean power of the complex multichannel signal. This is established from the trunk occupancy, which depends on the grade of service, and the percentage of time during the busy hour for which the given performance is to be expected.

On this basis, required transmitter power can be expressed as a function of the grade of service. When expressed in terms of a smooth spherical earth reference, it is concluded that the optimized system lends itself to development of 100- and 250-watt installations. In connection with this, it is concluded that the optimum design reliability should be determined from the slope of the bivariate probability distribution of instantaneous fading, leading to a limiting value of 99.9%, expressed on a yearly basis. This concept also leads to the use of a system efficiency factor which may be expressed in terms of "optimized" transmitter power. In addition, an economic index can be established which gives a measure of the economic and technical feasibility of the system in terms of the principal performance criteria. Various methods of reducing transmitter power by establishing variable parameters are received on the basis of the optimal design. A new technique is suggested in which traffic volume controls the noise bandwidth, and it is believed that the transmitter power can be reduced substantially by this procedure.

One general conclusion may be drawn from a study of the data presented here: it would appear that an unnecessarily high price still must be paid for the nonavailability of equipment tailored to the optimal requirements of the system. On the other hand, the optimized system, together with the capabilities of traffic controlled bandwidth and the use of load-matching devices to increase potential revenue, should permit commercial breakthrough for the tropospheric-scatter technique.

Tubes or Transistors: A Realistic Assessment

R. E. MOE
NONMEMBER AIEE

THE POPULAR NOTION that transistors will undoubtedly replace vacuum tubes in the near future has been widely publicized partly because of the natural enthusiasm and optimism of the many new firms starting into the business of designing and manufacturing semiconductor devices. There is, of course, no doubt that transistors will take over some of the application areas previously served by tubes, and that there will be some areas where either tubes or transistors will serve equally well, but there are many fields where tubes are and will continue to be superior. The advantages and disadvantages of each device, under the wide variety of operating conditions and circuit requirements, should govern the choice for a particular application, and the following discussion is intended to bring out those which are pertinent to such an analysis.

The purpose of this discussion is to present briefly a few extracts from the available data, and list references giving more complete information, to allow a realistic assessment of performance and reliability factors of interest to the designer of electronic equipment. Broadly, these break down into two groups: entertainment, on the one hand, including radio and TV (television), and industrial and military on the other. In the first case, cost will continue to be the governing factor dictating the use of tubes except in the personal portable field, and the output stages of car radios. In the industrial and military fields, where cost is less of a factor, the relative performance and reliability factors must be examined critically, in order to resolve this tendency to play up and perhaps oversell the glamour of this newcomer to the field of electronic devices.

Accordingly, the following points have been chosen as prime factors in this analysis to guide the designer's choice, depending, of course, on his equipment specification requirements:

1. Power input (efficiency)
2. Ambient or hot spot temperature
3. Upper frequency limit
4. Noise figure
5. High-voltage requirement
6. High power output requirement
7. Spread of characteristics and tolerances
8. Combination and multiple units
9. Nuclear radiation
10. Reliability
11. Physical size and weight

The following paragraphs give the major pros and cons for each of these points, and a few pertinent quotations and references. More detailed information is available from the references.

Power Requirements

If available power input is limited, and high power output is not a prime requirement, transistors are the logical choice. For example, in hearing aids, personal portable radios, or even space satellites, which are supplied by battery power, the low drain and high efficiency of these devices are the prime factors. On the other hand, if the equipment is to be a-c operated, these are of little consequence, and other factors will govern; these may well favor tubes over transistors. For example, for fixed station receivers and transmitters, or multiple PA (public address) systems, tubes should be simpler and more economical.

Ambient Temperature

Because of the inherent nature of semiconductors, their characteristics are far more sensitive to changes in temperature than are tubes, so that germanium and to a lesser extent silicon units show considerable variation in parameters with changes in temperature, and reach a limiting capability around 100 C (degrees centigrade) and 200 C junction temperature, respectively. Tubes, on the other hand, can operate well above 200 C bulb temperature in the glass types, and over 400 C in ceramic, with practically no change in characteristics. Thus, the use of transistors under varying ambient conditions requires a great deal of attention to temperature compensation elements and feedback circuits where in most cases these precautions are unnecessary when using tubes.[1] In fact, the serious degradation in performance of transistors with increasing temperature may well make their use uneconomical because of the low gain per stage, or limited output available at the high end of the operating temperature range, well before the advertised temperature limit is reached.

Another illustration is the necessity for precautionary measures when soldering transistor leads, to prevent overheating the junction and damaging it permanently.

To quote Captain W. I. Bull: "Presently the temperature requirements for components range from −65 C to +200 C. Guided missile and Mach 2-plus manned aircraft may require components capable of providing reliable operation in ambients of 250 C to over 500 C. The goal for the development of an entire line of high-temperature, 500 C component parts is 1965. In view of the temperature limitations of germanium and silicon transistors, new semiconductor materials will have to be investigated [and this means developed, perfected, and reduced to practical manufacture—R.E.M.], and device development programs must be initiated on the most promising materials if the military's high-temperature part objective is to be met. Of course, ceramic electron tubes, to mention a dirty word, will be available in the event high-temperature transistors have not been developed."[2]

Frequency

At the present time, and with presently available constructions and techniques, transistors become increasingly difficult and expensive to build for operation above 500 kc. Refinements, of course, are being introduced, but there is a fundamental conflict between barrier thickness, area, and carrier mobility, versus capacitance, gain, and power handling ability (heat dissipation) with increasing frequency. Tubes, of course, have these problems to some extent owing to transit-time effects and interelectrode capacitance loading, but to a much smaller extent. Even the most optimistic predictions by transistor manufacturers provide little hope that they will take over present vhf (very-high-frequency) and uhf (ultrahigh-frequency) tube applications, from 100 to 1,000 mc (megacycles), in the forseeable future, unless other considerations than cost and gain govern the choice. As an example, some mobile communications equipment are now being transistorized. There are

Paper 60-73, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted June 5, 1959; made available for printing December 8, 1959.

R. E. Moe is with the General Electric Company, Owensboro, Ky.

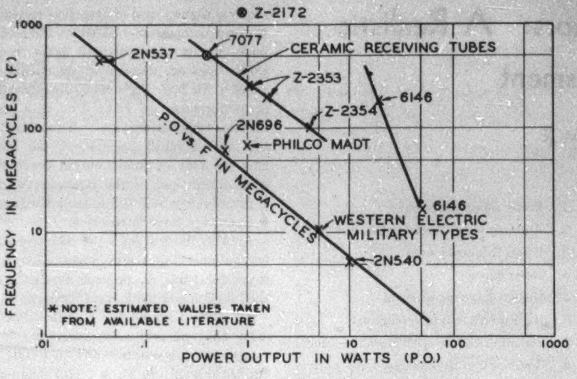

Fig. 1. Tube and transistor output versus frequency

very few transistor types registered for this kind of operation, and none with approved military specifications; see Fig. 1.

Also, several set manufacturers have produced experimental samples of transistorized portable TV receivers, but they will admit that it was necessary to exercise a great deal of selection to find the right kind of transistor to perform several of the more critical functions; this would certainly not be practical at this time.

Noise

Although relatively free of microphonics and variable leakage path noise contributions, transistors have an inherently higher random noise output than tubes, when considered on a noise power basis ($KT\Delta f$). Thus transistors may well be chosen for low level stages of audio preamplifiers to eliminate microphonics and hum, but be unsuitable for wide-band i-f (intermediate-frequency) or r-f (radio-frequency) amplifiers in radar or television, where a noise figure approaching the theoretical minimum is a prime requirement. The ceramic *7077* is appreciably better than the best transistor for ultra-low-frequency flicker noise; see Fig. 2.

High Voltage

Because of the inherently better insulation afforded by vacuum devices, it is expected that tubes for high-voltage applications, both diodes and multi-element, will be simpler, more economical, and more reliable than semiconductors for some time to come. Such things as high-voltage sweep tubes, rectifiers, and dampers for supplying 20 kv to television picture tubes or radar indicator scopes will be difficult to displace, unless some more efficient methods are found which can tolerate the lower breakdown voltage limitations of semiconductors.

Another aspect of this same weakness is found in the inability of transistors to withstand power supply transients as experienced in aircraft generator systems, which have been found to vary between −25 and +80 volts on a 28-volt d-c system,[3] or diode breakdown when using a continuity meter to check out a circuit, inadvertently applying excess reverse voltage to the semiconducting element. In fact, the elaborate protective devices necessary in the former case make such applications of dubious value.

To quote N. W. Caquelin: "In summary it can be said that transistors and other semiconductor devices can be successfully used in environments exhibiting the hazard of extreme positive and negative voltage transients *if* proper design techniques are used. It must be recognized that protection of equipment from transients, especially that using power transistors, represents some sacrifice in required space (size or parts density), efficiency (power dissipation and box temperature), equipment cost (cost of added components and cooling system), and to a lesser degree, weight. As the state of the art in the use of transistors is still relatively young, more desirable protection systems or higher voltage transistors may be developed in the future. Until then, we must either eliminate the transient from the primary power source or else accept the additional components of the protective systems. The reduction of primary power transients would undoubtedly improve the reliability of other components in airborne equipments."[3]

High Power

Because of the elaborate measures necessary to cool the junction of a power transistor, and the relatively expensive components necessary to filter and regulate a low-voltage high-current supply, vacuum tube power amplifiers will probably continue to have an economic advantage. A modifying factor here, however, is introduced by the possibility of eliminating the output transformer in the case of low-impedance loads, such as the voice coil of a loud-speaker, allowing this saving to balance out the difference noted above. The choice then rests on a companion characteristic, linearity, which is easier to achieve with tubes than with transistors.

In addition to the fact that linear characteristics are easier to achieve with tubes, transistors have the added difficulty of variable input and output impedance from small to large signals, making driving and matching difficult, and adding to the distortion.

Spread and Control of Characteristics

At present, the properties of semiconductors are more difficult to control in production than those of tubes, resulting in a much wider spread of product characteristics. In most cases, this spread is too wide for any one intended application, requiring the selection and labeling of several different portions of the over-all product falling into various groupings for gain, breakdown voltage, etc. This has produced a tremendous multiplicity of type numbers (over 700, not counting experimental), with various combinations of these properties, and, depending on the yield in each area, widely varying costs. Some of this variation will undoubtedly be reduced by further manufacturing refinements, but some of it may be inherent in the nature of the device, because of the sensitivity of the semiconducting material to extremely minute amounts of contamination. As a result, where spread of characteristics or close tolerances, or the ability to turn out a uniform product over an extended period is a prime consideration, tubes should continue to be superior.

For example, the custom is to release a quantity of type numbers for transistors made with a given physical arrangement, and test them to identical limits and characteristics, except for one critical parameter. In other words, it is impossible to control this latter characteristic, so it must be accomplished by selection. For instance, the following groups of types are identical except for alpha cutoff frequency!

2N444—0.5 mc
2N445—2.0 mc
2N446—5.0 mc
2N447—9.0 mc
2N519—0.5 mc
2N520—3.0 mc
2N521—8.0 mc
2N522—15.0 mc
2N523—21.0 mc

This is obviously a serious obstacle to standardization.

For further evidence, the following news item is of interest: "Transistor Preferred Circuits. National Bureau of Standards program to develop preferred transistor circuits, similar to preferred tube circuits developed earlier, has run into a snag because of extremely wide variability of characteristics in transistors. Whereas transconductance of a group of Mil-standard tubes normally varies only ±10%, corresponding important characteristics of transistors, such as short-circuit current gain, may vary 200% or more."[4]

Also, examination of the few military specifications available for transistors will reveal that they control only a very few characteristics, and these to very much looser AQL (Acceptable Quality Level) values than the corresponding tube characteristics. By contrast, military specifications for tubes now represent an extremely good guarantee of reliability over a 1,000-hour period.

The really basic consideration here is admirably outlined and explained in reference 5. While the entire article is well worth reading, the main point is that in intrinsic devices, the various factors such as frequency, power density, coherence of electron flow, and some elements of circuitry are functions of submicroscopic or ionic arrangements, and so interrelated as to be essentially uncontrollable. On the other hand, tube structures separate the beam forming, power producing, and frequency control functions far better, and give far more flexibility to the circuit designer.

Multiple-Unit Devices

As a corrolary to the above difference in product control and variability, it is easy to see that tubes will continue to have an economic advantage in multifunction units, such as twin triodes or triode-pentodes, where such combinations in transistors would not prove practical. For example, if the yield of a particular tube element, when tested to the allowable customer limits, were 90%, the yield of a 2-unit tube with random variations in each element would be 0.9×0.9, or 81%. Contrast this with present transistor yields in any one spread of characteristic limits of around 25%, and a twin-unit yield would become 0.25×0.25, or about 6%.

Nuclear Radiation

A survey of the available unclassified data shows transistors to be definitely vulnerable to high-energy gamma radiation, which does not affect tubes to any measurable degree. For thermal and fast neutrons, the various reports indicate that for equal dosage, glass tubes will last about 100 times as long, and ceramic tubes about 1,000 times as long as a transistor. To quote a report of the American Society for Testing Materials:

> Thermal neutrons are not a major contributing factor to the deterioration of semiconductor devices.
>
> For the integrated doses used, gamma radiation causes surface damage which results in changes in leakage currents. Partial recovery may occur when the device is removed from the radiation field.
>
> Fast neutrons appear to cause bulk changes in materials.
>
> In reactor irradiations, silicon rectifying devices which deteriorate will probably fail in the forward direction with increases in forward resistance and break-point voltage. For the integrated doses used, germanium devices generally suffer major damage in the reverse direction only.
>
> For most applications, silicon diodes and rectifiers tested could probably be used to $10^{13}\ nv_0t$, and the silicon and germanium transistors irradiated could probably withstand $5\times10^{11}\ nv_0t$ under the conditions of test. These limits are considerably below the limits that would be caused if radiation damage on the bulk materials above is considered. The basic processes of semiconductor devices are probably disturbed by the presence of the radiation field, causing the radiation resistance of the devices tested to be considerably lower than would be expected by considering the basic properties of the semiconductor materials.[6]

An examination of another voluminous study, an Admiral Report, reveals this same ratio. "The *6L6WGB* beam power, the *5639* subminiature video amplifier, the *5840* subminiature pentode, the *5670* miniature twin tridoe, and the *5876* subminiature uhf survived the irradiation, but had control grid currents in excess of the maximum specification... The *6112* subminiature twin triode, and the *5751* miniature triode all survived the CP-5 experiment."[7] The interesting point, however, is that the transistor tolerance limit is about equal to the human tolerance limit, and that tubes are relatively unaffected at this dosage. This means that while it may be possible to evacuate personnel and protect them from an atomic explosion, it would be highly impractical to bury or shelter all electronic equipment, and if the equipment is expected to survive in operating condition, it had better use tubes.

It is interesting to note that the U.S. Army Signal Corps has become concerned about this and other tactical aspects of the use of transistors in the design of military gear, including missiles, and is publishing a comparison of its own, entitled "A Report of the Current Status and Future Trends in Electronic Tube and Transistor Electronics."

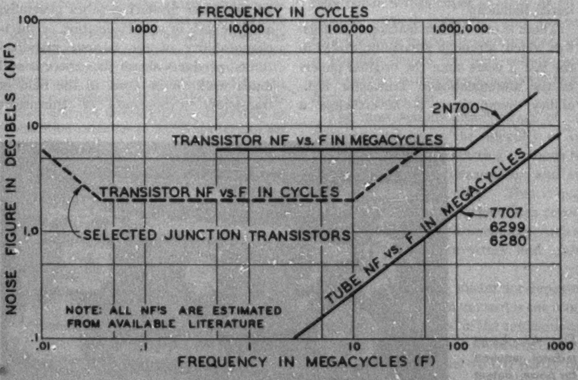

Fig. 2. Tube and transistor noise performance

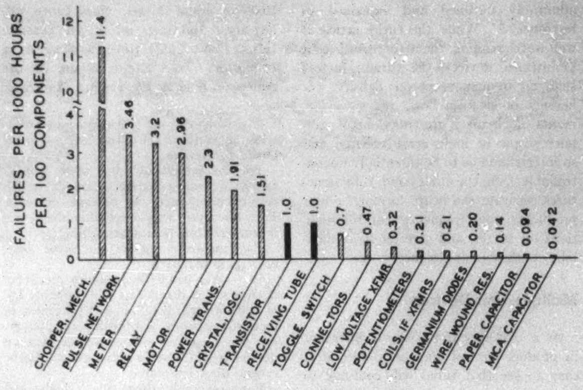

Fig. 3. Component failure rates

Additional material may be found in references 8 and 9.

Reliability

In terms of survival under equivalent operating conditions, there is very little information comparing tubes and transistors directly, except for some studies by Bell Laboratories on some of their own early types. These indicate comparable figures for their best tubes and best transistors, under practically ideal operating conditions of around 0.03% per 1,000 hours. Other less accurate figures in military gear have given about 0.1% per 1,000 hours for both.

As a practical matter, voluminous specifications, both manufacturers' and military, are available which guarantee a "floor" under allowable failure rates of tubes, and a very good probability that most lots will give better than 99% survival at 1,000 hours under maximum rated conditions, whereas such survival specifications and documented data are completely lacking for transistors. This is not to say that transistors do not have a very high potential reliability, possibly somewhat better than that of tubes, but that prediction, control, and statistical evidence of consistent survival under comparable environmental conditions are not yet available, and will probably take 10 years to accumulate. This will render impossible any calculations of system reliability or the value of such provisions as multiple channel redundancy.

A typical list of failure rates of components in a number of military equipments is shown in Fig. 3, where both tubes and transistors have been used in various portions of the equipment, as well as germanium and silicon diodes. It will be noted that in this particular set of data, the tubes and transistors came out about even at 1.0% per thousand hours. It should be noted, however, that in general it takes 3 or 4 times as many transistors to perform the same function as currently available military tube types, because of their lower gain-bandwidth factor and single-unit limitations, so that it would appear that the over-all equipment reliability using tubes is still about 3 to 4 times as good.

In fact, one example of comparable designs of a servo-amplifier required only 8 tubes in the original prototype, but wound up with 40 transistors in the redesigned version! Obviously, it will take a considerable improvement in the reliability of transistors to make up for this initial handicap.

There is one further feature of transistors which, although greatly improved in the last 2 years since the original papers in the aforementioned Transistor Reliability Symposium, is nevertheless a serious and disturbing factor, and that is simply shelf life. There is, of course, the effect of storage at high temperatures, which shows definite deterioration at 85 C for germanium,[10] and also the effect of small amounts of contaminants inside the sealed enclosure affecting the surface condition of the germanium crystal.[11] As sealing, exhaust, and gettering techniques approach that of vacuum tubes, this effect will undoubtedly be reduced, but the inherently greater sensitivity of the resistivity of the semiconducting surface to extremely minute amounts of contaminants is a problem which is not, fortunately, found in tubes.

Physical Size and Weight

While transistors obviously have the advantage over tubes on both of these counts, except for ceramic tubes, the unit itself is not the whole story. In the case of power transistors the heat sink and radiator must be many times the size of the transistor, and may well be larger than a tube of the same output rating, since the junction temperature must be kept much lower than that of the tube envelope. Similarly, in large installations involving many thousand units, the air conditioning may have to be just as large for transistors, in spite of their lower power consumption, since the allowable rise can not be as great. Heat flow and thermal calculations are fairly long and involved, so it is impossible to generalize, but this hidden factor must be borne in mind when considering tubes versus transistors from this standpoint; see Fig. 4.

Conclusions

There is ample evidence that transistors are far from displacing tubes generally, and the lack of standardization or interchangeability of the various manufacturers' products shows that there is still much work to be done in the field of transistors. Proponents of transistors

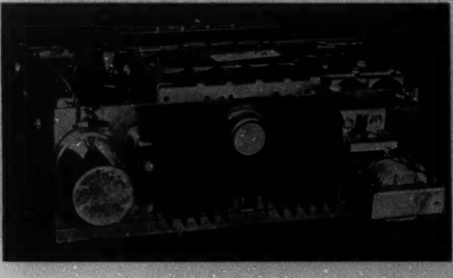

Fig. 4. Large radiator required for power output transistor

Vol
Pt.
196

make many claims for the future, but, except for some of the obvious and inherent differences in "modus operandi," tubes can claim the same opportunities for future improvements in costs via new designs and automation, and superior performance via new techniques now under development.

In the end, the equipment designer must base his decisions on the available evidence, and say, "Show me your data."

The Empretron, a Mercury Pool Arc Tube Allowing Operation at Repetition Rates in the Kilocycle Range

K. G. HERNQVIST
NONMEMBER AIEE

F. H. NORMAN
NONMEMBER AIEE

Synopsis: The Empretron is a new mercury pool arc tube for switching applications. The arc between the mercury pool cathode and the main anode is initiated by a vacuum spark. The spark discharge occurs between two continuously replenishable electrodes, one being an electrode partly immersed in the mercury pool and the other, the starter electrode, a mercury reservoir supported above the mercury pool. Starting is accomplished by applying a high-voltage pulse to the starter electrode. The resulting spark discharge develops into an arc between the cathode and the main anode. The minimum energy necessary for arc initiation, 10^{-3} to 10^{-2} joules per start, is determined by the stray capacitance between the starter electrode and the mercury pool. Operation at repetition rates up to 5,000 cps (cycles per second) has been demonstrated. This is about one order of magnitude higher than the upper limit of 400 cps for the conventional ignitron.

Because of a materials problem resulting from the requirement that the outside of the starter electrode remain unwetted by mercury, the present tube design is limited to operation at relatively low duty cycles for the main arc. The main use of this device is therefore in pulse modulator service.

IN CERTAIN respects the mercury pool arc comes closer to the ideal of an electronically controlled switch than any other known device. Its resistance in the nonconductive state is almost infinite, withstanding voltages of hundreds of kilovolts. The anode voltage in the conductive state is very low; it can be measured in tens of volts. The mercury pool cathode is very rugged, allowing passage of thousands of amperes current. Transition from the conductive to the nonconductive state[1,2] may occur within times as short as 10^{-6} seconds. These properties and its long tube life have made the mercury pool arc a popular device for high-voltage and high-current switching applications, rectifiers, inverters, etc.

The most serious disadvantage of the mercury pool arc is the difficulty of arc initiation. Reliable starting methods require large power consumption and expensive starting circuitry. This is particularly objectionable where high repetition rates of starting are required, such as in high-frequency inverters and pulse modulators.

The most reliable starter for repeated starting that has been devised is the semiconductor starter used in the conventional ignitron tube.[3,4] Here a current is sent through a semiconductive rod partly immersed in the mercury pool. This starter requires a starting energy of about 1 joule per start and appears to be limited to repetition rates not exceeding about 400 cps.

The electrostatic-type starter[5] is considerably less power consuming. Here the starter electrode is electrically isolated from the mercury pool by a dielectric material such as glass or ceramic. A high positive voltage pulse is applied to the starter electrode for arc initiation. This device has not been of any commercial importance because of its limited life. Destruction of the dielectric material usually occurs after less than 100 hours of operation.

It is the object of this paper to describe an electrostatic starter which preserves the property of low power consumption for starting yet offers possibilities of reliability and long life. Here the arc discharge is initiated by a vacuum spark. The spark discharge occurs between two continuously replenishable electrodes, one being the mercury pool cathode and the other a mercury reservoir supported above the mercury pool. The name Empretron will be used for this device.

Description of the Principle of Operation and the Tube

Except for the case of glow-to-arc transitions it appears that the first step in the process of mercury pool arc initiation must be field electron emission from

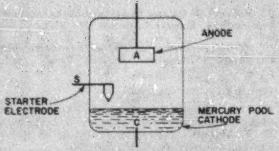

Fig. 1. Schematic diagram of tube for vacuum spark initiation of a mercury pool arc

the cathode. This is usually assumed to be true for presently known arc starting methods.[4,5] It is also corroborated by studies of the maintenance of the mercury pool arc.[6,7]

Consider a 3-element tube as shown in Fig. 1. Near the mercury pool cathode *C* is placed the starter electrode *S*. The anode *A* is placed farther away. Before starting, the space between *S*, *A*, and *C* is occupied only by neutral mercury atoms, the vapor pressure being determined by the temperature of the mercury pool and the tube walls. This pressure is about 10^{-3} mm (millimeters) of Hg at room temperature. After the arc has been established a vapor pressure of several hundred mm of Hg has been built up in the immediate vicinity of the cathode. The pressure falls off very rapidly away from the cathode, being about 10 mm of Hg at 10^{-3} cm (centimeters) from the cathode and about 10^{-3} mm of Hg at the tube walls. Furthermore a very dense plasma has been built up close to the cathode surface, a plasma capable of supplying sufficient positive space charge at the cathode surface to support electric fields of the order of 10^6 volts per cm or higher. It is the purpose of the arc starting mechanism to achieve the transition between these two states. In the Empretron, part of the energy necessary for this process is supplied by the starter circuitry and the remainder is delivered by the anode supply. The starter only supplies the seed for an arc cathode spot, the seed being a vacuum spark between *S* and *C*, only developed to the point where the anode can take over and build up the discharge to a normal arc.

The process of establishing a vacuum spark is believed to proceed as follows.[8] Consider a positive high voltage suddenly applied between *S* and *C*. The resulting high field will eventually result in field electron emission from *C*. Since the mean free path for these electrons is much longer than the separation between *S* and *C*, the electrons emitted will be accelerated and impinge on the starter electrode. Since the field emission current density is extremely high the energy input per unit area to *S* is also high, resulting in immediate vaporization of electrode material at *S*. Thus a high vapor pressure will build up around *S*, the vapor front proceeding toward *C*. Consequently new electrons emitted from *C* will encounter ionizing collisions between *C* and *S*. The ions thus formed will proceed toward the cathode and contribute to the electric field strength at the cathode. This process will now rapidly proceed to the point where ions, generated between *S* and *C* both by direct ionization and by secondary processes,[7,9] alone are capable of maintaining the high electric field at the cathode surface. Meanwhile the vapor pressure in the vicinity of the cathode surface starts building up because of the ion impact. Thus a point is eventually reached when the electric field between *C* and *A* starts to become important and a current flow to the anode builds up the main arc.

It is evident that to utilize this process for reliable arc starting the following conditions must be satisfied: 1. The spacing between *S* and *C* must be small, yet accurate and not changing in time. 2. The starter electrode must consist of an easily vaporizable material, to give a high rate of vaporization. 3. The starter electrode, as well as *C*, must consist of a continuously replenishable material. The Empretron incorporates a mercury pool arc starter built on these principles.

The tube is shown in Figs. 2 and 3. Fig. 4 shows the details of the starter assembly. The starter electrode is supported immediately above a pointed nickel electrode which is partly immersed in the mercury pool. The nickel is wet with mercury, thus keeping the point covered at all times by a film of mercury. The starter electrode itself consists of a mercury reservoir which, through the wetted capillary tubing I, communicates with the lower pointed portion of the starter electrode. This provides a mercury meniscus at the lower part of the starter electrode at all times. The mercury is prevented from dripping out of the reservoir by the surface tension at the meniscus, provided that *T* has a sufficiently small diameter. Also the outside of the starter electrode is prevented from being wet by mercury by the wetting shield or by special surface treatment of

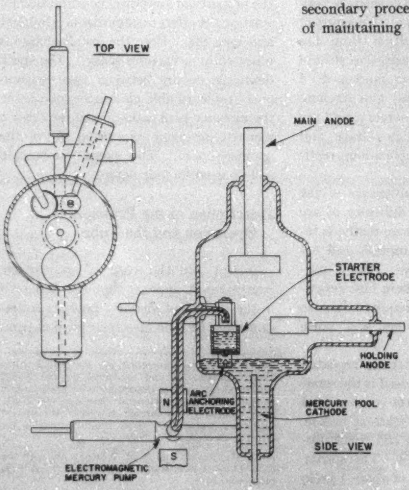

Fig. 2 (left). Empretron, using electromagnetic pump

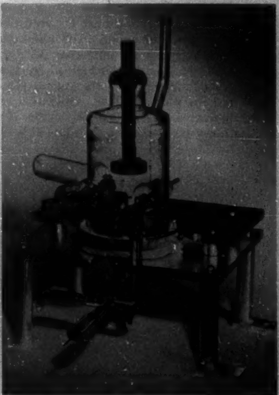

Fig. 3 (right). Empretron

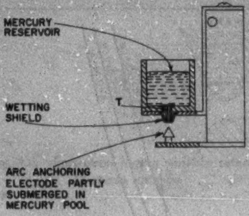

Fig. 4. Starter assembly

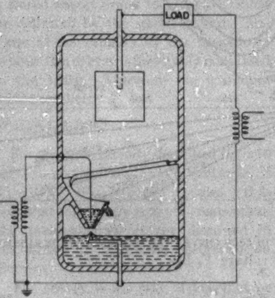

Fig. 5. Empreton using condensed mercury for reservoir

the starter electrode. The mercury in the reservoir is constantly replenished either by allowing mercury condensed on the walls to flow into the reservoir as shown in Fig. 5 or by means of an electromagnetic pump as shown in Fig. 2. In the first method, Fig. 5, the condensed mercury is pulled down by gravity and collected by the gutter slightly tilted toward the starter. In the second method, Fig. 2, mercury is pumped up from the mercury pool.

Operation of the tube consists of applying a high positive voltage to S. After a time which is determined by the field strength between S and C a vacuum spark breakdown occurs between C and the mercury meniscus at the lower part of S. The arc is established between C and the main anode or the holding anode.

Maximum Prebreakdown Energy

The prebreakdown energy is the energy required to raise the vapor pressure between the starter electrode and the cathode to a value high enough for breakdown to occur. It will be shown in this section that this energy is much less than the energy which is inevitably used in the breakdown process itself.

As discussed in the preceding section the process of establishing a vacuum spark involves a front of vapor proceeding from the starter as well as field electron emission from the cathode. The value of vapor density necessary for breakdown is very difficult to estimate. However it is known that when a uniform vapor pressure in the region between C and S has attained a certain value, breakdown in accord with the Paschen curve will occur. The energy necessary for vaporization to obtain this pressure represents the upper limit of required prebreakdown energy. Fig. 6 shows a typical Paschen curve. For the case of interest, the pressure p_0 before application of starter voltage, as well as the spacing d between C and S, is very small. Thus the line $p_0d=\text{constant}$ lies to the left of the minimum of the Paschen curve. Assume that a voltage V_s is suddenly applied between S and C. This may represent the point $(V_s;p_0d)$ in Fig. 6 which lies outside of the breakdown region. As evaporation of the starter electrode sets in, the pressure rises in the region between S and C. When the point $(V_s;p_1d)$ in Fig. 6 has been reached, breakdown is certain to occur. The maximum prebreakdown energy is the energy required to raise the vapor pressure between S and C from p_0 to p_1. Because of the high density of energy input to S other sources of heat loss such as heat conduction may be neglected.

The Paschen curve for mercury is shown in Fig. 7. The part to the right of the minimum is taken from data by Llewellyn Jones and Galloway,[10] the part to the left from Guseva and Klarfeld.[11] For high voltages and low values of pd the curve can be expressed as[11]

$$V=\frac{210}{(pd)^2} \tag{1}$$

where V is in volts, p in mm of Hg, and d in cm.

The energy required to raise the temperature of mercury from room temperature to the boiling point and for evaporation[12] is $\eta=1.13\times10^{-19}$ joules/atom. Assuming a plane parallel geometry of area A cm^2 between S and C the maximum prebreakdown energy in joules can be written as

$$W_{PB_{\max}}=\eta\times3.56\times10^{16}(p_1-p_0)Ad \tag{2}$$

Since $p_0<<p_1$ and inserting equation 1

$$W_{PB_{\max}}=5.83\times10^{-2}\frac{A}{V_s} \tag{3}$$

As an example take $A=0.1$ cm^2 and $V_s=10^4$ volts yielding

$$W_{PB_{\max}}=5.8\times10^{-5}\text{ joules}$$

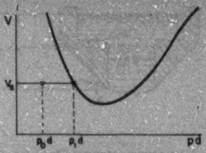

Fig. 6. Typical Paschen curve

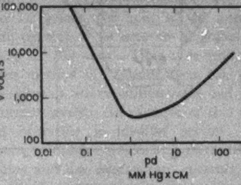

Fig 7. Paschen curve for mercury vapor

Breakdown measurements using series resistance indicate that the actual prebreakdown energy is much lower than $W_{PB_{\max}}$. This is also corroborated by the measurements of Boyle, Kisliuk, and Germer.[8]

Breakdown Time Lag

It has been found[5] that breakdown between a mercury cathode and an electrode occurs at much lower average electric fields (V_s/d) than is necessary for appreciable field emission currents. The reason for this is the mechanical disturbance in the mercury surface caused by the electric field. Under the influence of the electric field, microscopic deformation of the liquid surface into sharp points results in much higher local fields at the cathode surface than at a rigid surface. These sharp points are the centers for field electron emission. There is a certain time lag τ between the application of the field and the formation of these sharp points. This time τ proceeds and is usually much longer than the process of raising the vapor pressure described in the previous section.

Both theoretical and experimental studies of the time lag τ have been done. Warmholz[5] has measured the time lag in breakdown between a mercury cathode and a mercury electrode. These results have been verified by studies on the Empretron starter. It appears that for field strengths $E_s=V_s/d$ exceeding 250 kv/cm the time lag τ in μsec (microseconds) is approximately given by the empirical expression

$$\tau=280\times Exp\left(-\frac{E_s}{422}\right) \tag{4}$$

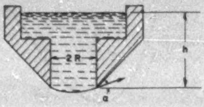

Fig. 8 (left). Schematic drawing of starter electrode

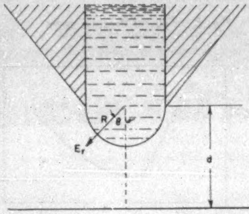

Fig. 9 (left). Schematic drawing showing shape of mercury meniscus at stability limit

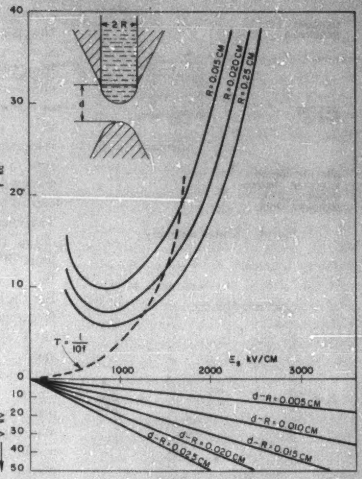

Fig. 10 (right). Frequency limits for Empretron

where E_s is measured in kv/cm. Thus a field of 422 kv/cm gives a time lag of about 100 μsec.

Meniscus Stability

Of primary importance for the operation of the Empretron is the stability of the mercury meniscus at the lower portion of the starter electrode. Fig. 8 shows schematically a cross section of the starter electrode. It will be assumed that the inside of the narrow cylindrical feed tube, with a diameter of $2R$, is well wetted by the mercury but that the outside of the starter electrode is unwetted. The head of mercury h is then supported by the surface tension at the meniscus at the lower part of the feed tube. The equilibrium condition when no potential is applied between S and C is

$$9.81\rho\ \pi R^2\ h=2\pi\ R\sigma\sin\ \alpha \qquad (5)$$

or

$$h=\frac{2\sigma\ \sin\ \alpha}{9.81\ \rho\ R} \qquad (6)$$

where h and R are expressed in meters, $\sigma=$ surface tension in newtons/m (per meter) and $\rho=$ specific weight in kg/m^3. The angle α is defined in Fig. 8. The stability criterion is $\alpha<90$ degrees. For mercury at room temperature $\sigma=0.47$ newtons/m and $\rho=13.5\times10^3$ kg/m^3. As an example take $R=10^{-4}$ m and $h=10^{-2}$ m. In this case, according to equation 6, $\alpha=8$ degrees.

In the case when a high voltage is applied between S and C the additional electrostatic force F on the mercury meniscus must be considered. This force adds to the gravitational force of equation 5. In analyzing this case the following assumptions will be made: 1. $F>>9.81\ \rho\pi R^2h$. This can always be satisfied by making h small enough. 2. The meniscus shape is spherical. The experimental observations indicate that this is a good approximation. 3. The normal component of the electric field at the meniscus surface varies as $E_r=E_s\cos\theta$ where E_s is the maximum field and θ is defined in Fig. 9.

For the case of most interest the voltage is applied to the starter periodically at a repetition rate f starts per second. The voltage between S and C is a train of pulses of pulse duration τ, as seen in equation 4, and frequency f. It will be assumed that the inertia of the mercury column is large enough so that the average electrostatic force is given by

$$F=F_0\ \tau\ f \qquad (7)$$

where F_0 is the force for a d-c potential applied between S and C. With the above assumptions F_0 for the stability limit $\alpha=\pi/2$ is given by integration of the force over the meniscus surface.

$$F_0=\int_0^{\pi/2}\pi\ \epsilon_0\ E_s^2R^2\cos^2\theta\ \sin\theta\ d\theta=\frac{\pi}{4}\epsilon_0E_s^2R^2 \qquad (8)$$

For the limiting case, $F=2\pi\ R\sigma$ or from equations 4, 7, and 8

$$Rf\ E_s^2\times Exp\left(-\frac{E_s}{422}\right)=1.52\times10^7 \qquad (9)$$

where R is in cm, f in sec^{-1}, and E_s in kv/cm. Equation 9 represents the criterion for meniscus stability. It is plotted in Fig. 10 with R as a parameter. The region of meniscus stability is to the right of each curve. E_s is related to the applied voltage V_s by

$$E_s=\frac{V_s}{d-R} \qquad (10)$$

This relation is plotted in the lower part of Fig. 10. As an example of the use of Fig. 10, assume a case where $f=20$ kilocycles, $R=6$ mils, $d=10$ mils. According to Fig. 10 this will require a starting voltage V_s larger than 18 kv for stable operation.

A further restriction on the operating range is set by the practical requirement that the time lag τ must be short compared to the period f^{-1}. If one makes the arbitrary assumption at $\tau\leq0.1\ f^{-1}$ equation 4 yields

$$f\leq357\times Exp\left(\frac{E_s}{422}\right) \qquad (11)$$

This requirement limits the operating parameters to the region to the right of the dotted curve in Fig. 10.

Arc Initiation Energy

As discussed in a foregoing section, the energy necessary for establishing an arc discharge consists of two parts. One part, which will be called the arc initiation energy W_i, is delivered by the starter. The other part is delivered by the anode circuit and is of no consequence for the starter circuit.

Quite independently of the physical process of arc initiation, there exists a lower limit on W_i which is determined by the stray capacitance C_s between the

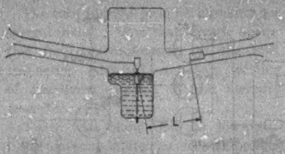

Fig. 11. Empretron having variable cathode to anode distance

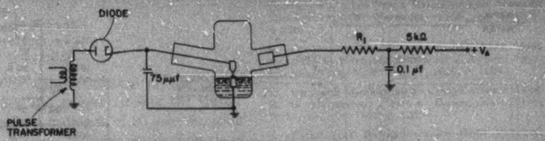

Fig. 12. Diagram showing test circuit for Empretron

starter electrode *S* and cathode *C*. When a voltage V_s is applied between *S* and *C*, a stored energy equal to 1/2 $C_sV_s^2$ must be delivered by the starter circuit. Because of the rapidity of the breakdown process this energy is inevitably consumed in the spark. Therefore the minimum initiation energy is

$$W_{t_{\min}} = 1/2\ C_sV_s^2$$

For the tube already described, $C_s \approx 10$ μμf (micromicrofarad). For example, if $V_s = 10$ kv, $W_{t_{\min}} = 5 \times 10^{-4}$ joules. It is seen that this energy is much greater than the prebreakdown energy discussed in the section on Maximum Prebreakdown Energy.

The energy $W_{t_{\min}}$ may or may not be sufficient for reliable starting depending on the operating conditions. An important factor is the electric field which the potential between the anode and the cathode exerts at the point of the spark breakdown. The necessary degree of development of the seed for the arc cathode is difficult to estimate theoretically and has to be determined experimentally for each particular tube design. As an example of the effect of the anode potential and anode-to-cathode distance on the misfiring rate, tests were performed on the tube structure shown in Fig. 11. The distance *L* between the main anode and the mercury pool could be varied. Measurements were performed at $L = 2$, 4.5, and 9 centimeters. The test circuit is shown in Fig. 12. High-voltage pulses were applied to the starter electrode at a 60-cps repetition rate. The pulse voltage V_s was 18 kv which was sufficient to assure a 60-cps breakdown rate for a spacing $d = 0.010$ inch. The capacitance C_s was 75 μμf, resulting in an energy 1/2 $C_sV_s^2 = 1.22 \times 10^{-2}$ joules per start. The anode supply voltage V_A and the anode current-limiting resistor R_1 were variable and adjusted to yield a peak anode current of 10 amp (amperes). The number of anode firings per second was measured by means of a counter coupled to the anode. For each spacing *L*, the firing rate was measured as a function of anode voltage V_A. The results are shown in Fig. 13. As seen, the misfiring rate increases with *L* and decreases with V_A. The geometry is unfortunately too complicated to give any significance to the dependance of firing rate on V_A/L.

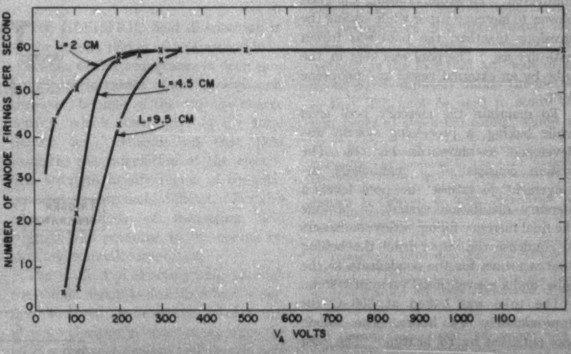

Fig. 13. Diagram showing anode firing rate as a function of anode voltage with cathode to anode distance L as a parameter. 60 corresponds to 100% firing

Mercury Consumption in the Starter Electrode

A factor of great practical importance in the operation of the Empretron is the amount of mercury evaporated from the starter electrode. The demand on mercury replenishment to the starter reservoir determines the type of replenishment method to be used.

From the evaporation energy, discussed in a preceding section, the evaporation rate is found to be 10 grams per hour for a power input of 1 watt to the starter. This may be a representative figure for the evaporation rate of a tube operating with repetition rates in the kilocycle region.

For the replenishment method shown in Fig. 5, mercury evaporated by the action of the main arc is condensed on the tube walls and allowed to flow into the starter reservoir. The evaporation rate from the mercury pool cathode varies greatly depending on the operational conditions. Evaporation rates in the range 0.2 to 36 milligrams per amp of arc current have been reported.[13,14] The lower value corresponds to 7.2 grams per hour at an average arc current of 10 amp or 72 grams per hour at 100 amp. Thus it is seen that this method of replenishment can only be used at low repetition rates and high current levels. An example of this type of operating is inverter service. For pulse modulator service at high repetition rates and low average arc currents, the method incorporating an electromagnetic pump must be employed.

Tube Technology

The requirement that the upper starter electrode should not be wet on the lower outside surfaces has presented a materials problem. A variety of materials and shielding coatings, including sapphire, was tried before arriving at the present structure. The severe environmental conditions such as local heating by electron impact, ion bombardment, etc., peel off or reduce most materials to expose clean metal which promptly wets with mercury. A metal cup is used for its good heat conductivity.

The present starter reservoir is made of molybdenum which is then carburized. This surface layer of molybdenum carbide has extreme resistivity to mercury wetting. The carburizing process consists of raising the cup to 1,500 C (degrees

centigrade) for several hours by r-f (radio-frequency) heating in an atmosphere of toluene bubbled hydrogen. The capillary tube, a nickel tube of 0.006-inch inside diameter is inserted in the molybdenum cup after carburizing.

The inside of the nickel capillary and the pointed cathode electrode, after a chemical cleaning, are prewet with mercury before assembly of the tube.

Mercury-wetted surfaces are maintained with great difficulty, exposed in air or to high-temperature baking cycles during tube processing. They stay wet indefinitely, however, when stored under a pool of mercury. For this reason the electrodes, after mounting in place, were submerged in a mercury pool which was maintained until processing was completed. To avoid exposing the glass blower to mercury vapor while sealing the envelope together, the pool was frozen with dry ice. The pool was kept in the tube by an external vessel and neoprene hose.

To maintain the mercury pool level while baking, a processing system was developed, as shown in Fig. 14. The system consists of a manometer arrangement to adjust the pool level, a mercury distillation system to provide the final mercury filling, series condensers to condense the vapor from the boiling pool, a return for the condensate to the tube, and a conventional vacuum system.

The tube was baked at 360 C for approximately 24 hours. The anode was outgased by r-f heating. The pool was lowered and the starter was operated for 1/2 hour, anode potential applied. At this point the protective pool was completely withdrawn and the manometer tube sealed off. The still was operated until the proper level was reached. Seal-off completed the tube processing.

Life testing was done in the circuit shown in Fig. 15. Test parameters were as follows:

Starter

Firing Rate . . . . $f=60$ pps
Pulse Length . . . . $\tau=100$ μsec
Pulse Voltage . . . . $V_s=15$ kv
Capacitance . . . . $C_s=75$ $\mu\mu$f

Anodes: Main and Holding
Voltage . . . . $V_A=250$ volts
Peak current = 4 amp
Duty cycle = 0.001

The test was interrupted at 650 hours. No outside wetting of the starter reservoir was apparent, and the anode firing followed the starter perfectly.

An additional test was performed with the parameters shown in the following tables:

Starter

Firing rate = 60 pps
Pulse length = 100 μsec
Pulse voltage = 15 kv

	Anodes	
	Holding	**Main**
Voltage	250 volts	249 volts

The tube showed good performance for several hours. After that, erratic operation forced abandonment of the test. Inspection revealed complete wetting of the lower portion of the mercury reservoir.

These tests show that for low-duty-cycle pulse-modulator service, the present structure will provide reasonably long tube life. For long duty cycles however a materials problem still exists.

High-Frequency Tests

The Empretron has been tested by H. Cooke and O. Dow of the RCA Laboratories at firing rates of up to 5,000 pps. The circuit used is shown in Fig. 16. The tube had the following parameters:

Starter
Pulse rate = 5 kc burst for 20 millisec per second
Capacitance = 37 $\mu\mu$f
Voltage = 10 kv
Pulse width = 10 μsec
Spacing $d = 0.005$ inch

Anode
Voltage = 200 volts
Peak current = 4 amp
Duty cycle = 0.03

To avoid overloading of the power supplies and trigger circuits the starter was pulsed in bursts of 20 μsec duration each second. Reliable anode firing was demonstrated up to 5,000 pps. Limitations of anode heat dissipation in the experimental tube prevented operation at higher repetition rates.

Potentials in D-C Corona Fields

GAYLORD W. PENNEY
FELLOW AIEE

RICHARD E. MATICK
NONMEMBER AIEE

Synopsis: A probe method has been devised for measuring potentials in d-c corona fields which are uniform for a short distance in one direction. In unipolar corona, a probe supported by perfect insulators assumes a potential sufficiently above the space so that no more ions can reach the probe. For a cylindrical probe with its axis along an equipotential, this excess or "error potential" is proportional to the diameter of the cylinder. To minimize this error a fine wire is used as the probe. A frame is designed which both supports the wire and shields it from fields other than the field being measured. The fine wire is electrically connected to an electrostatic voltmeter, and the frame to a source of variable potential. A potential is measured by slowly increasing the potential of the frame and recording both frame and wire potential. Under proper conditions, the space potential is the point where wire and frame potentials are equal.

Potentials have been measured as a function of position in a corona field produced by a row of wires between parallel grounded planes. Potentials can be measured quite precisely so that gradients can be determined with reasonable accuracy; they can be measured close to the passive electrode which is the region of greatest importance in electrostatic precipitation. The method can also be used in abnormal corona where there are both positive and negative ions.

A method is outlined for calculating the potential distribution when no space charge (corona current) is present in the geometry consisting of wires between parallel planes, and results are presented. Curves are presented which show how the potential and electric field distribution changes as the corona current is changed under various conditions.

THE ELECTRIC field distribution in the corona region of a precipitator is, of course, of first importance in determining the performance of the precipitator. However, because of the way the charge density, which contributes to the total electric field, depends on that field strength, the calculation of the electric field strength in any region of irregular geometry is extremely difficult. For this reason, methods of measuring field strength and potential in the corona region are especially important.

The method of shooting balls through the corona region as described by Cooperman[1] required the measurement of charge at two velocities in order to separate the effects of charge density and electric field strength. This is difficult experimentally and it led to a considerable uncertainty in results. The method of measuring charge acquired by a ball falling through the corona as used by Penney and Hewitt[2] gave a better measurement of field strength but considerable uncertainty as to the exact position of the field strength measured. This was especially true in regions where the field strength increases in the direction of the field so that the ball is deflected into an increasingly stronger field, which is normally the condition near the dust-collecting electrode of usual precipitators. For this reason the ball-dropping technique is not suitable in the region which is of greatest importance to the performance of a precipitator. Another serious weakness of charged ball methods is the fact that any ions of the wrong sign completely nullify the method so that it cannot be used to study certain types of abnormal corona which are

very detrimental to the performance of a precipitator.

A probe method has the advantage that there is no uncertainty in the position of the measurement. Probe methods were developed by Langmuir and others for for measuring potentials in low-pressure discharges where the mean free path for electrons or ions is large so that uncertainties were primarily due to the energies of the individual ions. In corona at atmospheric pressure the kinetic energy of the individual ions is not large. In this case the major difficulty is due to the fact that there are ions of only one sign which are driven along lines of force so that they charge any insulated probe to a potential higher than that of the space if the probe were not there. This paper describes a method of minimizing this error so that the potential of a point in space can be determined with considerable accuracy. Potential is a scalar quantity so that, once the space potential has been determined, it is a simple matter to obtain the electric field as the gradient of potential. This probe technique can be used only for measurements of d-c corona; it cannot be used in a-c corona.

General Discussion

The probe to be described requires that the potential to be measured must be uniform for an appreciable distance in one dimension and that the probe be oriented so that its axis extends in the direction along which the potential is uniform. If the probe is a cylinder of uniform diameter, the charge per unit length which it acquires due to the movement of ions of the same sign will be proportional to the diameter and proportional to the field strength. If such a long cylinder is parallel to a grounded plane, the potential which such a probe attains, in excess of the potential of the space if the probe were absent, is approximately proportional to the charge per unit length. This excess or error potential is thus proportional to the diameter of the probe and to the maximum field strength in the region to be measured. Since the field being measured must not be changed, the practical method of minimizing the error potential is to use a small probe. This requirement indicates that the probe should be a fine wire. But if such a fine wire is brought out from a high-potential region and connected to an electrostatic meter, its potential may be influenced by the distortion of equipotential surfaces near the ends of the apparatus; this is because the probe will charge to the largest magnitude of potential through which its center line passes(plus the small error potential, of course). Also, it will lose charge by corona along any length located in a low-potential region. Since the wire can receive ions from the field at a very limited rate, any loss of charge or leakage current gives a reduction in potential and so must be eliminated. The probe then consists of a fine wire supported by a frame which forms a shield to protect the wire from extraneous potential regions through which it must pass. The frame also provides for a transition to a large lead going to an electrostatic voltmeter and with the potential of the frame controlled so that the presence of the frame controlled so that the presence of the frame does not disturb the potential of the fine wire.

Error Potential

The error potential is the difference between the magnitude of the potential of the probe and that of the corresponding line in space if the probe were not there. This potential difference or error is due to the charge which the probe receives from the unipolar ionized field. An exact calculation of this error potential would be very difficult because of the nonlinear nature of the problem. However, with the following simplifying assumptions a solution is readily obtained. It will be assumed that:

1. The probe is a wire of infinite length and is parallel to an infinite grounded plane.
2. The field intensity is the same as that existing at the center location of the cylinder before the cylinder is introduced, and is produced by an infinite plane electrode located at a large but finite distance from the wire; also there are very few ions present so their space charge has a negligible effect on the field.
3. The charge on the wire is equilibrium charge obtained in an initially uniform field containing a small number of ions and with the wire located a large distance from any electrode.

These assumptions become better and better approximations to the actual case as the wire diameter is decreased. With these assumptions, the potential of the wire can be readily calculated by the superposition of the field due to the charge of the wire, on the uniform field between the planes. The equilibrium charge acquired by the wire is independent of the charge density and it is easily shown by a method similar to White's[3] that the charge per unit length ρ_l is

$$\rho_l = 4\pi a \epsilon_0 E_0 \qquad (1)$$

rationalized meter-kilogram-second units, where

ϵ_0 = permittivity of space, 8.85×10^{-12} farads per meter
a = wire radius, meters
E_0 = field strength, volts per meter

The potential of this wire above the corresponding line in space if the wire were not there (error potential) is plotted in Fig. 1(A) as a function of distance from the grounded electrode for four different wire sizes. These curves show the importance of using a fine wire as a probe. In applying these curves for error potential to actual corona, there are some situations where the approximation will not be good. If the probe is within a few diameters of any other electrode the field around the probe will be distorted so that equation 1 does not represent the charge on the probe. Another difficulty is due to the fact that the probe disturbs the distribution of ions between the probe and the passive electrode. However, in order to minimize the error potential a fine wire probe is required and as the probe diameter is decreased the calculated error potential becomes a better approximation to the actual situation.

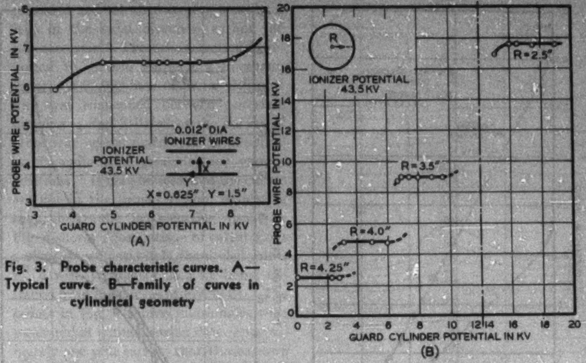

Fig. 3. Probe characteristic curves. A—Typical curve. B—Family of curves in cylindrical geometry

A wire of 0.003-inch diameter has been used as a probe. In Fig. 1(B) the error potential in volts for a wire 0.003 inch in diameter is plotted as a function of distance from the grounded plane for four values of field intensity. Since the foregoing assumptions used for calculations become better approximations as the wire diameter is decreased, the curves of Fig. 1(B) should give an estimate of the actual error potential. The error potential for a 0.003-inch-diameter wire is usually negligible. For example, the curve for 3×10^6 volts per meter shows an error potential of 165 volts at a distance of one inch from the grounded electrode. The potential at this point would be 7,620 volts, so the error potential is then 2.16%. Thus, for precise work, a correction for error potential can be approximated; see reference 4 for a more complete discussion of this error potential.

Technique for Obtaining Correct Probe Potential

Considerations of error potential dictate the use of a fine wire as a probe. If this fine wire is supported by the guard cylinders and frame as shown in Fig. 2, the potential of the guard cylinder must be controlled so that the fine wire can assume its own undisturbed potential. If the magnitude of the potential of the guard cylinder is sufficiently lower than that of the wire, there will be a corona from wire to guard cylinder, which will lower the magnitude of the wire potential. As the magnitude of the potential of the guard cylinder is increased, a point is reached where this corona from wire to guard cylinder ceases, so there is no leakage from the wire which then can attain its own potential. Under proper conditions, as the magnitude of the potential of the guard is further increased, the wire potential will remain constant. In this case the probe wire potential will remain constant until the magnitude of the guard potential is sufficiently larger than the wire to direct ions to the wire and hence increase the magnitude of its potential. Thus, the space potential is the potential of the wire in the region where wire potential is independent of guard cylinder potential except, of course, for the small error potential. An electrostatic voltmeter is used to measure the wire potential. Since it has a high insulation resistance it draws essentially no current.

The design of the guard cylinders as shown in Fig. 2 was arrived at experimentally. As mentioned above, in the flat region of the curve of wire versus guard cylinder potential the guard cylinder has no influence on the wire potential. It was found experimentally, on special apparatus, that a square-ended cylinder (i.e., one which is cut off perpendicular to its axis) influenced the wire potential when the probe was near the grounded plane, so the curve is not really flat in the desired region.

Although the increase in magnitude of the wire potential effected by the guard cylinder has been measured and found to be small (on the order of the error potential) it leads to difficulties in defining the true space potential as well as intro-

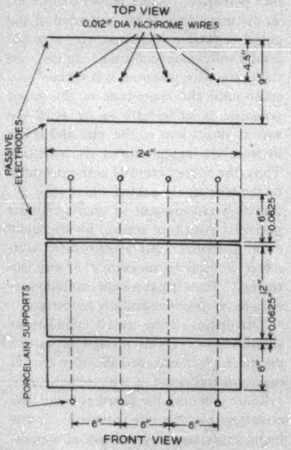

Fig. 5. Arrangement of wires between two parallel-grounded plates

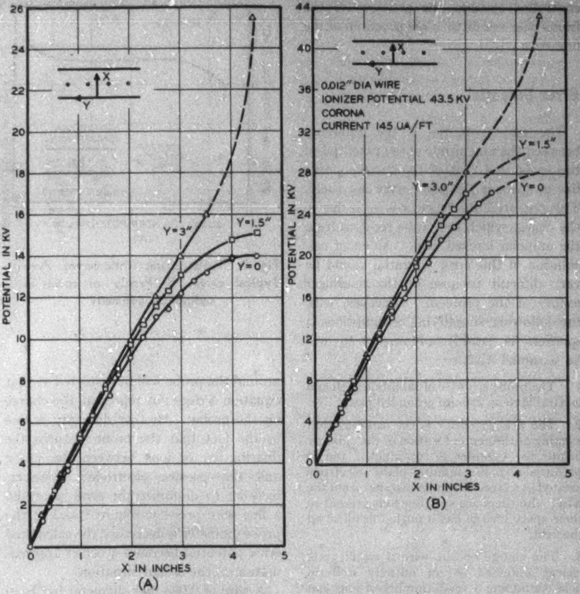

Fig. 6. Measured potential distribution in geometry of Fig. 5. Ionizer potentials in kv: A—25.5 B—43.5

ducing an additive error. It was further found experimentally that when the probe was cut on an angle as shown in Fig. 2 and with the slanted face facing the passive electrode, no influence of cylinder on wire potential could be measured in the prescribed region, while if the slanted face was turned 180 degrees, i.e., facing the active electrode (ionizer wires) the influence of guard cylinder on wire potential was much greater than that of the square-end cylinder. Experimental investigations indicated that this influence or "end effect" of the square-ended guard cylinder on the wire potential, in the region where the probe potential should be independent of guard cylinder potential, is due to a three-dimensional distortion of equipotential surfaces which causes the wire to charge slowly to a magnitude of potential above the desired value. (A more complete discussion of the end effect of the guard cylinders is given in reference 5.) It suffices to say that satisfactory results were obtained with the probe as shown in Fig. 2, and this was the design used.

The guard plate shown in Fig. 2 attached to the guard cylinder, near the point where the electrostatic voltmeter lead attaches to the probe wire, was necessary to prevent stray ions from accumulating on the connection, which would have increased the voltmeter reading. The polystyrene spacer shown at the top of the probe cylinder was made so that the probe wire was completely enclosed, thus preventing any stray ions near the top from reaching the wire.

In all apparatus used, grounded shields were attached near the bottom of the apparatus for the reason just described, as well as for keeping stray ions away from the electrostatic voltmeter itself.

In view of the foregoing, the space potential can be defined as the potential at which the wire and guard cylinder potentials are equal. A typical curve showing the variation of probe wire potential with the potential of the probe frame is shown in Fig. 3(A). The potentials shown on the curve as well as all others in this paper are actually negative but are not designated as such.

A probe wire below its correct potential can always receive ions from the field. However, a probe above its true potential cannot lose any charge until the difference in potential is so great that a loss of charge occurs by corona or other form of leakage from the wire. A curve such as that in Fig. 3(A) can be obtained in either of two ways. The magnitude of guard cylinder potential can be started at a low value and gradually increased, or it can be started at a high value and gradually decreased; in either case, precautions must be taken because of the capacitance between wire and guard cylinder. If the magnitude of the guard

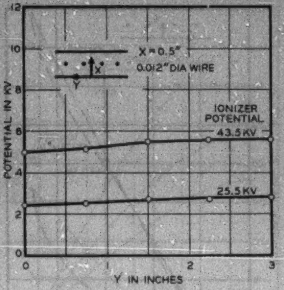

Fig. 7. Potentials measured along a line 1/2 inch from passive electrode

cylinder potential is gradually increased, the wire should be slightly discharged by means of a large resistance to ground to drain off the excess charge resulting from the capacitance effect. This should be done after each change of guard cylinder potential. Otherwise, the flat region will not appear to be flat but will have a definite slope, yielding erroneous results.

If the curve is obtained by decreasing the magnitude of the cylinder potential, the same procedure should be used until a point is reached just where the flat region begins. Then, as the magnitude of cylinder potential is further decreased, the capacitance effect between wire and cylinder will cause the magnitude of the wire potential to decrease momentarily, but it will immediately charge back to the proper value. Thus, the flat region will be obtained without the need of externally discharging the wire. Both of the methods were used with satisfactory results throughout the experimental work.

For similar reasons, both potential sources must be reasonably well regulated since any momentary increase in potential imparts an increased charge to the wire which cannot escape, thus giving the wire a potential whose magnitude is above the value corresponding to the steady potential of the field.

Tests to Prove Accuracy of Probe Method

To verify the use of the probe for measuring potentials, measurements were made using a concentric wire and cylinder. The potential distribution for this geometry can be accurately calculated for comparison with measured values.[5] The cylindrical apparatus consisted of a 9-inch-diameter cylinder, 1 foot long, and two 9-inch-diameter end sections each 6 inches long. The two end sections are grounded and are used to give a uniform field in the axial direction within the 1-foot section. The 1-foot section is returned to ground through a microammeter. A 0.0063-inch-diameter nichrome wire was suspended between porcelain supports. Fig. 3(B) gives the curves of probe wire versus guard cylinder potential in the cylindrical geometry for various positions. It may be seen that the curves are flat in the proper region, indicating that the probe is operating properly. Fig. 4 shows a comparison of calculations and measured potentials, the circled points for a wire voltage of 23.5 kv being obtained from the curves of Fig. 3(B). The points in Fig. 4 shown in triangles were measured at a much earlier date (approximately one year earlier) than those shown in circles. If this can be used as a measure of the reproducibility of the measurements, then one would say the results are quite reproducible. Again, it is pointed out that all potentials are actually negative. It may be seen that calculated and measured values are in good agreement, the maximum error being approximately 10%. The measured points are consistently higher than the calculated curves which can be accounted for, at least in part, by the error potential previously discussed.

Potential Measurements for Wires Between Parallel Plates

Wires between parallel plates are widely used for industrial precipitators but the resulting potentials have not been amenable to calculation. The probe method is useful for measuring potentials in this situation. Measurements have been made for various conditions in the geometry consisting of wires spaced 6 inches from center to center midway between parallel grounded planes spaced 9 inches apart. This arrangement is shown in Fig. 5. Figs. 6(A) and (B) show measurements of space potentials for wire voltages of 25.5 and 43.5 kv respectively. These measurements are precise and re-

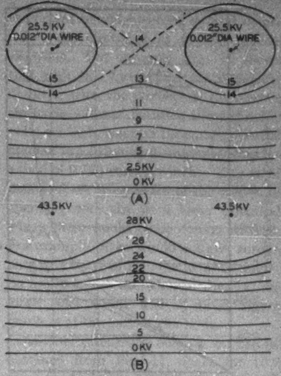

Fig. 8. Equipotential lines. A—As obtained from Fig. 6(A). B—As obtained from Fig. 6(B)

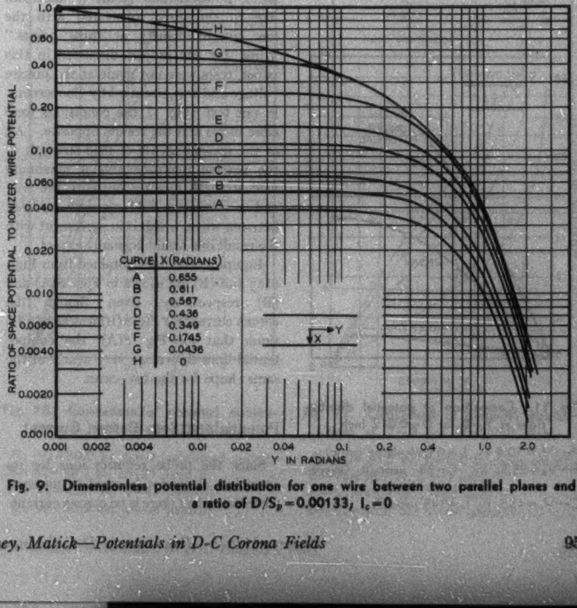

Fig. 9. Dimensionless potential distribution for one wire between two parallel planes and a ratio of $D/S_p = 0.00133$, $I_c = 0$

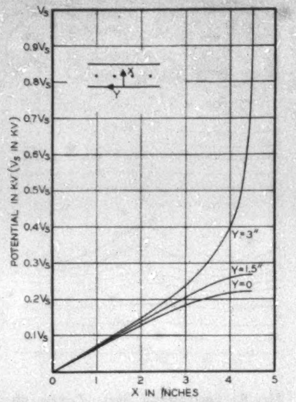

Fig. 10. Normalized potential distribution at zero corona current for four wires of 0.012-inch diameter between two infinite parallel planes

peatable, and are believed to be quite accurate.

Potentials are measured to within 1.5 inches of the wire. The remainder of the curve is shown as a dashed line. As a basis for drawing the upper portion of the dashed curve, the slope at the wire was calculated with the use of the following equation:

$$E_0 = \frac{V_0}{r_0 \ln \dfrac{r_0}{R_0}} \qquad (2)$$

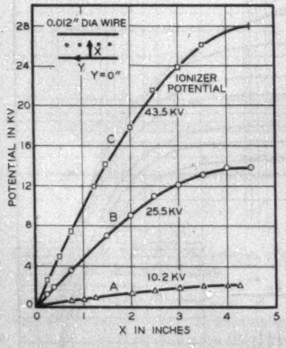

Fig. 11. Comparison of potential distributions at Y=0 for D=0.012 inch

A—V_s=10.2 kv, I_c=0 (calculated curve)
B—V_s=25.5 kv, I_c=35 μamp/ft (microamperes per foot)
C—V_s=43.5 kv, I_c=145 μamp/ft

where

E_0 = electric field intensity at wire surface
V_0 = voltage necessary to initiate corona
r_0 = radius of wire
R_0 = distance to passive electrode

This is the equation for a wire in a concentric cylinder. At the wire the field is influenced relatively little by the shape of the passive electrode and so this should be a good approximation to the field at the wire for a wire between parallel planes. This equation, of course, assumes that the field at the wire is independent of corona current so long as corona exists.

The condition at the passive electrode is of primary importance in determining the rate of precipitation. To study the condition in this region, potentials were also measured along lines parallel to the passive electrodes. These measurements are plotted in Fig. 7.

Experimental results obtained by Cooperman[1] and shown in his Fig. 4 give a field strength near the passive electrode of 17.6 electrostatic units directly opposite a wire, as compared with 27 midway between wires. These figures indicate that the electric field strength is more than 50% greater between wires than directly opposite a wire. This is directly opposite to the result which one would normally expect and so started considerable discussion. Cooperman says, "The technique was not pushed to a high level of accuracy . . ."; in his conclusion he says, "There are indications that the field-strength at the plate surface is maximum between the wires, however this result is uncertain due to the error associated with the low current density at these points." While, for the project discussed in this paper, tests were not made at the precise voltage and wire size used by Cooperman, in one test (Fig. 7) the conditions were close to his and the results opposite. All of the measurements of field-strength at the passive electrode give a maximum field strength directly opposite the wire and a minimum field strength midway between wires, which is in agreement with the result one would normally expect.

Equipotential lines obtained from Figs. 6(A) and (B) are shown in Figs. 8(A) and (B) respectively. Even though the corona current for Fig. 8(B) was nearly 3.5 times that for Fig. 8(A), the equipotential lines shown are very nearly of the same shape for the two cases.

Potentials at Zero Corona Current

Since the probe requires ions for its operation, it cannot be used to measure potentials when there is no corona current.

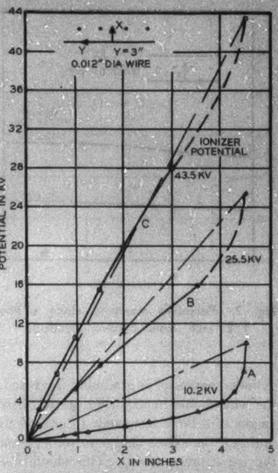

Fig. 12. Comparison of potential distributions at Y=3 for D=0.012 inch

A—V_s=10.2 kv, I_c=0 (calculated curve)
B—V_s=25.5 kv, I=35 μamp/ft
C—V_s=43.5 kv, I_c=145 μamp/ft

However, in this case, the equation governing the space potential is linear, and so potentials can be calculated for many boundary conditions. For a wire between parallel planes, the potential can be calculated using the method of conformal transformation. The method is discussed in the Appendix. Dimensionless curves showing the potentials in space for unit potential on a wire with $D/S_p=0.00133$ are given in Fig. 9. As explained in the Appendix, potentials for other wire sizes can be obtained from this same set of curves provided that D/S_p is not less than 0.00133. Since the problem is linear, potentials for more than one wire can be obtained by the super-

C—$D=0.012$ inch, $I_o=145$ μamp/ft

Effect of Corona Current on Potential Distribution

It is very desirable to know how the potential distribution and hence electric field intensity depend on the corona current. The corona current can be varied by changing the wire potential with the electrodes unchanged, or it can be varied by changing the wire size while keeping the potential constant. The curves of Figs. 14 and 15 show space potentials when 43.5 kv is applied to wires ranging from 0.012- to 0.16-inch diameter. The curves of Figs. 11 and 12 show how the field distribution changes with corona current for wires 0.012 inch in diameter. The curves of Figs. 16 and 17 show a similar comparison for wires 0.080-inch diameter. The slope of the curves in Figs. 11, 12, and 14 through 17 gives directly the electric field intensity. The reason is that because of symmetry, there exists only an x component of electric field intensity along the lines $y=0$ and 3 inches. Furthermore, because of symmetry, the total electric field intensity evaluated at the point $x=4.5$, $y=0$ inches must be identically equal to zero. It may be seen that all the results are in agreement with this. These curves illustrate the extent to which corona current determines the electric field at the passive electrode. For example Fig. 14 shows that with 43.5 kv applied to a 0.16-inch-diameter wire, the gradient at the passive electrode midway between wires is 4,250 volts per inch, whereas the same potential applied to 0.012-inch-diameter wires gives a field of 9,750 volts per inch. This is, of course, directly opposite to the results of changing wire size at a lower potential where there would be no corona current. For example, 10 kv would not give corona on a wire 0.012 of inch diameter or larger. So for 10 kv on the wires of Fig. 14, the larger wire would give a much higher gradient at the passive electrode.

Another interesting comparison can be obtained from Fig. 11 where for 10.2 kv applied to wires 0.012 inch in diameter the gradient at the passive electrode and midway between wires is 750 volts per inch, but if the potential is increased to 43.5 kv, the gradient is 10,000 volts per inch. Thus, an increase of 327% in potential on the wires gives an increase in gradient at the passive electrode of 1,123%.

All these measurements have been made for the case of no dust loading. Heavy dust loadings will have some effect

on the space potential distribution but such cases have not been studied.

Measurement of Abnormal Corona

In the case of the charged-ball method for measuring a field any ions of the wrong sign destroy the validity of the method since even a very small percentage of ions of the wrong sign gives a very large reduction in the equilibrium charge acquired by the ball. However, in the probe method which has been described here, any ions of the wrong sign cause the probe to assume more accurately the potential of the space to be measured and thus reduce the error potential. If there could be equal numbers of positive and negative ions and their mobilities were equal, there would be no error potential due to excess charge. In contrast, the ball-dropping method would give no charge and therefore no measurement at all.

With abnormal corona, in addition to measuring potential, the probe can be used to obtain some information regarding the concentration of ions of each sign. The probe frame or guard is held at the potential of the space as determined in the usual manner. Then, with a high-impedance circuit a current is drawn from the probe wire and a curve of current versus change in wire potential is obtained. By comparing the shape of this curve above and below the potential of the space, that is, comparing the current, when positive ions are being attracted to the probe, with the current when negative ions are attracted to the probe, some indication of the relative concentrations of positive and negative ions can be obtained. This method has been used in one case where the concentration of positive ions was almost the same as the concentration of negative ions so that the slope of the curve of current versus probe wire potential was nearly symmetrical about the space potential point. Work is planned to extend the method to cases where the concentrations of positive and negative ions are quite unequal.

Conclusions

In unipolar corona a fine wire probe takes a potential only slightly above the potential of the same line in space if the probe were removed. The method of gradually increasing the potential of the frame and guard, and recording wire potential as a function of guard potential gives a region over which the guard potential can be varied without changing the wire potential. This interval of unvarying wire potential is the true probe potential or is the potential of the space plus the small error potential; usually this error potential is negligible. For more precise work, since the error potential is small, a reasonable approximation of the error potential will bring the result within the region of instrument uncertainties.

With this method, potentials can be measured quite precisely throughout the corona region. The field close to the large or passive electrode of a precipitator very largely determines the rate of precipitation and so is of primary importance. The probe method permits measuring this field with good accuracy. For the cases investigated, the charge associated with the corona current has very little effect on the direction of the equipotential line at any point in space. But there is a large change of gradient of potential with corona current, so that for a wire potential of the order of 50 kv the gradient at the passive electrode is greater for fine wires than for large wires.

The probe method can be used for measurements in abnormal corona where ions of both signs exists. In this case the error potential is less than it is where there are ions of only one sign.

Nomenclature

A = wire diameter in w plane
$k = \frac{\pi}{4} \times \frac{S_p}{2}$ radians/inch
D = wire diameter in inches
I_1 = corona current per foot of ionizer wire
S_p = parallel plane separation
S_w = wire to wire spacing
x, y = co-ordinate system with origin on passive electrode, midway between ionizer wires (in inches)
X, Y = co-ordinate system with origin at the center of an ionizer wire in radians
x', y' = X, Y expressed in inches, i.e., $X = kx'$, $Y = ky'$
q_n = charge on wire n when V_1 is applied to all of the wires between the two parallel planes
V_n = potential at wire n due to charge q when there are no charges on any other wires
V_s = applied ionizer potential (all wires present)
V = potential at specified point between parallel planes
$w = u + iv$ complex plane
$Z = X + iY$, complex plane

Appendix

When there is no space charge present (i.e., no corona current) it is possible to calculate the potential distribution for a single wire midway between two parallel planes by making use of a conformal transformation. Since there is no space charge, the problem is linear and solutions for single wires can be superimposed to give the potential distribution for a number of wires such as in Fig. 5. Only 2-dimensional field problems will be here discussed, i.e., it is assumed that there is no variation of the field in the axial direction of the ionizer wires.

Wholey and Eldred[6] have shown that the transformation

$$w = \tan Z \tag{3}$$

can be written in the form

$$R^2 = u^2 + v^2 = \frac{\tan^2 X + \tanh^2 Y}{1 + \tan^2 X \tanh^2 Y} \tag{4}$$

where $w = u + iv$ and $Z = X + iY$.

This transforms the coaxial cylinders shown in the w-plane in Fig. 13 into the elliptical wire midway between the two parallel planes shown in the Z-plane in Fig. 13. The two parallel planes in the Z-plane (i.e., $X = \pm\pi/4$) correspond to the outer (larger) cylinder in the w-plane (i.e., $R = 1$), while the elliptical wire in the Z-plane corresponds to the inner (small) cylinder in the w-plane (i.e., $R = A$).

In the Z-plane, X and Y are expressed in radians, while in the w-plane u and v have no dimensions. Furthermore, $\pi/4$ radians in the Z-plane must correspond to one half the parallel plane separation in the actual geometry. Let x' and y' be the co-ordinates in inches corresponding to X and Y (in radians) respectively. The solution in the Z-plane is general since the grounded plane separation can be changed merely by changing k, and the wire diameter can be changed by changing X_0 (which in turn determines Y_0, since $A = \tan X_0 = \tanh Y_0$). It should be noted that x', and y' have their origin at the center of an ionizer wire, while the x, y co-ordinate system used previously for defining the probe position has its origin on the passive electrode midway between wires.

The potential distribution in the Z-plane when only one wire is present is obtained by solving for the potential distribution in the coaxial cylinders (w-plane) as a function of R and substituting equation 4 for R. The potential distribution for coaxial cylinders is well known and when equation 4 is substituted for R, the resulting equation is

$$V = \frac{V_n}{2 \ln A} \ln \left(\frac{\tan^2 X + \tanh^2 Y}{1 + \tan^2 X \tanh^2 Y} \right) \tag{5}$$

Dimensionless potential distribution curves are plotted as a function of Y in Fig. 9 for several values of X for a ratio or wire diameter to plane separation (i.e., D/Sp) of $0.012/9 = 0.00133$.

The curves of Fig. 9 are dimensionless and therefore apply to any single wire located midway between parallel grounded conducting planes for the ratio. $D/Sp = 0.00133$. Since any equipotential surface can be replaced by a conductor at the proper potential the curves of Fig. 9 can be used to obtain fields for any larger wire by considering that the proper equipotential is replaced by a conducting suface (wire) at the appropriate potential. For example, for a wire of 0.02096 radian diameter (i.e., a 0.12-inch-diameter wire between two planes 9 inches apart) the curves of Fig. 9 give a wire potential of 0.66 at a radius of 0.06 inch

($X=0$, $Y=0.01048$ radians). The values as read from the curves are then the potential resulting from a potential of 0.66 on a 0.12-inch diameter.

Theoretically the equipotential surfaces obtained from Fig. 9 are ellipses and so theoretically the wires must be elliptical but, fortunately for small wires (for $Sp=9$ inches, a wire of 0.375-inch diameter can be considered small), the ellipses are so close to circles that for most practical purposes the curves represent the potentials for circular wires.

Superposition can then be used to find the potential due to more than one wire. For the geometry shown in Fig. 5, the potential near wire 1 will be primarily due to the charge on wire 1 but will have some contribution from the charges on the other wires. When a potential V_s is applied to the several wires, each individual wire acquires charges such that the superimposed fields give the potential V_s on each wire.

From Fig. 9, a potential of 1.00 on a wire of 0.012-inch diameter and $S_p=9$ inches produces a potential of 0.037 at $x'=0$, $y'=6$ inches ($X=0$, $Y=1.0408$ radians). At $x'=0$, $y'=12$ inches ($X=0$, $Y=2.096$ radians), the potential is only 0.0047. At 18 inches from the wire, the potential is less than 0.001 and is negligible. Thus at wire one

$$V_s=V_1+0.037V_2+0.0047V_3 \tag{6}$$

and at wire 2

$$V_s=V_2+0.037V_1+0.037V_3+0.0047V_4 \tag{7}$$

By symmetry

$$V_1=V_4 \text{ and } V_2=V_3$$

Substituting these values into the above equations and solving yields

$$V_1=0.96V_s \text{ and } V_2=0.925V_s$$

If this method is extended to wires which are larger and closer together, one must be sure that the ellipse representing the wire is sufficiently close to the actual shape and that when potentials are superimposed, the resulting potential is sufficiently uniform over the cross section of any wire.

Rectifier Unblocking From a Generalized Analysis of Self-Saturating Magnetic Amplifiers

H. C. BOURNE
MEMBER AIEE

D. NITZAN
ASSOCIATE MEMBER AIEE

THE UNBLOCKING of the self-saturating gate rectifier of the resetting core in magnetic-amplifier circuits is a well-known phenomenon. Circuit behavior during this unblocked period, a condition sometimes called gate-limited reset, may result in appreciably different response times and different gains than would otherwise be expected. The purpose of this paper is to derive analytic predictions of the occurrence of this phenomenon which will be useful in the analysis and design of self-saturating magnetic amplifiers.

The analytic prediction of gate-limited reset will be obtained from a generalized analysis applicable to the three standard single-phase self-saturating magnetic-amplifier circuits. Such an analysis requires approximate analytic representations of the nonlinear solid-state elements in the circuits, the ferromagnetic cores, and the semiconductor rectifiers. Further, since phenomena associated with instantaneous values are to be examined, these representations must give approximate information about the instantaneous state of the nonlinear elements and not just the average characteristics. Another severe restriction, which is rather arbitrarily placed on these representations, is that the resulting formulation of circuit behavior should be amenable to reasonable analytic treatment. Two core functions, which are as realistic as possible within these restrictions, are chosen. The rectifier function presents a minor problem in comparison. Experimental results will give an indication of the validity of the representations and the degree of approximation involved.

The combination of an alternating square-wave gate supply and d-c control, and the combination of sinusoidal gate supply and rectified sinusoidal control, are examined.

Nomenclature

e_s, E_s = instantaneous and half-cycle average gate supply voltage
R_L, R_0 = load and total series gate resistance
I_{md}, I_{m0} = core-magnetizing currents corresponding to full and zero reset
G = core conductance
R_s = internal resistance of gate supply voltage
R_f = forward resistance of rectifier
R_w = gate-winding resistance plus forward rectifier resistance
$R_x=1/G_x$ = gate winding resistance plus reverse rectifier resistance
N_c, N_G, N = control turns, gate turns, and turns ratio N_G/N_c
e_1, E_1, e_2, E_2 = instantaneous and half-cycle average induced voltages in a resetting and gating core
eL, EL, e_0, E_0 = instantaneous and half-cycle average net and gross output voltage
e_c, E_c = instantaneous and half-cycle average control voltage
α = firing angle
e_{res}, E_u = instantaneous voltage across a rectifier and forward bias voltage of a silicon rectifier
$E_{c,u}$, $R_{c,u}$, α_u = E_c, R_c, and α corresponding to $e_{res}=E_u$

Analytic Core Models

The loop and node equations of magnetic-amplifier circuits contain terms which involve the induced voltage and the magnetizing current associated with ferromagnetic cores. Unfortunately, the relationship between these two variables, which describe the terminal properties of the core winding, depends on the present

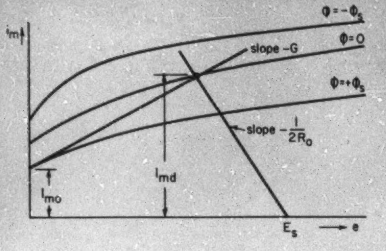

Fig. 1. Graphical representation of I_{md}, I_{m0} and G on core characteristics (magnetizing current versus excitation voltage with flux as a parameter. Initial flux corresponds to saturation)

and past states of the core material. Even if a common initial state, e.g., positive saturation, is assumed, the relationship between net magnetomotive forces F and the rate of change of flux $d\phi/dt$, with flux ϕ as a parameter, is nonlinear.[1] In a previous paper, a test procedure is developed by which the nonlinear characteristics of a resetting core may be obtained.[2] A graphical procedure is then devised which accurately predicts the core behavior in the prefiring and postfiring intervals regardless of the associated circuitry, e.g., the control circuit resistance.

In an analytic treatment these nonlinear core characteristics must be sufficiently linearized to give realistic results with reasonable effort. Two core models, designated A and B are considered. Core model A approximates the magnetizing current of a square-loop material by I_{md} during the prefiring period (mode 1) and by I_{m0} during the postfiring period (mode 2). Both symbols imply referral to the gate circuit. I_{md} is defined as the average magnetizing current when the core is fully reset by $E_s - 2I_{md}R_0$. I_{m0} is by definition the threshold magnetizing current corresponding to the static **B-H** loop at saturation. I_{md} and I_{m0} are related to typical core characteristics as shown in Fig. 1.

Approximate values of I_{md} and I_{m0} may be obtained by other means. To a reasonable approximation, I_{md} may be identified with the dynamic coercive force under rated sinusoidal excitation. Alternatively, I_{md} and I_{m0} may be identified with the magnetizing current at full and zero reset in the constant-current reset test. For small values of R_c a smaller value for I_{m0} than the one defined by Fig. 1 should be taken as a result of initial gating along minor loops before the end of the postfiring period.

Core model B involves a mathematically continuous rather than discontinuous linear approximation of the core characteristics and is inherently a more satisfying representation. After Kikuchi[3] and Feth[1] the magnetizing current is given by

$$i_m = I_{m0} + Ge \tag{1}$$

I_{m0} is the same as defined previously, and the core conductance G may be evaluated as

$$G = \frac{I_{md} - I_{m0}}{E_s - 2I_{md}R_0} \tag{2}$$

so that I_{md} corresponds to the magnetizing current at full reset in both cases; see Fig. 1. Neither core function predicts the changes in gain or the shearing of the transfer characteristic caused by different values of control circuit resistance. As the analysis will show, both core functions will inherently linearize the predicted operation from zero to full output.

Circuit Equations

Since phenomena associated with the instantaneous states of the nonlinear magnetic amplifier circuits are to be examined, equations relating instantaneous voltages and currents to the known excitations must be derived. The circuit diagrams of the doubler, bridge, and center-tap circuits are shown in Fig. 2. In the normal range of contol during the prefiring interval of the positive half-cycle (mode 1) core 1 is resetting from saturation and core 2 is gating. The corresponding equivalent circuits are shown in Fig. 3, with the leakage current of the blocked complementary rectifier of the bridge circuit neglected. During the postfiring interval of the positive half-cycle (mode 2), core 2 has saturated and the equivalent circuits are still valid

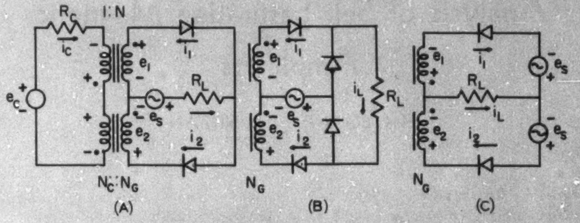

Fig. 2. Self-saturating magnetic-amplifier circuits; control circuits identical

C—Center-tap

Table I. Self-Resistances and Mutual Resistances of Gate Loops

	Doubler	Bridge	Center Tap
R_{11}	$R_x+R_L+R_s$	$R_x+R_f+R_s$	$R_x+R_L+R_s$
$R_{22}(=R_0)$	$R_w+R_L+R_s$	$R_w+R_f+R_s+R_L$	$R_w+R_L+R_s$
R_{12}	R_L+R_s	R_f+R_s	$-R_L$

with $e_2=0$, and the magnetizing current constraint removed from core 2.

The three loop equations and the two core-constraint equations based on core model *B* and applicable during mode 1 are

$$\begin{Vmatrix} 0 & 0 & R_c & 1/N & 1/N \\ R_{11} & R_{12} & 0 & 1 & 0 \\ R_{12} & R_{22} & 0 & 0 & 1 \\ 1 & 0 & -1/N & -G & 0 \\ 0 & 1 & 1/N & 0 & -G \end{Vmatrix} \begin{Vmatrix} i_1 \\ i_2 \\ i_c \\ e_1 \\ e_2 \end{Vmatrix} = \begin{Vmatrix} e_c \\ e_s \\ e_s \\ I_{m0} \\ I_{m0} \end{Vmatrix} \tag{3}$$

in which R_{11}, R_{22} $(=R_0)$, and R_{12} are the self-resistances and mutual resistances of the gate loops; see Table I. Equation 3 may be modified for core model *A* by substituting $G=0$ and I_{md} for I_{m0}. During mode 2 the equations apply if the last row and last column of the matrix are eliminated, and they apply to core model *A* with $G=0$. Equations applicable to the negative half-cycle may be easily inferred from these by symmetry considerations although, by the same token, they would contain no new information.

The solution of these equations is straightforward even if somewhat tedious; it is necessary in order to predict approximately the occurrence of any instantaneous misbehavior in the circuit. Appropriate solutions of these equations will be used in the section dealing with gate-rectifier unblocking but, first, the dynamic operation of the circuits will be derived by a method not requiring such solutions.

Output Difference Equations

If instantaneous values (waveshapes and firing angle) are not of concern, then the equation describing the dynamic operation of the magnetic amplifiers in normal operation may be obtained directly. Alternating square-wave gate supply and d-c control is assumed initially.

CORE MODEL B

In core model B the control circuit loop equation is

$$Ne_c=N^2R_c\frac{i_c}{N}+e_2-e_1 \tag{4}$$

The magnetizing current constraint of the resetting core is

$$G_x\left(e_s-e_1-\frac{e_LR_{12}}{R_L}\right)-\frac{i_c}{N}=I_{m0}+Ge_1 \tag{5}$$

in which the first term represents the reverse current of the gate rectifier. Substitution of i_c/N from equation 5 into equation 4 and integration over the half-cycle, designated the *n*th half-cycle, yields

$$\begin{aligned} NE_c(n)=N^2R_c(G_xE_s-I_{m0})-\\ (1+GN^2R_c+G_xN^2R_c)E_1(n)+E_2(n)-\\ E_L(n)G_xN^2R_c\frac{R_{12}}{R_L} \end{aligned} \tag{6}$$

The half-cycle average voltages across the cores are related to the load voltages on this and the next half-cycle $(n+1)$ as follows

$$E_1(n)=E_1(n+1)=E_s-\frac{E_L(n+1)R_0}{R_L}$$

$$E_2(n)=E_s-\frac{E_L(n)R_0}{R_L} \tag{7}$$

Substitution of equations 7 into equation 6 results in the output difference equation:

$$\begin{aligned} E_L(n+1)=\frac{NR_L}{R_0}\frac{E_c(n)}{1+N^2R_c(G+G_x)}+\\ \frac{E_L(n)\left(1+G_xN^2R_c\frac{R_{12}}{R_0}\right)}{1+N^2R_c(G+G_x)}+\\ \frac{R_L}{R_0}\frac{N^2R_c(I_{m0}+GE_s)}{1+N^2R_c(G+G_x)} \end{aligned} \tag{8}$$

Dynamic transfer functions to any degree of approximation desired may be obtained directly from this linear first-order difference equation. The quantities often of chief interest are the voltage gain and the time constant associated with the exponential portion of the response, which is characterized also by a half-cycle delay. The gain is obtained by assuming steady-state conditions and finding E_L/E_c which gives

$$\begin{aligned} K_v=\frac{NR_L}{R_0}\frac{1}{N^2R_c\left[G+G_x\left(1-\frac{R_{12}}{R_0}\right)\right]}\\ =\frac{NR_L}{R_0}k_{v0} \end{aligned} \tag{9}$$

in which k_{v0} is the gross voltage gain on an equal turns basis. The time constant is given by

$$\tau=\frac{1}{\ln\left[\frac{1+N^2R_c(G+G_x)}{1+\frac{G_xN^2R_cR_{12}}{R_0}}\right]}\cong\frac{1}{\ln\frac{k_{v0}+1}{k_{v0}}} \tag{10}$$

half cycles. For time constants greater than 4 or 5 half-cycles, the natural logarithm may be approximated by the first two turns of its series expansion to give

$$\tau\cong\frac{1}{N^2R_c\left[G+G_x\left(1-\frac{R_{12}}{R_0}\right)\right]}=k_{v0} \tag{11}$$

CORE MODEL A

The same method applied to core model *A* is somewhat more complicated because of the discontinuous nature of the core function. Integration of the control circuit loop equation over a half-cycle gives the equivalent of equation 6 as

$$\begin{aligned} NE_c(n)=N^2R_c\left[G_xE_s-\frac{I_{md}\alpha(n)}{\pi}-\right.\\ \left.I_{m0}\left(1-\frac{\alpha(n)}{\pi}\right)\right]-(1+G_xN^2R_c)E_L(n)+\\ E_2(n)-\frac{E_L(n)G_xN^2R_cR_{12}}{R_L} \end{aligned} \tag{12}$$

Equation 7 still applies, and in addition:

$$\begin{aligned} \frac{\alpha(n)}{\pi}\cong\frac{E_2(n)}{(E_s-2I_{md}R_0)}\\ =\frac{\left(E_s-\frac{E_L(n)R_0}{R_L}\right)}{E_s-2I_{md}R_0} \end{aligned} \tag{13}$$

Substitution of equations 7 and 13 into equation 12 gives the output difference equation for this core model.

$$\begin{aligned} E_L(n+1)=\frac{NR_L}{R_0}\frac{E_c(n)}{1+N^2R_cG_x}+\\ \frac{1-N^2R_c\left(G-\frac{G_xR_{12}}{R_0}\right)}{1+N^2R_cG_x}E_L(n)+\\ \frac{R_L}{R_0}\frac{N^2R_c(I_{m0}+GE_s)}{1+N^2R_cG_x} \end{aligned} \tag{14}$$

in which $G=(I_{md}-I_{m0})/(E_s-2I_{md}R_0)$ has been defined exactly as in core model *B*.

The voltage gain from equation 14 is identical with that obtained for core model *B* and, in fact, the steady-state characteristics predicted by these core models are identical in every respect. This is not surprising since both core models result in a linear transfer characteristic between the same end points. In theory, the time constant differs, since, from this core model

$$\tau=\frac{1}{\ln\left[\frac{1+N^2R_cG_x}{1-N^2R_c\left(G-\frac{G_xR_{12}}{R_0}\right)}\right]}\cong\frac{1}{\ln\frac{k_{v0}}{k_{v0}-1}}\ \text{half cycles} \tag{15}$$

However, for time constants greater than

4 or 5 half-cycles the appropriate approximation predicts the same result as obtained for core model *B* in equation 11. Actually in practical cases, for the range of time constants less than 4 or 5 half-cycles, the unblocking of the gate rectifier of the resetting core invalidates both "exact" expressions given by equations 10 and 15, as will be shown. Experimental results with the rectifiers replaced by switching transistors in order to force operation in the normal modal sequence indicate that equation 10 gives better correlation for fast response times.

In all the above equations if rectifier reverse current is small compared with magnetizing currents ($G>>G_x$), G_x may be made zero to obtain the corresponding, less complex, expressions.

Sinusoidal Excitation

In the previous derivation of the difference equation, alternating square-wave gate excitation and d-c control have been assumed. These results may be extended to sinusoidal gate excitation and rectified sinusoidal control with a few additional approximations.

Both core models bear considerably less resemblance to the actual core function if sinusoidal excitation is used rather than square-wave excitation. Core model *A* is particularly poor in mode 2 with low control resistance. Core model *B*, if applied to instantaneous values, as was intended, predicts a sinusoidally bulging **B-H** loop, which is certainly not observed experimentally. However, the following approximations are suggested.

In the case of core model *A* with sinusoidal excitation, the transcendental modes at the beginning and end of the half-cycle, which exist because of the theoretical inability of the excitations to supply I_{md} and I_{m0} instantaneously, are neglected. Further, the sinusoidal variation of the half-cycle-average output voltage with firing angle is approximated by the linear function which agrees at $\alpha=0$ and $\alpha=\pi$. With these two approximations the results are identical with those for square-wave excitation.

In the case of core model *B*, if the transcendental modes are neglected as before, and the **B-H** loop is assumed to have the sinusoidally bulging sides predicted by this core model, then the results are obviously the same as those previously obtained. No approximation regarding the firing angle versus output is necessary. However, if equation 1, defining this model, is assumed to apply to half-cycle average values, the results are again the same as those obtained previously. Of course, in this case the assumption concerning the linear relationship between firing angle and output is necessary.

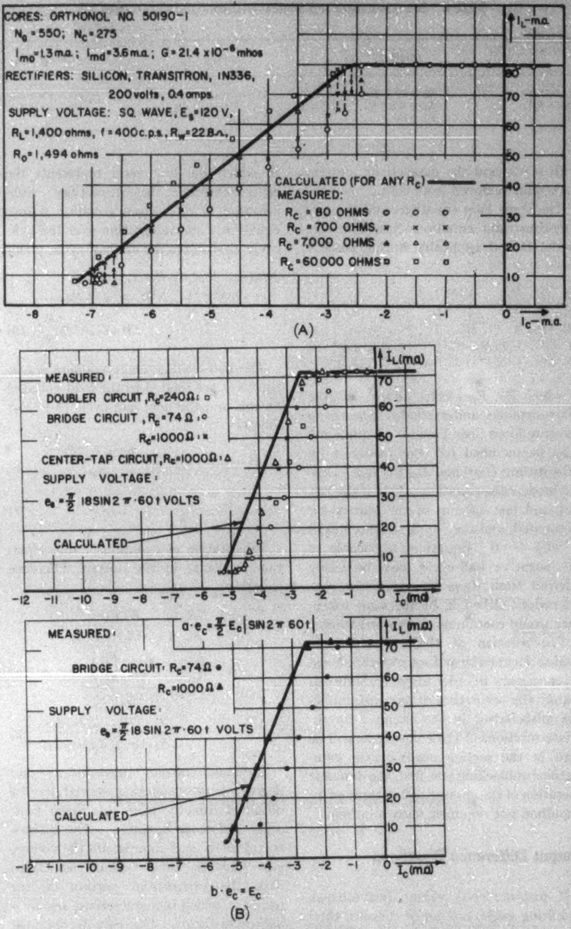

Fig. 4. Steady-state transfer characteristics with normal rectifier behavior

A—With square-wave excitation
B—With sinusoidal excitation

With approximations comparable to those suggested above, equations 8 and 14 are also applicable to sinusoidal gate excitation and d-c control.

Experimental Verification

Rectifier unblocking, when present, is eliminated experimentally by the use of switching transistors which are synchronized with the supply voltage.

The circuitry common to square-wave and sinusoidal excitation is as follows: Cores, Magnetics Inc.; Orthonol no. *50190;* 1-mil tape; inside diameter = 1 inch; outside diameter = 1.75 inch; height = 0.5 inch; $l_{Fe}=10.96$ centimeters; $A_c=0.909$ square centimeter; $G=21.4\times10^{-6}$ mhos, $N_G=550$; $N_c=275$; $R_f=4.6$ ohms; $R_w=22.8$ ohms; $R_x\cong\infty$ (silicon recti-

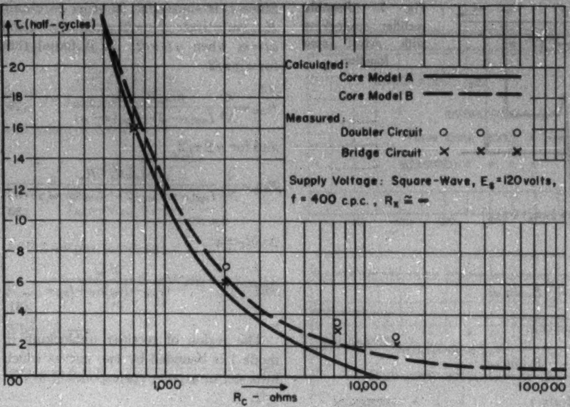

Fig. 5. Time constant versus R_c

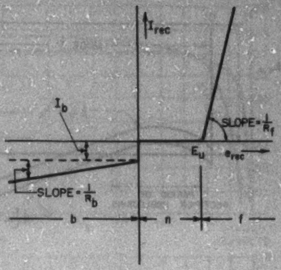

Fig. 6. Semiconductor rectifier model

fiers, transitron *1N336;* 200 volts; 0.4 ampere).

SQUARE-WAVE EXCITATION

$E_s = 120$ volts, $f = 400$ cycles per second, $R_L = 1{,}400$ ohms, $R_s = 71$ ohms, $I_{md} = 3.6$ ma (milliamperes), $I_{m0} = 1.3$ ma. Fig. 4(A) shows a comparison between calculated and experimental transfer characteristics.

The unstable region of ferroresonance nature around full output when R_c is small is caused by the winding capacitance of the resetting core.

An output voltage transient response to a step control voltage is half-cycle integrated and recorded by a Polaroid camera. The resulting time constant values for various values of R_c are compared in Fig. 5, with the calculated values based on core models *A* and *B*. For a control resistance $R_c = 1/N^2G$, in this case 11,700 ohms, core model *A* predicts half-cycle response. For $1/N^2G < R_c < 2/N^2G$ core model *A* predicts stable decaying oscillations, for $R_c = 2/N^2G$ sustained oscillation at a frequency half of the supply frequency and for $R_c > 2/N^2G$ unstable exponential oscillations. Of course none of these predictions are found experimentally. The breakdown of this core model at large R_c stems from the assumption that $I_{md} - I_{m0}$ stays constant regardless of R_c. Actually $I_{md} - I_{m0}$ decreases as R. increases and, when $R_c \to \infty$ $I_{md} - I_{m0} \to 0$. Core model *B* predicts closer results, especially when R_c is large. Its predictions of infinite R_c for half-cycle response is verified experimentally. For low values of R_c the two predicted curves approach each other and have better correlation with measured values.

Table II. Calculated and Measured Time Constant with Sinusoidal Excitation

Circuits	Rc, Ohms	Calculated τ, Half-Cycle	Measured τ, Half-Cycle Rising E_L	Measured τ, Half-Cycle Falling E_L
Doubler	240	15	15	16
Bridge	500	7	8	9
Center tap	1,000	4	5	6

SINUSOIDAL EXCITATION

Here $e_s = \pi/2 \times 18 \sin 2\pi \times 60\, t$ volts, $R_L = 218$ ohms, $R_s = 2$ ohms, $I_{md} = 2.65$ ma, and $I_{m0} = 1.3$ ma. Experimental and calculated transfer characteristics and time constant are compared in Fig. 4(B) and Table II respectively.

The Criterion for Rectifier Unblocking

When $|e_c|$ is large, the reflected voltage across the gate side of the resetting core may unblock the corresponding self-saturating rectifier. For analysis purposes an amenable, yet realistic, rectifier model is desired. Such a model for a silicon rectifier is shown in Fig. 6.

Referring to Fig. 6, the rectifier of the resetting core is blocked when $e_{rec} \le E_u$. From Fig. 2 the blocking voltage across the rectifier of the resetting core, if the rectifier leakage current is neglected, is $e_1 + R_{12}i_L - e_s$. Consequently, the criterion for a blocked rectifier is

$$e_1 + R_{12}i_L - e_s \le E_u \tag{16}$$

The value of E_c, at which equation 16 becomes an equality, and referred to as $E_{c,u}$, may be found by substituting the expressions for e_1 and i_L from equation 3.

Rectifier Unblocking Under Square-Wave Excitation

MODE 1

Both core models *A* and *B* predict no rectifier unblocking in mode 1. This may be verified by showing that for $\alpha = \pi$, which is the extreme condition corresponding to e_c a minimum, $e_{rec} < 0$. However, with the actual instantaneous magnetizing current i_m, it is found that

$$E_{c,u} = -\frac{1}{N}\left[i_m(N^2R_c + 2hR_0) + 2E_u\right] \tag{17}$$

in which $h = 1 - R_{12}/R_0$, and rectifier unblocking is possible, as shown in Fig. 7.

MODE 2

In mode 2

$$i_L = \frac{E_s - E_u}{R_0} \tag{18}$$

Based on core model *A*

$$e_1 = -NE_c - I_{m0}N^2R_c \tag{19}$$

Substitution into equation 16 gives

$$E_{c,u} = -\frac{1}{N}\left[I_{m0}N^2R_c + hE_s + (2-h)E_u\right] \tag{20}$$

For a given α the corresponding control resistance is

$$R_{c,u} = \frac{1}{N^2}\,\frac{hE_s + (2-h)E_u}{\dfrac{\alpha}{\pi}(I_{md} - I_{m0})} \tag{21}$$

The maximum value of R_c that may be used without causing rectifier unblocking is determined with $\alpha = \pi$.

PERIOD OF RECTIFIER UNBLOCKING
$-\frac{1}{N}\left[i_m(N^2R_c+2hR_0)+2E_u\right]$

Fig. 7. Possible rectifier unblocking with actual core function

$$R_{c,u(\pi)}=\frac{1}{N^2}\,\frac{hE_s+(2-h)E_u}{I_{md}-I_{m0}} \tag{22}$$

For $R_c\to\infty$, $\alpha=0$ and $I_{c,u(R_c=\infty)}=-NI_m{}^0$ Similarly, based on core model B

$$e_1=-\frac{NE_c+I_{m0}N^2R_c}{1+GN^2R_c} \tag{23}$$

$$E_{c,u}=-\frac{1}{N}\left\{I_{m0}N^2R_c+[hE_s+(2-h)E_u]\times(1+GN^2R_c)\right\} \tag{24}$$

$$R_{c,u,\pi}=-\frac{1}{N^2G}\,\frac{[hE_s+(2-h)E_u](1+2GR_0)}{E_s[1-h(1+2GR_0)]-E_u[1+(2-h)(1+2GR_0)]-2I_{m0}R_0} \tag{25}$$

and

$$I_{c,u(R_c=\infty)}=-N\{I_{m0}+G[hE_s+(2-h)E_u]\} \tag{26}$$

By substituting the values for h of each circuit and letting $\alpha=\pi$, it is concluded that according to core model A rectifier unblocking in mode 2 is possible in the three circuits, whereas core model B excludes this possibility from the center-tap circuit.

For design purposes, a region of rectifier unblocking is obtained by plotting $E_{L,u}$ (E_L corresponding to $E_{c,u}$) versus $E_{c,u}$ with R_c as a parameter. Evaluation of $E_{L,u}$ is based on the linear transfer characteristics assuming no rectifier unblocking. This step is valid since ($E_{c,u}$; $E_{L,u}$) is on the boundary between the regions of blocked and unblocked rectifier.

Rectifier Unblocking Under Sinusoidal Excitation

Rectifier unblocking under sinusoidal excitation becomes rather cumbersome due to the possible presence of transcendental equations depending on α. Additional complexity arises when rectifier unblocking occurs simultaneously in the two modes of operation.

Only core model A is considered. It is assumed that

$$e_s=\frac{\pi}{2}E_s\sin\omega t$$

and that

$$e_c=\frac{\pi}{2}E_c|\sin\omega t|$$

Mode 1

In mode 1, referring to Fig. 2,

$$e=e_s-E_u-Ne_c-I_{md}(N^2R_c+2R_0) \tag{27}$$

Substitution of equation 27 and $i_L=2I_{md}$ into equation 16 yields

$$E_{c,u}=-\frac{1}{N}\,\frac{2}{\pi\sin\omega t}(2hI_{md}R_0+2E_u+I_{md}N^2R_c) \tag{28}$$

Since e_c is sinusoidal, in order to obtain $E_{c,u}$, substitute $\omega t=\pi/2$ when $\alpha\geq\pi/2$ and $\omega t=\alpha$, when $\alpha\leq\pi/2$. It is found that for $\alpha\geq\pi/2$

$$R_{c,u}=\frac{4}{N^2}\,\frac{hI_{md}R_0+E_u}{I_{md}(\alpha-2)+I_{m0}(\pi-\alpha)} \tag{29}$$

and for $\alpha\leq\pi/2$

$$R_{c,u}=\frac{4}{N^2}\,\frac{hI_{md}R_0+E_u}{I_{md}(\alpha\sin\alpha-2)+I_{m0}\sin\alpha(\pi-\alpha)} \tag{30}$$

As $R_c\to\infty$

$$\alpha_{u(R_c=\infty)}=\sin^{-1}\frac{2I_{md}}{(I_{md}-I_{m0})\alpha_u+I_{m0}\pi} \tag{31}$$

The region of rectifier unblocking in mode 1 is bounded by two curves which intersect at a point corresponding to $\alpha=\pi/2$.

Mode 2

Following the same procedure, in mode 2

$$E_{c,u}=-\frac{1}{N}\left\{hE+\frac{2}{\pi\sin\omega t}\times[I_{m0}N^2R_c+(2-h)E_u]\right\} \tag{32}$$

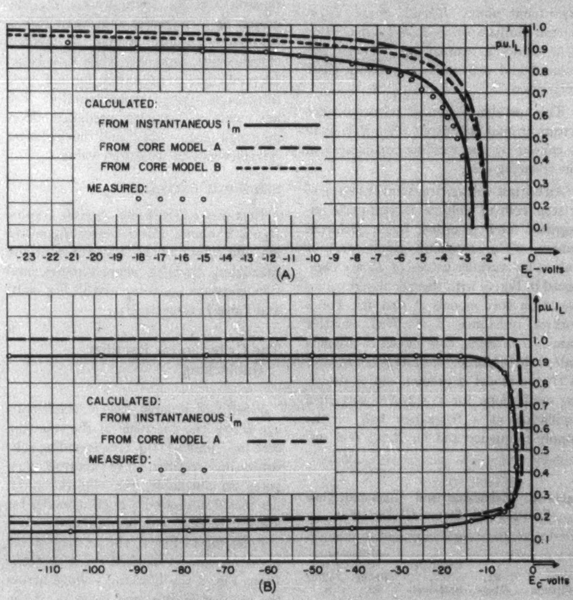

Fig. 8. Region of rectifier unblocking in Mode 2, doubler circuit

A—Square-wave excitation
B—Sinusoidal excitation

Contrary to mode 1, substitute $\omega t=\pi/2$, when $\alpha\leq\pi/2$ and $\omega t=\alpha$ when $\alpha\geq\pi/2$. When $\alpha\leq\pi/2$

$$R_{c,u}=\frac{1}{N^2}\frac{\pi hE_s+2(2-h)E_u}{I_{md}\alpha+I_{m0}(\pi-\alpha-2)} \qquad (33)$$

and when $\alpha\geq\pi/2$

$$R_{c,u}=\frac{1}{N^2}\frac{\pi hE_s+\dfrac{2(2-h)E_u}{\sin\alpha}}{I_{md}\alpha+I_{m0}\left(\pi-\alpha-\dfrac{2}{\sin\alpha}\right)} \qquad (34)$$

At full output, $\alpha=0$, so

$$R_{c,u(0)}=\frac{1}{N^2}\frac{\pi hE_s+2(2-h)E_u}{I_{m0}(\pi-2)} \qquad (35)$$

When $R_c\rightarrow\infty$

$$\alpha_{u(R_c=\infty)}=\sin^{-1}\frac{2I_{m0}}{(I_{md}-I_{m0})\alpha_u+I_{m0}\pi} \qquad (36)$$

MODES 1 AND 2

Rectifier unblocking may occur simultaneously in the two modes of operation. However, an unblocked current in one mode of operation has only a second-order effect on the unblocked current in the other mode of operation. As such, the equations derived previously for each mode separately may still be used to a good approximation. The over-all region of rectifier unblocking is the area covered by the region of rectifier unblocking in either mode of operation or in both modes.

Six combinations of rectifier unblocking are possible:

1. Complete in mode 1 alone.
2. Mode-limited in mode 1 alone.
3. Complete in mode 1 plus mode limited in mode 2.
4. Mode limited in modes 1 and 2.
5. Mode limited in mode 2 alone.
6. Complete in mode 2 alone.

Experimental Verifications

The circuit parameters are identical with those described in the experimental investigation with no rectifier unblocking. The regions of rectifier unblocking are found experimentally by decreasing E_c slowly for each value of R_c and recording $E_{c,u}$ and $E_{L,u}$ at the first appearance of the unblocked current. Calculated regions of rectifier unblocking based on the core models and an independently measured i_m, are compared with experimental regions in Figs. 8 and 9.

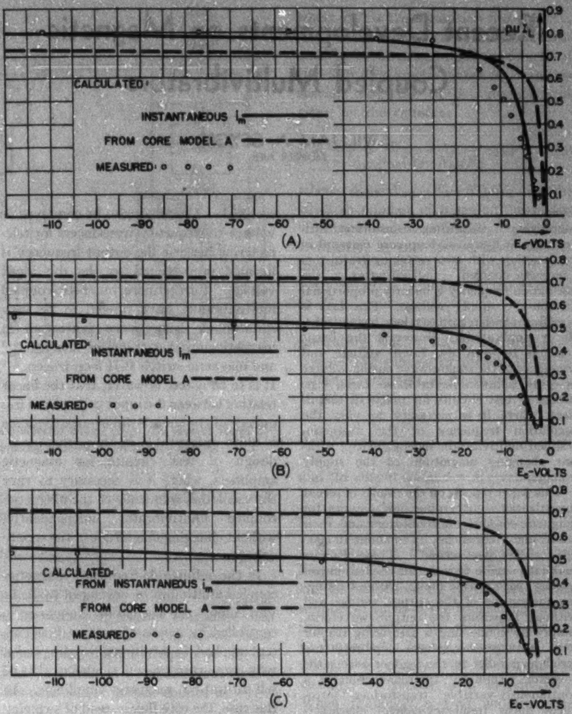

Fig. 9. Region of rectifier unblocking in mode I, sinusoidal excitation

A—Doubler
B—Bridge
C—Center tap

Conclusions

Two core models which yield linear relations may be used in a general analysis of the self-saturating magnetic amplifier. Difference equations, and steady-state and transient characteristics may be derived, assuming no rectifier unblocking. Based on this analysis, the criterion for rectifier unblocking may be determined. Regions of rectifier unblocking, superimposed on a family of steady-state transfer characteristics, may be calculated for various conditions and used to check analysis and design procedures.

The quantitative effect of rectifier unblocking on the time constant is discontinuous and, consequently, the concept of a time constant is no longer very meaningful. Theoretically, the increase in τ due to rectifier unblocking can be found by replacing R_t by R_u during the periods in which the rectifier is unblocked.

Recent Developments on Magnetic-Coupled Multivibrators

WILLIAM A. GEYGER
MEMBER AIEE

Synopsis: In a static d-c to a-c converter employing a saturating transformer with rectangular-hysteresis-loop core material in conjunction with two switching transistors (magnetic-coupled multivibrators), the oscillation frequency is linearly proportional to the d-c supply voltage. This fact is significant with regard to telemetering-transducer applications. However, the linear relation between d-c input voltage and frequency of the square-wave output voltage is quite unfavorable in those cases, e.g., design of test circuits for magnetic amplifiers, where it is necessary to vary the oscillation frequency of the magnetic-coupled multivibrator independently, without changing magnitude of the supply voltage.

This paper reports on the results of recent investigations concerning new circuits for magnetic-coupled multivibrators and their use at high frequencies, up to about 100,000 cps (cycles per second). These circuits make it possible to vary the oscillation frequency, within wide limits, without changing magnitude of the output voltage and without impairing the output waveform, simply by connecting a saturating reactor with rectangular-hysteresis-loop core material in parallel to the load or across the collector terminals. Interconnection of a continuously-variable transformer introduces linear frequency-control characteristics and permits coarse and fine adjustment with regard to frequency and magnitude of the square-wave output voltage.

A STATIC d-c to a-c converter employing a saturating transformer with rectangular-hysteresis-loop core material in conjunction with two switching transistors[1] is finding an increasing application as a square-wave power supply for magnetic amplifiers, induction motors, gyros, and torque relays. These magnetic-coupled multivibrators[2–5] are widely used in d-c power supply devices, where a low-voltage direct current is converted into a square-wave alternating current transformed to a high-voltage level and rectified. They may also be employed as voltage-to-frequency transducers for telemetering because the output frequency is linearly proportional to the d-c input voltage. Furthermore, magnetic-coupled multivibrators have proved to be very suitable as square-wave generators in magnetic-amplifier transient analyzers[6–8] and magnetic-switch B-H loop tracers.[9,10] It is to be noted, however, that the linear relation between d-c input voltage and frequency of the square-wave output voltage is quite unfavorable in those cases, e.g., design of test circuits for magnetic amplifiers, where it is necessary to vary the oscillation frequency of the magnetic-coupled multivibrator independently, without changing magnitude of the supply voltage.

In the adjustable-frequency magnetic-coupled multivibrator developed by R. L. Van Allen,[3] the oscillation frequency is controlled by means of a direct bias current applied to additional windings of a twin-core arrangement, similar to that of self-saturating magnetic amplifiers. In this case, the core flux instead of swinging between saturation levels,[2,4,5] is reset to an unsaturated value on alternate half-cycles. Van Allen's circuit, therefore, operates on variation of the core flux density in such a way that oscillation frequency can be controlled inversely proportional to the core flux. However, as a result of d-c bias magnetization of the cores, the output waveform deteriorates from its clean rectangular shape. This is undesirable in many applications of such d-c to a-c converters.

The author, when working with a differential-type magnetic-coupled multivibrator,[5] made the rather startling discovery that the oscillation frequency can be varied, within wide limits, without changing the magnitude of the output voltage and without impairing the output waveform, simply by connecting a saturating reactor with rectangular-hysteresis-loop core material in parallel to the load or across the collector terminals. Interconnection of a continuously-variable transformer made it possible to obtain linear frequency-control characteristics and to introduce coarse and fine adjustment with regard to both frequency and magnitude of the square-wave output voltage.

Since the anouncement of new circuits for magnetic-coupled multivibrators with wide-range frequency control,[11,12] further research and development work has been conducted toward the use of these circuits at high frequencies, up to about 100,000 cps. This paper reports on the results of these investigations.

Principle of Wide-Range Frequency-Control Circuits For Magnetic-Coupled Multivibrators

GENERAL

In the original form of the switching-transistor d-c to a-c converter introduced by G. H. Royer[2] and in the differential-type magnetic-coupled multivibrator described by C. H. R. Campling,[5] actual frequency of the square-wave output voltage is linearly proportional to the d-c input voltage. If a transformer with rectangular-hysteresis-loop core material is used and transistor switching occurs when the core saturates, the oscillation frequency is given by

$$f_0=\frac{E_{DC}}{4B_SA_TN_{eff}}\times 10^8 \qquad (1)$$

where E_{DC} is the d-c input voltage (volts), B_S is the saturation-flux density of the core material (gausses), A_T is the actual cross-sectional area (cm^2) of the transformer core, and N_{eff} is the effective number of turns of the transformer windings. In Royer's circuit, N_{eff} is the number of turns of the collector windings (N_2), whereas in Campling's arrangement N_{eff} is the difference (N_2-N_1) between the number of turns of collector windings and that of the emitter windings (N_1). On the other hand, in both circuits,[2,5] the output voltage E_{AC} is linearly proportional to the input voltage E_{DC}.

The basic principle of wide-range frequency-control circuits for magnetic-coupled multivibrators[11] consists essentially of varying, either step-by-step or continuously, the effective number of turns (N_{eff}) of windings which determine the frequency of oscillation in accordance with the relationship:

$$N_{eff}=\frac{E_{DC}}{4B_SA_Tf_0}\times 10^8 \qquad (2)$$

derived from equation 1. Because it is impractical to vary actual numbers of turns of the four winding units of the saturating transformer which operates in conjunction with the two switching transistors, the new method of wide-range frequency control employs additional components in the multivibrator circuit in

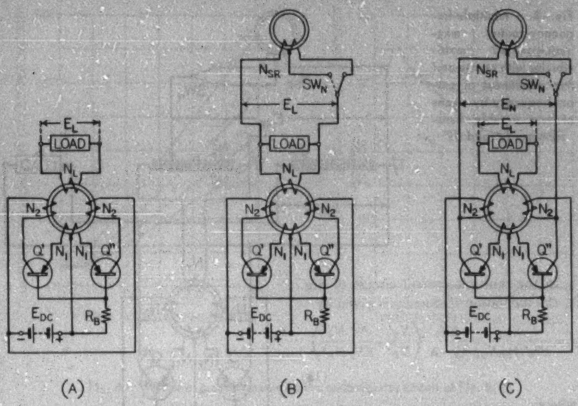

Fig. 1. The differential-type magnetic-coupled multivibrator circuit (A), and several forms of basic multivibrator circuits (B) and (C), providing wide-range frequency control

such a way that N_{eff} can be most readily varied through tapped windings and/or continuously-variable transformers.

Basic Circuits

In accordance with the schematic diagrams of Figs. 1 and 2, the evolution of new circuits may be characterized as follows:

In the differential-type arrangement, Fig. 1(A), as described by Campling,[5] the frequency of oscillation is given by

$$f_o=\frac{E_{DC}}{4B_S A_T(N_2-N_1)}\times 10^8 \qquad (3)$$

where $N_{eff}=(N_2-N_1)$ represents the effective number of turns of the magnetic-coupled multivibrator. The two p-n-p germanium transistors, Q' and Q'', are connected with collector windings N_2 and emitter windings N_1 of a saturating transformer with rectangular-hysteresis-loop core material and with a common-base resistor R_B limiting the base-to-emitter drive. The d-c input voltage E_{DC} may be supplied from a battery as illustrated in Fig. 1(A), or from a battery eliminator (power-supply transformer with full-wave rectifier and filter network).

When connecting a saturating reactor with rectangular-hysteresis-loop core material in parallel to the load terminals, as indicated in Fig. 1(B), the output frequency can be varied, within wide limits, without changing the magnitude of the output (load) voltage E_L and without impairing the output waveform by varying the effective number of turns N_{SR} of this saturating reactor (switch SW_N).[11] In this case, the peak voltage applied to the saturating-reactor winding N_{SR} will be

$$E_{SR}=E_{DC}\frac{N_L}{N_2-N_1} \qquad (4)$$

Provided that the product $B_S' A_{SR} N_{SR}$ of the saturating reactor is smaller than the product $B_S A_T(N_2-N_1)$ of the transformer, the output frequency will be solely determined by the parameters of this reactor and is then defined as

$$f_o=\frac{E_{SR}}{4B_S' A_{SR} N_{SR}}\times 10^8 \qquad (5)$$

where B_S' is the saturation flux density, A_{SR} is the actual cross-sectional area, and N_{SR} is the actual number of turns of the saturating reactor across N_L. In this special case, the output frequency is given by the equation

$$f_o=\frac{E_{DC}}{4B_S' A_{SR} N_{SR}(N_2-N_1)/N_L}\times 10^8 \qquad (6)$$

where $N_{eff}=N_{SR}\ (N_2-N_1)/N_L$ is the effective number of turns of the multivibrator circuit, as defined by equation 2. Evidently, in this special case, the frequency of oscillation is inversely proportional to N_{SR} and linearly proportional to N_L.

It is also possible to place the loading saturating reactor across an additional transformer winding or preferably across collector terminals, as shown in Fig. 1(C). In this case

$$N_{eff}=N_{SR}\frac{N_2-N_1}{2N_2} \qquad (7)$$

and the output frequency is given by

$$f_o=\frac{E_{DC}}{B_S' A_{SR} N_{SR}(N_2-N_1)/(2N_2)} \qquad (8)$$

Equation 6 makes it evident that linear frequency-control characteristics can be introduced by varying the actual number of turns of the transformer winding, across which the saturating reactor is connected. In the example of Fig. 2(A), this number of turns can be changed by means of a switch SW_E. When providing a load winding with numerous taps, the output frequency may be varied step-by-step, without changing

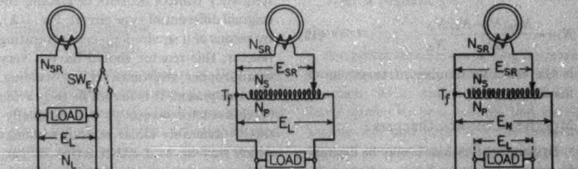

Fig. 2. Several forms of basic multivibrator circuits with linear frequency control, (A) with switch SW_E, (B) and (C) with continuously-variable transformer T_f

the magnitude of the output voltage and without impairing the output waveform. Of course, it is also possible to perform linear frequency control by varying actual number of turns of an additional secondary winding with properly distributed taps.

Fig. 2(B) illustrates a very convenient method for performing linear frequency control by means of a standard low-power adjustable transformer T_f connected across the load terminals. This simple arrangement makes it possible to vary the frequency continuously by moving the slider of T_f, i.e., by varying the turns ratio N_S/N_P, without changing the magnitude of output voltage E_L and without affecting the output waveform in an undesirable way. In this arrangement, the oscillation frequency is defined by the relationship

$$f_o=\frac{E_{DC}}{4B_S'A_{SR}N_{SR}}\frac{N_L}{N_2-N_1}\frac{N_S}{N_P} \tag{9}$$

where

$$N_{eff}=\frac{N_{SR}(N_2-N_1)}{N_L}\frac{N_P}{N_S} \tag{10}$$

is the continuously-variable effective number of turns of the multivibrator circuit; see equation 2.

In order to obtain greater flexibility, it is generally preferred[11] to connect the primary winding of the variable transformer T_f across the collector terminals, as indicated in Fig. 2(C). In this case, the output frequency is given by

$$f_o=\frac{E_{DC}}{4B_S'A_{SR}N_{SR}}\frac{2N_2}{N_2-N_1}\frac{N_S}{N_P} \tag{11}$$

where

$$N_{eff}=\frac{N_{SR}(N_2-N_1)}{2N_2}\frac{N_P}{N_S} \tag{12}$$

is the effective number of turns, as defined by equation 2.

MULTIPLE-CONTROL CIRCUITS

In some applications it may be desirable to provide coarse and fine adjustment of output frequency. Fig. 3 shows an example of a refined multivibrator circuit having coarse and fine adjusting transformers T_f' and T_f''. The large primary voltage for T_f' (coarse adjustment) is derived from the voltage E_N across both collector windings N_2. The small primary voltage for T_f'' (fine adjustment) is derived from a separate secondary winding N_T. The load is connected in this example across both collector windings. In this case, $E_N=2\ E_{DC}\ N_2/(N_2-N_1)$. Interconnected transformers may be used here in a similar way to provide coarse and fine adjustment of output voltage.[11]

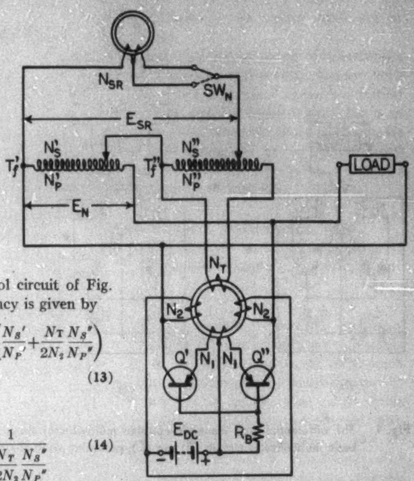

Fig. 3. Multiple-frequency-control magnetic-coupled multivibrator with coarse and fine adjustment of output frequency by means of two variable transformers, T_f' and T_f''

In the multiple-control circuit of Fig. 3, the oscillation frequency is given by

$$f_o=\frac{E_{DC}}{4B_S'A_{SR}N_{SR}}\frac{2N_2}{N_2-N_1}\left(\frac{N_S'}{N_P'}+\frac{N_T}{2N_2}\frac{N_S''}{N_P''}\right) \tag{13}$$

where

$$N_{eff}=N_{SR}\frac{N_2-N_1}{2N_2}\frac{1}{\dfrac{N_S}{N_P'}+\dfrac{N_T}{2N_2}\dfrac{N_S''}{N_P''}} \tag{14}$$

is the effective number of turns of the multivibrator circuit (equation 2). With the ratio $N_T/(2\ N_2)=1/10$, fine adjustment of output frequency can be achieved by varying the slider position of transformer T_f'', i.e., by varying N_S''.

Design Considerations

The more important aspects of proper design of the new multivibrator circuits of Fig. 1(B) and (C), Fig. 2(A) to (C), and Fig. 3 may be summarized as follows:

1. Because the fundamental principle of the described method for wide-range frequency control consists in loading the original differential-type circuit, Fig. 1(A), by means of a square-loop-core saturating reactor, this reactor should have a very small copper resistance of its winding. For this reason, it is favorable to provide on this reactor several groups of equally-rated (preferably bifilar-wound) windings which may be used either series- or parallel-connected to vary the oscillation frequency step-by-step over wide ranges.

2. In order to obtain optimized switching performance and to minimize "spikes" in the output square wave, magnetic-leakage effects must be reduced to the minimum. When using the turns ratio $N_1/N_2=1/2$, the transformer can be considered to have $N_1+2\ N_1+2\ N_1+N_1=6N_1$ turns acting as collector windings $(2N_1)$ and emitter windings (N_1) respectively. In this way of design, six twisted wires may be hand-wound simultaneously around the core of the transformer which then has negligible magnetic leakage between its winding units.

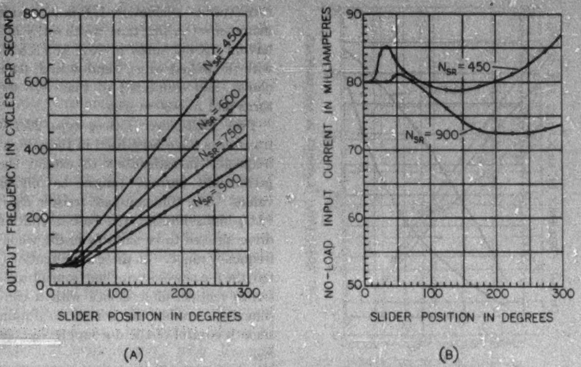
3. Although the transformer with windings N_1 and N_2 is always unsaturated with higher frequencies, it will operate with the lowest frequency between saturation levels, in accordance with the mode of operation of conventional multivibrator circuits, as shown in Fig. 1(A). It is, therefore, advisable to employ rectangular-hysteresis-loop core material also in this transformer, if the lowest part of the frequency range is to be utilized. However, when working only in the upper part of the frequency range, the transformer with N_1 and N_2 will never be saturated and will have correspondingly reduced core losses. In this case, lower-grade core material may be used in this transformer.

4. The continuously-adjustable transformer, Figs. 2(B) and (C), and Fig. 3, will, of course, never be saturated; and commercially-available components may be employed for this purpose. However, in order to minimize the magnetizing-current requirements of the adjustable transformer, it is necessary to use a standard low-power design. Of course, the scale of this transformer may be calibrated in cps for various values of d-c supply voltage E_{DC} and number of turns N_{SR} of the saturating reactor.

Performance Characteristics at Low Frequencies

DIMENSIONS OF COMPONENTS

A low-power (10-watt) prototype design with the circuit of Fig. 2(C) has been developed to be employed as a square



(A) (B)

Fig. 4. Results of measurements on the multivibrator circuit of Fig. 2(C)

A—Output frequency as a function of the variable-transformer slider position with the number of turns N_{SR} of the saturable reactor as a parameter

B—No-load input current as a function of the slider position with N_{SR} = 450 turns or 900 turns, respectively

Fig. 5 (below). Output waveform of the multivibrator circuit of Fig. 2(C) with:

A—Basic frequency 55 cps

B—Linear-range frequency 500 cps

C—Linear-range frequency 3,000 cps

wave generator for magnetic-amplifier transient analyzers[6–8] and magnetic-switch B-H loop tracers.[9,10] In these instrument applications, a very clean output waveform is of paramount importance to secure proper operation of the silicon-diode chopper circuits.

The transformer using an Orthonol 2-mil tape core (inside diameter = 1.5 in. (inches), outside diameter = 2.5 in., tape width = 1.0 in.) has 6×275 turns of No. *24* wire (6 twisted wires, hand-wound, 6×2.5 ohms) connected so that $N_1 = 275$ turns, and $N_2 = 550$ turns. The saturable reactor using Orthonol 2-mil tape core (inside diameter = $1^1/_4$ in., outside diameter = $1^5/_8$ in. tape width = 0.5 in.) has 6× 150 turns of No. *24* wire (6 twisted wires, hand-wound, 6×0.8 ohms), which may be used, series- or parallel-connected in various ways. Two germanium p-n-p transistors, type *2N158* (Q and Q''), are used in this design. The common-base resistor R_B limiting the base-to-emitter drive[5] is not critical ($R_B = 1{,}000$ ohms). The d-c power is supplied, in this case, from a transformer-rectifier-filter device with a continuously-variable transformer which permits smooth control of the d-c supply voltage E_{DC}.

FREQUENCY-CONTROL CHARACTERISTICS

In the prototype design of Fig. 2(C), both the output frequency f_o and the no-load input current I_{DC} have been measured as a function of the adjustable-transformer slider position, i.e., actual angular position (N_S) of the slider from its initial position ($N_S = 0$), with $N_{SR} = 450$, 600, 750, and 900 turns, respectively. Fig. 4(A) makes it evident that, within the initial range of from zero up to a certain slider position (e.g., 40 degrees with $N_{SR} = 900$), the saturable reactor (N_{SR}) remains unsaturated, and the transformer (N_1N_2) operates between saturation levels, in accordance with the conventional multivibrator circuit of Fig. 1(A). However, when moving the slider toward higher values of N_S, the saturable reactor starts to operate between its own saturation levels, while the transformer starts to have unsaturated mode of operation. That is, from zero up to a certain slider position (e.g., 40 degrees with $N_{SR} = 900$ turns), the transformer determines solely the output frequency (in this example, 55 cps). Then the saturable reactor takes over and represents the determining factor for the ranges 55 . . . 360 cps, 55 . . . 440 cps, 55 . . . 550 cps, and 55 . . . 740 cps, respectively. Thus, it is possible to perform smooth linear frequency control within these ranges.

Fig. 4(B) shows the no-load input current, I_{DC}, as a function of the variable-transformer slider position for $N_{SR} = 450$ turns, and $N_{SR} = 900$ turns. The considerable changes in magnitude of I_{DC} are caused by the fact that either the transformer (N_1N_2) is saturated, while the saturable reactor (N_{SR}) is unsaturated, or vice versa.

OUTPUT WAVEFORM

Fig. 5 presents oscillograms of the output voltage across the load resistor (output power, 10 watts) of the described prototype design for the "basic frequency" 55 cps (transformer N_1N_2 saturated, reactor N_{SR} unsaturated), and for the "linear-range frequencies" 500 cps and 3,000 cps (transformer N_1N_2 unsaturated, reactor N_{SR} saturated). With regard to the present applications in magnetic-amplifier test circuits[6–10] the spikes are sufficiently small. Moreover, if they are objectionable, they can be eliminated by connecting small capacitors (e.g., 0.05 microfarad) between collector and emitter of each transistor.[5]

Performance Characteristics at High Frequencies

GENERAL

A-c power supplies employing a square-loop-core saturating transformer in conjunction with switching transistors[2–5] have proved to be a suitable tool for reducing size and improving the performance of magnetic amplifiers by applying high power-supply frequencies in the range of 5 to 50 kc.[11–16] Recently, the author's investigations on high-frequency-operated low-level self-balancing magnetic amplifiers operating as audio amplifiers in conjunction with crystal-type radio receivers or standard turn-table equipment have shown that quite remarkable sound performance can be obtained with this arrangement. With regard to such special applications, the multivibrator circuits described in this paper have been investigated at high output frequencies, up to about 100 kc.

When applying magnetic-coupled multivibrators at high frequencies, eddy-cur-

B—No-load input current

rent losses in the saturating core must be reduced to the minimum. This can be achieved by using magnetic bobbin cores made of very thin tapes.[17] In the present investigations concerning comparison of performance characteristics of the multivibrator circuits of Fig. 1(A) and Fig. 1(C) in the frequency range 5 to 100 kc, small 4-79 molybdenum Permalloy bobbin cores (tape width = 1/8 in., tape thickness = 1/2 mil, 1/4 mil, or 1/8 mil, respectively) have been used with the turns ratio $N_1/N_2=1/2$. Six twisted wires have been hand-wound on these cores with various numbers of turns to be employed in the circuit of Fig. 1(A) as collector windings ($N_2=2N_1$) and emitter windings (N_1). In the wide-range frequency control circuit of Fig. 1(C), the unsaturated transformer consisted of a small Orthonol 2-mil tape core (inside diameter = 1.0 in., outside diameter = $1\,^1/_4$ in., tape width = 1/8 in.) having 6×400 turns of No. *32* (B.&S.) wire (6 twisted wires, hand-wound, 6×8 ohms), and connected so that $N_1=400$ turns and $N_2=800$ turns.

Two high-power Delco, type *2N174* transistors have been used in these high-frequency investigations to extend the permissible current ranges to higher values. The common-base resistor $R_B=1{,}000$ ohms limiting the base-to-emitter drive[6] proved to be suitable in the whole frequency range. In these investigations, too, the d-c power is supplied from a transformer-rectifier-filter device with a continuously-variable transformer to obtain smooth control of the d-c supply voltage E_{DC}.

Results of Measurements

In order to compare the performance characteristics of the new circuit of Fig. 1(C) with those of the original differential-type circuit, Fig. 1(A), both the output frequency f_o and the no-load input current I_{DC} have been measured as a function of the d-c supply voltage E_{DC}. A calibrated vacuum-tube oscillator is used in the conventional way for measuring actual output frequency of the multivibrator circuit by means of Lissajous figures displayed on the screen of a cathode-ray oscilloscope.

Fig. 6(A) presents results of measurements on the original circuit, Fig. 1(A). The bobbin core (80 wraps of 1/8-mil tape) has 6×200 turns of No. *34* wire (6 twisted wires, hand-wound, 6×4 ohms, and connected so that $N_1=200$ turns and $N_2=400$ turns).

Fig. 6(B) shows results of correspondingly performed measurements on the new circuit of Fig. 1(C). The same bobbin core with $N_{SR}=4\times200=800$ turns has been used here as the loading saturating reactor, in conjunction with a small unsaturated transformer having an Orthonol 2-mil tape core (inside diameter = 1.0 in., outside diameter = $1\,^1/_4$ in., tape width = 1/8 in.) with 6×400 turns of No. *32* wire (6 twisted wires, hand-wound, 6×8 ohms, and connected so that $N_1=400$ turns and $N_2=800$ turns).

Comparison between Figs. 6(A) and 6(B) makes it evident that there is a relatively small increase in no-load input current I_{DC} as a result of the additional core losses in the unsaturated Orthonol-core transformer of the circuit of Fig. 1(C). When using this circuit, the output frequency f_o has slightly lower values than in the original circuit of Fig. 1(A).

Fig. 7 shows results of measurements on the circuit of Fig. 1(C) with $N_{SR}=200$

to 1,200 turns. Evidently, the output frequency f_o can be varied, within wide limits, by varying actual number of turns N_{SR} of the loading saturating reactor, the windings of the unsaturated transformer remaining unchanged. When decreasing N_{SR}, the no-load input current I_{DC} increases, correspondingly.

In order to determine power-handling capacity and efficiency of the circuit under test, Fig. 1(C), input and output values have been measured with load resistance, $R_L = 400$ to 2,500 ohms, connected across the collector terminals. Fig. 8(A) output voltage E_{AC} and Fig. 8(B) output frequency f_o as a function of the d-c supply voltage E_{DC} with load resistance R_L as a parameter. Fig. 9(A) makes it evident that, with $E_{DC} = 20$ volts, maximum output power, $E_{AC}^2/R_L = 6$ watts, is obtained in the circuit under test with $R_L = 600$ ohms.

The circuit efficiency is defined by the expression

$$\eta = \frac{\text{output power } E_{AC}^2/R_L}{\text{input power } E_{DC}I_{DC}} \times 100\% \qquad (15)$$

Fig. 9(B) shows $\eta = f(R_L)$ with E_{DC} as a parameter. With $R_L = 800$ to 1,000 ohms, the circuit efficiency is about 60% to 65%.

Output Waveform

The oscillograms of Fig. 10 show the output waveform of the circuit of Fig. 1(C) with $f_o = 10$, 50, and 100 kc. In the most interesting frequency range of 10 to 50 kc, a quite acceptable trapezoidal waveform is obtained, which is suitable for high-frequency operation of magnetic amplifiers.

Fig. 10. Output waveform of the multivibrator circuit of Fig. 1(C) with the frequencies 10 kc, 50 kc, and 100 kc

Telemetering Transducer Applications

Because output frequency of the new multivibrator circuits, Figs. 2(B) and (C), can be made directly proportional to angular position of an adjustable-transformer slider shaft, these circuits may be used in telemetering transducer applications. In this way, angular or linear displacement can be converted to a corresponding frequency shift. Movement or rotation of the shaft may be controlled remotely with a conventional servo system.

Conclusions

1. The output frequency of differential-type magnetic-coupled multivibrators can be varied, within wide limits, without changing the magnitude of the output voltage and without impairing the output waveform, simply by connecting a square-loop-core saturating reactor in parallel to the load or across the collector terminals.

2. Continuous linear frequency control can be achieved by introducing a standard low-power adjustable transformer connected across the load or across the collector terminals. This possibility suggests application of the new multi-

vibrator circuits to telemetering systems.

3. The results of measurements presented in this paper make it evident that such multivibrator circuits with high output frequencies, up to 100,000 cps, are suitable for high-frequency operation of magnetic amplifiers, e.g., self-balancing magnetic amplifiers operating as audio amplifiers in conjunction with crystal radio receivers or standard turntable equipment.

Sparkover as Influenced by Surface Conditions in D-C Corona

GAYLORD W. PENNEY
FELLOW AIEE

SAMUEL E. CRAIG
NONMEMBER AIEE

SPARKOVER between clean electrodes has been investigated extensively but it is found that sparkover between contaminated electrodes exhibits very different results. With corona from a clean metal point to a plane, sparkover occurs at a considerably lower voltage if the point is positive.[1] Because of this, it is frequently assumed that positive corona will always result in the lowest sparkover voltage. A few experiments with contaminated electrodes show that sparkover is a complicated phenomenon and that negative corona does not always result in a higher sparkover voltage.

Some earlier work[2] indicates that, with positive corona, even small patches of insulating material on a wire could result in a condition called "abnormal corona," which frequently results in sparkover at relatively low voltages. This condition exhibits a marked dependence on wire size. Some aspects of this abnormal corona associated with high-resistivity material on the positive active electrode indicates that somewhat the same type of prebreakdown currents followed by sparkover at relatively low voltage might occur in negative corona with high-resistivity material on the positive passive electrode. Some preliminary experiments with high-resistivity materials on the passive electrode showed that this could result in marked reduction in sparkover voltage and that there seemed to be a correlation with resistivity.

The operating voltage of a precipitator is normally well below the sparkover voltage of a clean precipitator. This reduction in sparkover voltage is presumably due partly to dust suspended in the gas between electrodes and partly to dust on the electrodes. This paper is concerned only with the dust on electrode surfaces.

Flares

In this paper the term "flare" is applied to a type of discharge which appears to originate as a bright point on the anode and "flares" out in a cone-shaped, bluish glow, extending toward the cathode; see Fig. 1. Flares are particularly easy to produce with positive corona by putting high-resistivity material about 10 mils thick on the active electrode. The flare originates at an edge or hole in the insulating layer. While the point of the flare appears as bright glow, it does not ignite a material such as paper. It is only in case of sparkover that the paper burns. From this it appears that the glow is in the gas and that there is no high surface temperature.

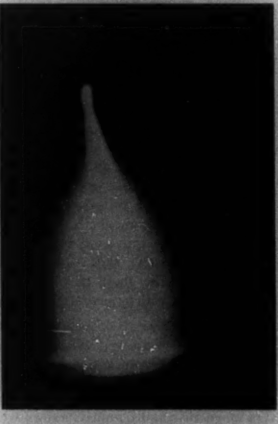

Fig. 1. Flare discharge: exposure 1/2 sec with 30,000 pulses per second; length of discharge 3 inches

---

Paper 60-103, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted September 30, 1959; made available for printing January 12, 1960.

Gaylord W. Penney and Samuel E. Craig are with the Carnegie Institute of Technology, Pittsburgh, Pa.

This work was supported in part by National Science Foundation grant *G2424* and was done in part by Samuel E. Craig in partial fulfillment of the requirements for the degree of Doctor of Philosophy at the Carnegie Institute of Technology.

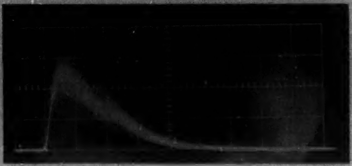

Fig. 2. Oscillogram of current pulse of flare discharge: exposure 3 sec with about 30,000 pulses per second. Time scale 0.1 μsec per division; current scale 18 ma per division

The current for a single flare has an average of 100 to 800 μamp (microamperes) but is made up of pulses having peak values of 10 to 60 ma (milliamperes). The pulse rises to a maximum in about 0.1 μsec (μsecond) and falls to less than 5% of the peak value in about 0.5 μsec. The time between pulses normally is about 33 μsec. The exact period between any two consecutive pulses may vary between 25 and 40 μsec. There is some random variation from one pulse to the next in both amplitude and time between pulses. The pulsation is not dependent on the external circuit or power supply. The pulse shape and its frequency of repetition are essentially the same regardless of the particular means by which the flare is produced; see Fig. 2.

These flares are easier to produce and are more stable in positive corona, but they can occur on the grounded electrode or anode in negative corona. Flares with negative corona are very important in precipitator operation since flares usually result in a very low flashover potential.

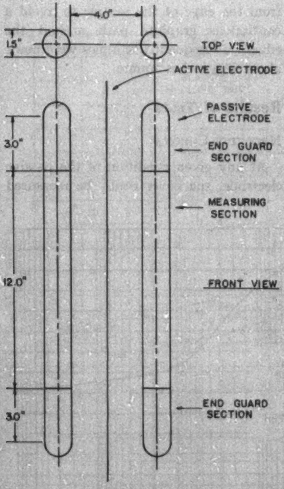

Fig. 3. Electrode dimensions used for sparkover tests

Apparatus

The tests were made with a wire at high potential between two parallel, grounded cylinders with all center lines lying in the same plane. This will be called the "wire between cylinders" arrangement. The arrangement was used because the discharge is relatively easy to see and photograph. The arrangement of electrode was enclosed in a box with a removable glass front.

Since the resistivity of most dusts and porous materials varies with the relative humidity, the temperature of the air in the box was varied to control the relative humidity. An electric heater was mounted in the box and a fan circulated the air very rapidly to insure a uniform temperature throughout the box. The large or passive electrodes were each 18 inches long. One of these electrodes consisted of a center section 12 inches long which was insulated from the end sections. This 12-inch insulated section was grounded through a meter for measuring the current per unit length of wire. The end sections served as guards and were grounded directly; see Fig. 3.

Early tests indicated that sparkover voltage depended on the resistivity of any coating on the anode. In the first apparatus with a single set of electrodes the resistivity was controlled by changing the relative humidity. But it takes a considerable time for it to reach equilibrium. Then, if the box is opened to make any change, it takes a considerable time for it to get back to equilibrium, and the relative humidity may not be exactly the same. To make it possible to change electrodes without disturbing the relative humidity, an apparatus was made with three pairs of passive electrodes and four active electrodes. These three electrode assemblies, shown in Fig. 4, were mounted in a box with the three shafts projecting through the box. Each shaft had a pointer outside the box. Thus, by rotating two shafts, any of the three pairs of cylindrical passive electrodes could be brought into the operating position. The third shaft had an insulating spider at each end. Four wires or active electrodes were supported by arms of these spiders. By rotating this shaft any one of these active electrodes could be brought into the operating position where it is connected to the high-voltage source by a member which also served as a latch. The other three wire electrodes were both out of the operating region and disconnected from the circuit. Thus, by operating controls outside of the box, any one of four active electrodes and any one of three pairs of passive electrodes could be placed in the operating position.

Since it is difficult to maintain a dust layer of uniform thickness, paper or cloth was used in most of the tests to cover the anode. Since such coverings tend to lower the sparking potential at some discontinuity in the covering, it is not necessary to cover the entire area. The electrode coverings on the electrodes in Fig. 4 show many dark spots where sparkover has occurred, but the number of these holes does not appreciably alter the sparkover potential provided that there is some break in the electrode covering. If an electrode is completely covered with an insulating layer having no holes, the initial sparkover voltage may be higher but, once the covering is punctured, the number of holes appears to be of no consequence. Most of the tests used paper or cardboard as the electrode covering. Some tests were made with ordinary cloth, glass cloth, and fly ash.

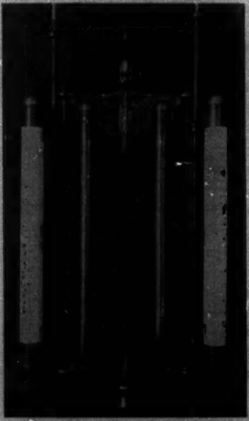

Fig. 4. Electrode assemblies

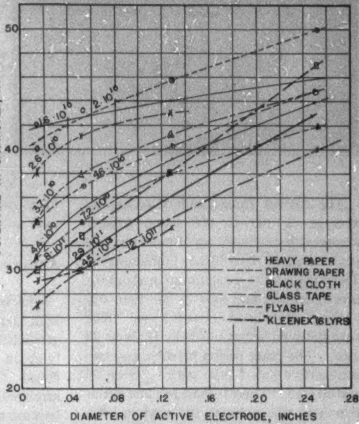
Measurement of Resistivity

The measurement of resistivity raises questions as to the equilibrium between the moisture content of the sample and the humidity of the air, particularly since the sample being tested is covered by the resistivity test electrodes. The test apparatus was designed to have the sample for the resistivity test in as nearly as possible the same condition as the material coating the electrodes. The resistivity tester was mounted in the same cabinet with electrodes. The upper electrode of the resisitivity tester could be moved by remote control so that one side of the sample was exposed to the atmosphere in the cabinet in the same manner as the electrode covering, except for the brief period when the resistivity was being measured and the upper test electrode was being pressed against the sample surface. The electrodes were each 2 inches square. The samples were very thin compared with 2 inches so that edge effects could be neglected.

First tests on the resistivity of heavy paper (cardboard 0.025 inch thick) showed that the current through the sample would commonly increase by a factor of 6 or 7 when the applied voltage was doubled. It was found that a much more linear relation between current and voltage was obtained when the sample was coated heavily with graphite where it contacted the electrodes. Apparently, for an uncoated sample, actual contact between the metal electrode and the sample occurs over only a fraction of the total surface, due to surface irregularities in the sample, and this fraction is increased by electrostatic force when the applied voltage is increased. This theory is substantiated by the fact that pressure on the electrodes affects the resistance through the uncoated sample, but pressure has no measurable effect when the sample is graphite coated. Subsequently, all paper samples were graphite coated where contact with a metal surface was involved. The graphite coating was kept about 1/4 inch away from the edge of the sample to avoid a continuous graphite path around the edge. Consequently samples were made about $2^1/_2$ inches square.

Fig. 5. Sparkover voltage as function of wire size for several passive electrode surface conditions with negative corona from a clean wire. Numbers at curves indicate resistivity of passive electrode coverings



Results of Tests

Negative Corona

At any given condition of the passive electrode, sparkover could be measured

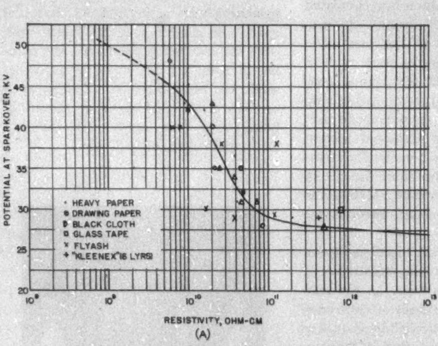


Fig. 6 Sparkover voltage as function of resistivity of passive electrode covering for negative corona from a clean wire. A—0.012-inch diameter. B—0.05-inch diameter. C—0.125-inch diameter

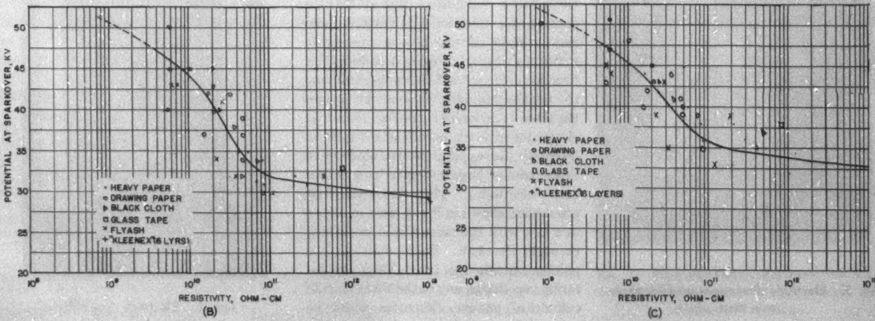

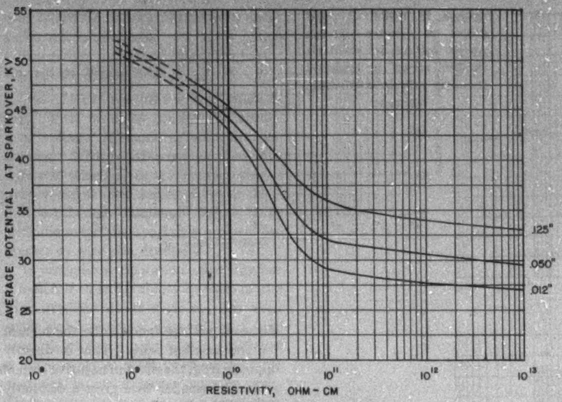

Fig. 7. Comparison of curves from Fig. 6

for four different sizes of active or high-voltage electrodes. Then, a pair of passive or large electrodes with a different covering could be brought into position and again sparkover measured with the same four active electrodes. The results of a number of such tests are plotted in Fig. 5. In this kind of test there is always considerable random variation. The curve for fly ash at 1.2×10^{11} ohm-cm (centimeters) lies below the curve for glass tape at 8×10^{11} ohm-cm and crosses the curves for heavy paper at 2.9×10^{11} ohm-cm and ordinary cloth at 4.5×10^{13}, but still fly ash at 2.6×10^{11} ohm-cm is up with the low-resistivity materials and the same fly ash at 1.2×10^{11} ohm-cm is down with the high-resistivity materials. All of the points for negative corona from a clean active electrode of 0.012-inch diameter are plotted as a function of resistivity in Fig. 6(A). While there is considerable scatter, there is a definite correlation with resistivity. Out of 31 points shown in Fig. 6(A) only four depart more than 10% of the flashover potential from the curve as drawn.

The results for a clean negative wire of 0.050-inch diameter are plotted in Fig. 6(B). In this case the correlation with resistivity is not as good, 11 out of 43 points lying at a potential more than 10% away from the curve as drawn. In spite of the scatter of the points the correlation with resistivity seems definite.

The curves of flashover voltage versus resistivity for three wire sizes are shown in Fig. 7. Because of the scatter and the number of conditions it was not considered feasible to show the points. In addition to the variation with resistivity, the flashover voltage decreases with wire size especially at higher resistivities.

In the case of negative corona with high-resistivity material on the active electrode, the results are essentially the same as when the active electrode is clean; see Fig. 8.

POSITIVE CORONA

In positive corona high-resistivity material on the passive electrode seems to have a somewhat smaller effect than in the case of negative corona. This is in agreement with the generally accepted idea that breakdown originates at the anode. Curves of breakdown potential versus wire size are shown in Fig. 9. In these cases breakdown is preceded by a high-current condition due to the back

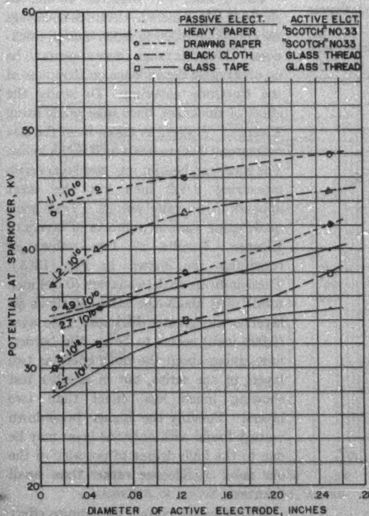

Fig. 8 (left). Effect of high-resistivity material on active electrode for negative corona. Numbers at curves indicate resistivity of passive electrode covering

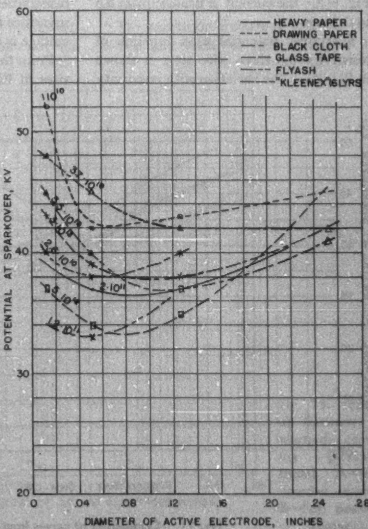
Fig. 9 (right). Sparkover voltage as function of wire size for several passive electrode surface conditions with positive corona from a clean wire. Numbers at curves indicate resistivity of passive electrode covering



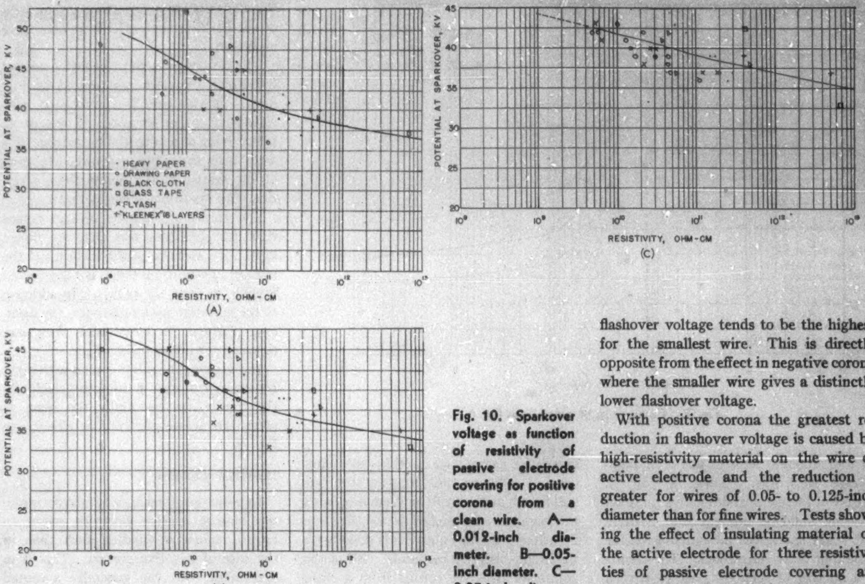


Fig. 10. Sparkover voltage as function of resistivity of passive electrode covering for positive corona from a clean wire. A—0.012-inch diameter. B—0.05-inch diameter. C—0.05-inch diameter

corona.[3] For the 0.012-inch wire the current may be as high as 5 ma per foot of wire prior to breakdown. For the comparable condition with negative corona Fig. 6(A), the current is usually from 0.5 to 0.8 ma.

Sparkover potential as a function of resistivity for three wire sizes is shown in Fig. 10. The variation with resistivity is not as great as in the case of negative corona but, still, the effects seems definite. With the 0.012-inch wire, Fig. 10(A) the highest flashover voltage is 37 kv for resistivities above 10^{12}, whereas for resistivities below 10^{10}, the lowest flashover voltage is 45 kv.

From the comparison of the three wire sizes in Fig. 11, it is evident that the flashover voltage tends to be the highest for the smallest wire. This is directly opposite from the effect in negative corona where the smaller wire gives a distinctly lower flashover voltage.

With positive corona the greatest reduction in flashover voltage is caused by high-resistivity material on the wire or active electrode and the reduction is greater for wires of 0.05- to 0.125-inch diameter than for fine wires. Tests showing the effect of insulating material on the active electrode for three resistivities of passive electrode covering are shown in Fig. 12. With insulating material on the wire or active electrode the flashover voltage is almost independent of resistivity of material on the passive electrode.

Effect of Thickness

The results for negative corona as shown in Fig. 6 include electrode coverings varying from 0.006 to 0.025 inch in thickness. Over this range there appears to be no observable dependence on thickness of the electrode covering. To study the effect of thickness, tests were made using Kleenex. A sheet as taken from the box measures 0.0032 to 0.004 inch in thickness. The sheet can be split into two layers each measuring 0.002 inch but the sheet appears to be quite porous. Tests were made using various numbers of layers of Kleenex. Results at two values of resistivity are shown in Fig. 13(A). These indicate that two layers (0.004 inch total) give about the same effects as six layers or any greater thickness. One layer (0.002 inch) seems to be on the borderline, giving about the same effect as two layers in one series, but in another test showing much less effect than two layers. Possibly the higher breakdown voltage found with only one layer may be due to the high degree of porosity of the one layer of Kleenex rather than small thickness.

With positive corona no definite effect

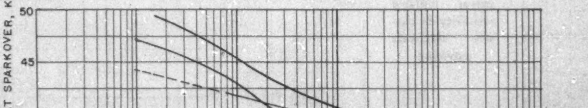

Fig. 11. Comparison of curves from Fig. 10

was discovered of thickness between 0.002 and 0.025 in thickness.

Effect of Wire Size

The effect of wire size is very interesting. With negative corona the sparkover voltage decreases as wire size decreases. With positive corona there is a wire size which gives a minimum sparkover voltage; this occurs between 0.05- and 0.125-inch diameter. Below 0.05-inch diameter the sparkover voltage increases as wire size decreases.

In precipitator operation a fine wire has a high self-cleaning ability because of the high gradient at its surface. But even with high-resistivity material on a fine positive wire, the reduction in sparkover voltage is not as great as when the same material is on a larger positive wire. High-resistivity material on a large positive wire usually produces flares, but the same material on fine wire will seldom result in a flare. In the present tests with fine wires, positive corona in general results in a higher sparkover potential than negative corona. However, for the wire sizes usually used in industrial precipitators, positive corona results in a distinctly lower sparkover potential than negative corona if there is any deposit on the wire.

Association of Flares with Sparkover

With high-resistivity material on a positive active electrode of 0.125-inch diameter, the flare type of discharge is particularly easy to produce and the flashover voltage especially low. The characteristic current pulses rise to a peak in 10^{-7} sec, and decay to a low value in approximately 5×10^{-7} sec. If the spacing to the passive electrode is four inches or greater it is relatively easy to produce a flare without accompanying sparkover. As the spacing is decreased, the probability of sparkover increases. At $1^1/_2$-inch spacing to the passive electrode, flares are almost always accompanied by frequent sparkover.

With negative corona the flares are associated with high-resistivity material on the passive electrode. Here they are much less stable and more likely to result in sparkover.

It appears that all cases of sparkover caused by high-resistivity material on anodes are preceded by these current pulses having about the same rise time. Of course, pulses having about the same rise and decay time have been observed by different experimenters and under somewhat different conditions. Parks[4] found higher current pulses having this characteristic rise and decay time. These were produced by applying a pulse between a sphere and plane. Other experimenters[5,6] have observed very similar pulses with clean electrodes at higher potential gradients. The characteristic rate of rise and decay of these current pulses would seem to indicate a common mechanism.

The repetition frequency and the rate of rise and decay of current appear to

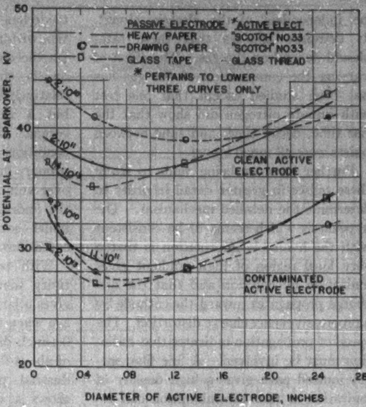

Fig. 12. Effect of high-resistivity material on active electrode for positive corona. Numbers at curves indicate resistivity of passive electrode covering

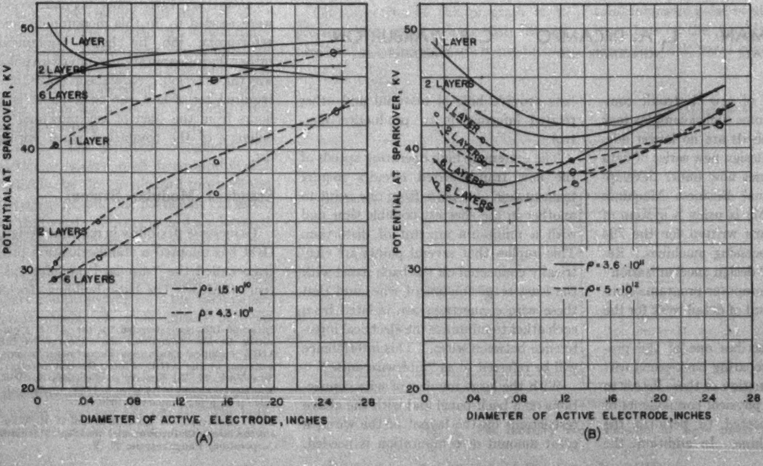

(A)

(B)

Fig. 13. Effect of thickness of electrode covering (Kleenex tissue). A—For negative corona. B—For positive corona

be independent of the electric circuit. It therefore appears that these rates should depend on the gas. The effect of varying the composition of the gas has not been studied except that one test with impure nitrogen did show that the rise time, decay time, and time between pulses were all much longer.

Further tests are being made to study these pulses in greater detail in order to determine the detailed mechanism. The hypothesis which seems to be consistent with the available information is that a very local region of high gradient gives ionization by collision and that the discharge propagates toward the cathode by a progressive space charge distortion. The speed of propagation indicates that radiation must be involved. A fine filamentary ionized path gives a high density of ionization so that recombination can account for the rapid decay of current. The present tests agree with Parks' tests in that if sparkover occurs there is a delay between the current pulse and the formation of a spark.

Conclusions

With negative corona there appears to be a definite correlation between sparkover voltage and the resistivity of any deposit or covering on the large or passive electrode. With positive corona, high-resistivity material on the passive electrode has a smaller effect and the correlation with resistivity is not as pronounced. On the contary, high-resistivity material on the small or active electrode has a relatively small effect with negative corona but a very large effect with positive corona. Thus it appears that the surface condition of the anode is the element of primary importance in determining sparkover voltage. This is in agreement with the findings of many other investigators under somewhat different experimental conditions.

With positive corona any high-resistivity material on the active electrode gives a large reduction in sparkover voltage when that electrode is of the order of 0.1-inch diameter. Thus with electrodes of about 0.1-inch diameter, as used in industrial precipitators, negative corona shows a considerably higher sparkover potential than positive corona. However, with a wire of less than 0.012-inch diameter as used in the low-voltage 2-stage precipitators, high-resistivity material on the positive active electrode has a much smaller effect, so that positive corona in general gives a higher sparkover potential.

While several types of high-resistivity materials were tested, it cannot be said that the tests are necessarily representative of all types of materials. It seems possible that some types exist which would not show the same correlation between resistivity and sparking. The effect of changes in atmosphere were not studied here; the tests reported were made with normal city air; the tests covered only a moderate range of absolute humidity.

These sparkovers at relatively low-voltage gradients are preceded by current pulses which characteristically rise to a peak in about 0.1 μsec and decay to a low value in 0.5 μsec. This rate of rise and decay of current seems to be a common characteristic of the prebreakdown currents observed by a number of investigators.

THE DESIGN of new electronic computers has become such a complex task that manual methods are no longer adequate. To help design new series of data processing machines now under development, International Business Machines Corporation (IBM) is using a system of computer programs written for the *704* and *705* data processing machines. Referred to as the "design mechanization" programs, these computer programs eliminate a large amount of detail work for the design engineer.

This paper describes one of the programs used for preparing back-panel wiring lists. The function of these lists is to describe how the physical components of circuits are connected to perform the logic of the machine. In addition, the lists provide bills of material and other related information to production control.

The extremely high operating speeds of the new transistorized circuits require transmission of a pulse from one point to another in the shortest possible time and with a minimum amount of distortion. This implies that several points are electrically connected on the back panel with the least total amount of wire, and that these wire connections are isolated from each other to minimize the electrical interference between wires. This interference will be referred to as "interwire noise."

With the large number of wire connections on a back panel and with the above restrictions on the layout of the wires, a great amount of computation is needed. Correlating these requirements now necessitates the use of a computer. Formerly, on an average, two engineering man-weeks were needed to do this monotonous and error-prone job by hand. Judgment rather than computation of interwire noise was the criterion. Now the average time required for a first run of a panel is 6 hours from the start of key punching to delivery of the completed panel wiring list.

Standard Modular System

To increase flexibility in machine design, IBM has adopted a standardization program called the "standard modular system" (SMS). The basic building blocks

in this system are printed circuit cards; see Fig. 1. The cards are plugged into a panel (Fig. 2) consisting of an array of sockets, numbered horizontally from left to right (1–28) and lettered vertically from top to bottom (A–K, excluding I). Pins protrude from the sockets to form a circuit card extension at the back of the panel; Fig. 3. The functioning of the circuits depends on how these pins are interconnected. The circuits that must be electrically common to perform a logical function possess certain pins which must be wired to each other. These pins as a group will be referred to as a "net." Each pin in the panel has a standard pin notation which represents its physical location. The notation designates the particular socket used horizontally and vertically by the circuit card to which the pin connects, and the particular pin letter for that card. Pins of a card are lettered from top to bottom (A–R, excluding I and O).

The matrix of pins, spaced 1/4 inch apart and projecting from the back panel, forms specific channels (spaces between rows) in which the wires must lie. Fig. 4 shows that these channels lie in four directions: horizontal (pin 6 to pin 7), vertical (pin 6 to pin 5), and two diagonals (pin 1 to pin 2 and pin 3 to pin 4). The horizontal channels fall into two categories, those that lie between: 1. horizontal rows of cards, referred to as major horizontal channels; and 2. horizontal rows of pins, referred to as minor horizontal channels. It can be seen from Fig. 4 that there is no straight-line route for a connection between pins 8 and 9.

General Description of Program

The objective of the program is to prepare back-panel wiring lists and a panel bill of material for use in production and assembly. Fig. 5 shows a general flow chart of the program. The wiring lists contain information about wire types, wire connections and their lengths, and wire routing. To accomplish this, the program accepts as input for multiple nets the pins that are electrically common, and determines the wire connections necessary to link these pins. It routes these connections in a simulated panel so that the total interwire noise of all the wires with the others on the panel is at a minimum. Since the back panel consists of a matrix

of pins 1/4 inch apart horizontally and vertically, the program converts the standard pin notation into an easily manipulated rectangular co-ordinate system with an eighth of an inch as its unit of length. Engineering tests have shown that the panel pins offer sufficient shielding for wires lying in adjacent channels. Hence, only interwire noise between wires which lie in the same channel and which overlap with each other needs to be considered. With the co-ordinate system, the program can consider the major horizontal (card row) channels as equivalent to six horizontal rows of imaginary pins which offer no shielding. This makes calculation of the noise interference between nonisolated wires in these channels practical.

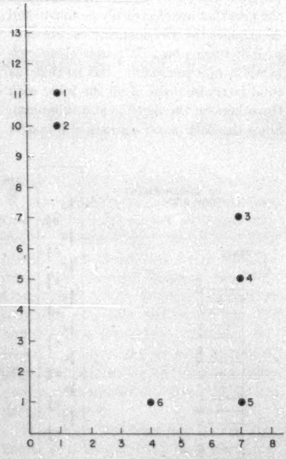
To do back-panel wiring, it is necessary that the *704* program receive certain information about the panel pins which are to be grouped together and made electrically common. This information, which is stored on magnetic tape and used as input to the program, is produced either from cards key-punched from lists prepared manually by the engineer, or from other computer programs of the design mechanization system. The latter programs use information received from the engineer to check the machine's logical design, to print lists of errors and component counts, and to formulate the standard notation for those pins that are to be connected on the back panel. The manually prepared lists of pins submitted by the engineer to do the same job lack the design mechanization system's ability to do error checking and to prepare bills of material, for instance, needed for machine production. However, the manually prepared lists do allow the engineer greater flexibility. He can specify to the program certain conditions that may be exceptions to the general rules; for example, his need to be able to:

1. preassign certain wire connections between pins, as well as the wire type used
2. designate pins that can only be used once
3. indicate certain wire types that must be used with particular pins
4. indicate certain wire types that must remain as he has preassigned them
5. indicate the maximum number of wraps (normally 2) that may be made to the pins of the panel

After the input has been translated into rectangular co-ordinate form, the program is ready to interconnect the pins of each net in an optimum manner, subject to production and engineering requirements.

Details of Procedure

Given *n* pins in a net, list in increasing order of length all the possible combinations of line segments which could link



(A)

M	Line	R	M'
1	1, 2	1	1
2	3, 4	2	2

6, 7

this net. Then select the $n-1$ shortest line segments which do not contain any redundant lines or violate any rules.

The procedure can best be explained by an example. Suppose that the net shown in Fig. 6(A) is the one to be connected. All possible combinations of distances are computed and then sorted on increasing length, Fig. 6(B). In all cases the distances are computed only along the four allowable directions. A number M is then assigned to each of these distances. The steps to achieve a solution can be traced by referring to Figs. 6(B) and (C).

1. Bring out the first line (1, 2). Put its points in a "synonym table" (ST).
Assign $M^1 = M$. ST *1*——1,2

2. Bring out the next line (3, 4). Neither point is in ST *1*, so:
Assign $M^1 = M$. Generate ST *2*——3, 4

3. Bring out line (5, 6). Neither point is in ST *1* or ST *2*, so:
Assign $M^1 = M$. Generate ST *3*——5, 6

4. Bring out line (4, 5). Point *4* appears in ST *2* and point *5* in ST *3*. Therefore, ST *3* is added to ST *2*, and then ST *3* is erased. Hence:
Assign $M^1 = M$. ST *1*——1, 2
ST *2*——3, 4, 5, 6

5. Bring out the line (4, 6). Both points appear in the same synonym table, hence there is a redundant line. Assign M^1 equal to 1+(the maximum M). The synonym tables remain the same as in step 4.

6. Follow the same procedure as step 5 for line (3, 5).

7. Bring out line (2, 3). Point *2* appears in ST *1* and point *3* appears in ST *2*. Therefore ST *2* is added to ST *1* and then erased, leaving:
ST *1*————1, 2, 3, 4, 5, 6
ST *1* now has n(6) points, thus signifying that a solution has been reached.

8. Finally, select the $n-1$ lowest values of M^1, thus finding the $n-1$ lines which connect the n points.

5,6
4,5
2,3

Note that this method closely parallels the procedures of Loberman and Weinberger.[1] However, the procedures discussed in their paper were not completely applicable when the lines to a point were subjected to restrictions. In extending their procedures to include the previously mentioned restrictions, the authors of this paper do not guarantee an optimum solution.

For a given net, the method described would require n^2-n storage locations in excess of those required for the program itself. However, to conserve memory space, since n may be large, all the computed lengths for possible connections are not saved. Instead, the *704* data processing machines program connects the points of the net by successively computing the next shortest line whenever a new connection is to be made. Tests are made to determine if a calculation is necessary, depending on the given restrictions. The program then saves the accepted wire connections obtained and simulates an initial solution for the routing of the panel.

The next consideration, after all the nets have been connected, is to reduce interwire noise pickup within each net of the panel below an allowable limit determined by the engineer. At the same time, the program attempts to keep the length of each wire in the net the same as the length found initially. Using the initial solution for a particular wire as a starting point, alternate routes of equal length (in most cases there are several) are examined to find the one with the lowest noise level at this particular point of the computation. That route is then accepted as the new solution. The following relationship is used to compute interwire noise:

Noise = amount of wire overlap (inches) × noise-generating constant

Fig. 7 shows an example of the routing process. Assume that wire (1, 2) is the first one to be routed. All the equal length paths within the parallelogram are tried, Figs. 7(B)–(G). Path *6* is the one with the least amount of noise, since that wire does not overlap at all with the other wires. Thus the noise on this net has been reduced from $N = X_1$ to $N = 0$, while the wire length has remained constant. In the same way the program then tries to reduce the noise on the second net (4, 5, and 4, 6).

In the process of rerouting a straight wire, it becomes necessary to add a slight amount to the wire length. For these cases, the program tries only a limited number of paths on each side of the straight wire.

It is apparent that the solution found for the first net may be affected by a rerouted wire in a later net. Theoretically the program should resolve all the wires affected by a routing change. However,

```

Fig. 9. Wiring list

because of machine time considerations, it was decided to allow the program to complete the routing of all the nets in the panel and then go back to the beginning and reroute the complete panel again. This was done to take into account the effect of all the rerouted wires on all the other wires in the panel.

The next step in the procedure is to test the computed noise level of each net in the panel against an allowable limit set by the engineer. If the noise level is excessive, the program reduces it below the limit by changing the type of wire used. Take as an example the configuration of Fig. 8, keeping in mind that there are many other wires in the panel which may have had an effect on this particular solution. Suppose that the total noise on all the wires in net *1* is greater than the allowable limit and that all the wires shown are single-strand. The program chooses the wire in net *1* with the highest noise level and changes it to a type of wire with the next lowest noise level as shown in the following breakdown. Thus the single-strand wire (3, 4) would be changed to a twisted pair. This procedure is repeated until the noise level specification is met for each net. Interwire noise decreases with each of the following changes in wire types:

1. Single-strand coupled to single-strand.
2. Single-strand coupled to twisted-pair.
3. Twisted-pair coupled to twisted-pair.
4. Single-strand coupled to coaxial (zero noise).
5. Twisted-pair coupled to coaxial (zero noise).
6. Coaxial coupled to coaxial (zero noise).

A secondary objective of the program is to alter previously computed panel wiring to accommodate engineering changes. To be considered a working tool by the engineer, it is necessary for the back-panel wiring program to incorporate any new additions and deletions to a panel without disturbing existing wires in their type or routing. The engineer can then investigate many variations on a particular panel, even override machine decisions under exceptional conditions, and receive results in time for evaluation. To production engineering and to the records-keeping area, the latest back-panel wiring list for a particular machine represents the most recent version of that panel.

The updating or change program for panel wiring closely parallels the methods used in the original wiring of a back panel. Input into the program may be from the design mechanization system as a result of a change or addition to logic design, or by a request from the

engineer to add or delete pins in an existing panel. Nets are processed one at a time to determine if they have been affected by the modification. If there have been no changes made to a net, the program enters its old wires into the simulated panel with its original routing. If updating results in enlarging a net by the addition of pins, the program will retain the original wiring of the net and its routing and connect the new pins to the old net by the same method described earlier. If updating results in reducing the number of pins in a net, the unwanted wires will be deleted, the remaining wire connections preserved, and the net reoptimized. Any new wires resulting from a change adhere to original panel restrictions.

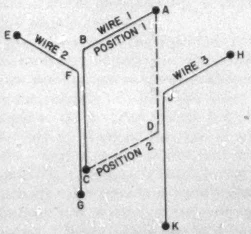

Fig. 13. Example of total panel interwire noise decrease

Since all the wires of the panel, both old and new, are entered into the machine, the increase in the noise interference caused by the additional wiring can be measured and steps can be taken to decrease this additional noise.

Output

When the simulated panel within the machine is completely wired and routed, the rectangular co-ordinates describing the connections are reconverted into back-panel pin notation. This information is stored on magnetic tape as a permanent record of the panel, containing panel identification, net number, wire length, wire type, and coded engineering data. Such invaluable aids in development and manufacturing as wiring lists, Fig. 9, bills of material, Figs. 10 and 11, and production time estimates, Fig. 12, can be extracted from this tape.

Summary and Conclusions

Briefly, the program initially minimizes over-all wire length on a panel while taking into account the following restrictions:

1. The maximum allowable number of connections to a pin.
2. Routing wires in channels to preserve wire length.
3. Accepting wire connections preassigned by the engineer.

It reroutes the wires, keeping their lengths constant to decrease the total overlap on the panel and hence to decrease total panel interwire noise. Noise is computed as follows:

$$\text{Noise (per net)} = L_1K_1 + L_2K_2 + \ldots + L_nK_n$$

where L_n = the length of overlap of a wire with another wire lying in the same channel and K_n = a function of length which depends on the wire types coupled together.

Essentially, by repositioning the wires into less dense channels, L (total overlap) is decreased, and by keeping K constant the total interwire noise in the panel is decreased; see the Appendix. After several iterations the final reduction of noise on each net is accomplished by keeping L constant and varying K, i.e., changing the wire types of the various wires that are coupled together.

The back-panel wiring program has produced to date 2,700 panels for the Poughkeepsie Product Development Laboratory groups. Previously, it required two engineering man-weeks to specify routings on a panel. By machine the average time to process a panel is 30 minutes of computer time and 6 hours of key punching and verification. This represents a saving in time (which is essential in all development projects) and in effective manpower (relieving the engineer from routine tasks and enabling him to work creatively), and results in a better solution. Under the old system, records were not always correctly updated, changes resulted in many clerical errors, engineering and production were not always assured of having the latest changes, and measurement of capacitance on the panel was impossible. Automation by the computer lays a greater burden on the engineer by requiring him to set down his problem in minute detail and by making him adhere more closely to the design rules he has set up. However, he is amply compensated by receiving more accurate results faster.

Appendix

Assume that three wires on a panel are located in the respective positions illustrated in the solid lines of Fig. 13. Assume that wire *2*(EFG) and wire *3*(HJK) have their positions fixed and that the program is attempting to reposition wire *1*(ABC). Insofar as the program attempts to decrease the total amount of overlap of all wires in the panel with all others, it can be seen from the illustration that wire *1* in position *1* has more overlap with wire *2* than wire *1* in position *2* has overlap with wire *3*. Hence by moving wire *1* from position *1* to position *2* the total overlap is decreased.

Since interwire noise is dependent upon length of overlap, moving wire *1* from position *1* to position *2* decreases the noise on wire *1*. It should be noted also that the increase in noise on wire *3* is less than the decrease in noise on wire *2*. Hence, by repositioning wire *1* to a location where its noise is decreased, the total panel interwire noise is decreased to produce a better solution.

Symmetrical Frequency Multiplier Circuits

GEORGE W. DICK
ASSOCIATE MEMBER AIEE

IN RECENT TIMES there has been considerable renewed interest in the use of static magnetic cores to produce power at a multiple of the frequency of a power source. Generally in these circuits, nonlinear magnetic reactors are connected in a symmetrical multiphase fashion, using the cores to produce harmonics and using symmetrical interphase connections to isolate desired groups of harmonics without the use of filters. In previous studies[1,2,3] several circuits of this type have been evaluated showing their characteristics when used either as a power supply or as a combined converter and power amplifier.

The synthesis and analysis of frequency multipliers of this type is complicated both by the presence of nonlinear elements and by the multiplicity of different linear network connections which can be used to isolate a particular group of harmonics. Examples of such topological variations are shown in Fig. 1 where only two nonlinear elements are used and even harmonic outputs are obtained. When from 2 to 6 nonlinear elements are used, the number of different circuit interconnections gives rise to roughly about 200 different frequency multipliers, many of which, as in Fig. 1, isolate the same harmonic output components. The selection of a best circuit of those in Fig. 1 for instance, will be related to economic factors and the particular application of the device, i.e., whether input power factor, saturating core cost, or output voltage level is most significant. The purpose, then, of the following investigation is two-fold. First, to determine generally what circuits constitute a frequency multiplier and to show what output frequencies are obtainable from such circuits. Secondly, to show the equivalence of various circuits so that the results obtained from a generalized analysis of one circuit can be used to evaluate several others.

General Discussion

A qualitative study of a general frequency multiplier circuit is proposed. By the application of methods of Fourier series and symmetrical component analysis, the synthesis and operation of this circuit and its equivalents will be defined. The following postulates are shown to be sufficient for the production and separation of groups of harmonics in a frequency multiplier, and they will be adopted as the basic assumptions of this study.

1. Time-varying driving voltages are periodic with a fundamental frequency $\omega_0 = \frac{2\pi}{T_0}$
2. Capacitive elements, if used within the system, do not create subharmonics or ferroresonant conditions.
3. Multiphase circuits consist of symmetrical arrangements of linear and nonlinear elements. Specific arrangements which have this property are to be defined.
4. All p-phase sets of voltages within the

Paper 60-66, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted June 22, 1959; made available for printing December 9, 1959.

GEORGE W. DICK, formerly with the University of Toronto, Toronto, Ont., Canada, is now with Bell Telephone Laboratories, Inc., Murray Hill, N. J.

This material represents a part of the author's doctoral thesis research at the Department of Electrical Engineering of the University of Toronto. The assistance of Prof. G. R. Slemon in supervising this project, is gratefully acknowledged. Both his and Prof. P. P. Biringer's suggestions have contributed to the theory and presentation of the paper.

The financial support of the Defense Research Board of Canada under Grant *4001–02* to the University of Toronto is also appreciated.

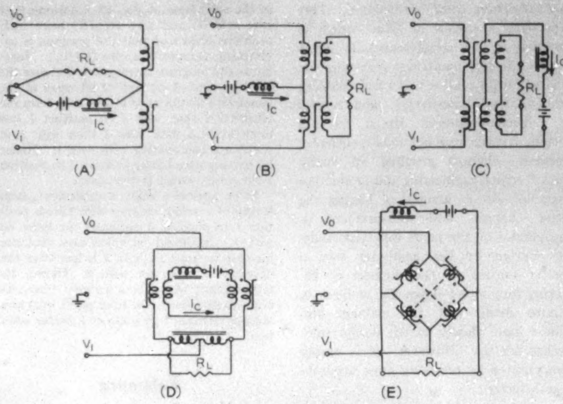

Fig. 1. **Equivalent frequency doubler circuits**

system, and including driving sources, are balanced in a time-sequential sense, i.e., if the voltages $v_0, v_1, v_2 \ldots v_{p-1}$ make up a balanced p-phase set

$$
\begin{aligned}
v_1(t) &= v_0(t - T_0/p)\\
v_2(t) &= v_0(t - 2T_0/p)\\
\vdots \quad & \quad \vdots\\
v_k(t) &= v_0(t - kT_0/p)\\
\vdots \quad & \quad \vdots\\
v_{p-1}(t) &= v_0(t - (p-1)T_0/p)
\end{aligned}
$$

A general circuit of this type is shown symbolically in Fig. 2. The circuit represents a tandem connection of symmetrical, multiphase series circuits, each composed of different sets of linear and nonlinear elements. Note that a nonspecific symbol has been chosen for the nonlinear element since it might represent a saturating core, diode, or other nonlinear electrical device. As a result of the basic assumptions it can be stated, regarding the nonlinear elements in any multiphase section of Fig. 2, that the currents through them as well as their terminal voltages must be time sequential in the steady state. Then without further reference to nonlinearities, except possibly to regard then as sources of harmonics, linear superposition methods may be applied to prescribe symmetrical phase-reducing networks between sections of specific circuits. Accompanying each phase reduction there is shown to be a related isolation of harmonic components.

Before proceeding it is worthwhile to note the significance of assumption 4 regarding multiphase voltages. When only fundamental and odd-harmonic voltage components are present, the conventional single-phase 3-wire, or Edison system, represents what is defined as a time-sequential system 2-phase system. Generally, however, there is a definite distinction between time-varying single-and 2-phase balanced systems. Fig. 3 shows that it is not possible to consider the single-phase voltage $V_{01}(t)$ as a time-sequential 2-phase system of voltages $V_{0n}(t)$ and $V_{1n}(t)$. Similar considerations must be applied if it is desired to convert a conventionally termed 2-phase source of harmonic voltages to a balanced 4-phase system.

Phase Sequential Harmonic Components

As a result of the previous basic assumptions the harmonic components of a p-phase set of voltages or currents can be defined in terms of the corresponding components at a reference node or branch of the set. Considering $v_0(t)$ a reference node voltage.

$$v_0(t) = \sum_{\omega=-\infty}^{\infty} V_0(j\omega) e^{j\omega t} \tag{1}$$

where

$$V_0(j\omega) = \frac{1}{T_0} \int_0^{T_0} v_0(t) \epsilon^{-j\omega t}\, dt \tag{2}$$

Since $V_0(-j\omega) = \bar{V}_0(j\omega)$, a complex or vectorial representation of $v_0(t)$, can be made by considering only the positive frequency components in the complete Fourier series of equation 1.

Let

$$V_0(t) = \sum_{\omega=0}^{\infty} V_0(j\omega) \epsilon^{j\omega t} \tag{3}$$

where

$$V_0(j0) = \frac{1}{T_0} \int_0^{T_0} v_0(t)\, dt \tag{4}$$

$$V_0(j\omega) = \frac{2}{T_0} \int_0^{T_0} v_0(t) \epsilon^{-j\omega t}\, dt \quad \text{For } \omega \neq 0 \tag{5}$$

hence

$$v_0(t) = \frac{1}{2} (V_0(t) + \bar{V}_0(t))$$

Then utilizing assumption 4 the harmonic components of $V_1(t)$ can be related to those of $V_0(t)$

$$
\begin{aligned}
V_1(j\omega) &= \frac{2}{T_0} \int_0^{T_0} v_0(t - T_0/p) \epsilon^{-j\omega t}\, dt\\
&= \epsilon^{-j\omega T_0/p}\, V_0(j\omega)
\end{aligned}
$$

Let

$\omega = q\omega_0$, where $q = 0, 1 \ldots \infty$

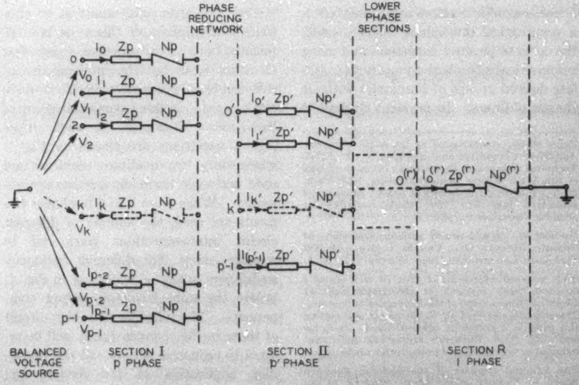

Fig. 2. **General frequency multiplier tandem configuration**

Vol
Pt.
196

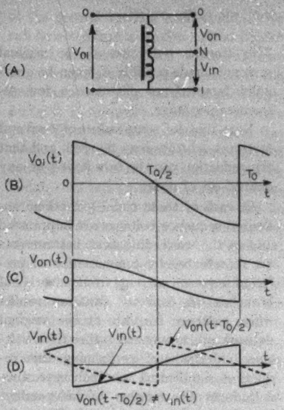

Fig. 3. Distinction between one- and two-phase time sequential voltages

$$V_1(j\omega)=\epsilon^{-jq\,2\pi/p}\,V_0(jq\omega_0)$$

Similarly $V_k(j\omega)$ referring to phase k

$$=\epsilon^{-jkq\,2\pi/p}\,V_0(jq\omega_0)$$

Since

$$\epsilon^{-jkq\,2\pi/p}=\epsilon^{-jk(q+np)2\pi/p}$$

for integers q, and n, by allowing q to take the values 0, 1, 2 … p-1, and n to take all positive integral values 0, n each harmonic component is defined by a different (q, n) and the complex Fourier series for $V_k(t)$ can be sectioned into p infinite subseries each of which corresponds to a particular q, and is related to the corresponding subseries of $V_0(t)$ by an individual phase operator

$$\epsilon^{\,jkq\,2\pi/p}$$

i.e.

$$V_k(t)=1\sum_{n=0}^{\infty}V_0(j(0+np)\omega_0)\epsilon^{j(0+np)\omega_0 t}+$$
$$\epsilon^{-jk1\cdot 2\pi/p}\sum_{n=0}^{\infty}V_0(j(1+np)\omega_0)$$
$$\epsilon^{j(1+np)\omega_0 t}\ldots+\epsilon^{-jkq\,2\pi/p}\sum_{n=0}^{\infty}V_0(j(q+$$
$$np)\omega_0)\epsilon^{j(q+np)\omega_0 t}\ldots+\epsilon^{-jk(p-1)2\pi/p}$$
$$\sum_{n=0}^{\infty}V_0 j(p-1+np)\epsilon^{(p-1+np)\omega_0 t} \qquad (6)$$

Each of these subseries of $V_0(t)$ represent a complex time functional component denoted by $V_{0q}(t)$ which may be referred to as a qth sequence component of $V_0(t)$

$$V_{0q}(t)=\sum_{n=0}^{\infty}V_0(j(q+np)\omega_0)\epsilon^{-j(q+np)\omega_0 t} \qquad (7)$$

and the real-time functional component is given by

$$v_{0q}(t)=\frac{1}{2}[V_{0q}(t)+\bar{V}_{0q}(t)]$$

where

$$\bar{V}_{0q}(t)=\sum_{n=0}^{\infty}V_0(-j(q+np)\omega_0)\epsilon^{+j(q+np)\omega_0 t}$$

Then

$$V_0(t)=\sum_{q=0}^{p-1}V_{0q}(t) \qquad (8)$$

$$v_0(t)=\sum_{q=0}^{p-1}v_{0q}(t) \qquad (9)$$

It is important to note that the sequence components $v_{0q}(t)$ are orthogonal time functions because any two of these obtained for different values of q do not contain similar elementary harmonic functions.

Since

$$\int_0^{T_0}V_0(j\omega_1)\epsilon^{j\omega_1 t}\,V_0(j\omega_2)\epsilon^{j\omega_2 t}dt=0 \text{ for } \omega_1\neq\omega_2$$

Then

$$\int_0^{T_0}v_{0q_1}(t)v_{0q_2}(t)dt=0 \text{ for } q_1\neq q_2$$

This property is used in a later section concerned with the design of circuit components on the basis of rms currents or voltages. It implies

$$[V_0(\text{rms})]^2=\sum_{q=0}^{p-1}[V_{0q}(\text{rms})]^2 \qquad (10)$$

From equation 6 the sequence components of $V_k(t)$ can be expressed in terms of those of $V_0(t)$

i.e.

$$V_{kq}(t)=\epsilon^{-jkq\,2\pi/p}\,V_{0q}(t) \qquad (11)$$

Giving

$$V_k(t)=\sum_{q=0}^{p-1}\epsilon^{-jkq\,2\pi/p}\,V_{0q}(t) \qquad (12)$$

The relationship between node voltages and the sequence components of the reference phase is conveniently shown in matrix notation by

$$[V_k(t)]=[\epsilon^{-jk,q\,2\pi/p}][V_{0q}(t)] \qquad (13)$$

The inverse relationship also must exist and is

$$[V_{0q}(t)]=[\epsilon^{+jk,q\,2\pi/p}][V_k(t)] \qquad (14)$$

Similar relationships will apply to balanced p-phase branch currents.

Synthesis of a Tandem Circuit

Apparently expressions 13 and 14 are identical to those used in fundamental frequency, symmetrical component analysis. It is noted however, that each of the sequence components described here are summations of vectorical harmonic components. If these vectors were known at any given time the transformation would give the value of the phase voltages. The expressions are used in this study since they give a single-phase frequency-domain interpretation of the time-sequence condition for multiphase voltages or currents.

First equation 13 can be used to define a symmetrical phase reducing network for the p-phase section of the general frequency multiplier circuit. In the following phase transformation for $p=6$ columns of the matrix indicate that certain sequence components occur at different nodes k in identical phase, i.e., for $q=0$, 2, 3, and 4.

$$\begin{bmatrix}V_0(t)\\V_1(t)\\V_2(t)\\V_3(t)\\V_4(t)\\V_5(t)\end{bmatrix}=\begin{bmatrix}1&1&1&1&1&1\\1&b&b^2&b^3&b^4&b^5\\1&b^2&b^4&1&b^2&b^4\\1&b^3&1&b^3&1&b^3\\1&b^4&b^2&1&b^4&b^2\\1&b^5&b^4&b^3&b^2&b\end{bmatrix}\begin{bmatrix}V_{00}(t)\\V_{01}(t)\\V_{02}(t)\\V_{03}(t)\\V_{04}(t)\\V_{05}(t)\end{bmatrix}$$

where

$$b=\epsilon^{-j2\pi/6}$$

The zero sequence components will always be in phase for all lines regardless of the value of p. A symmetrical p to 1 phase reduction can always be made by joining all k nodes to a common $0'$ node. The effect of such a nodal reduction is to reduce the number of independent phase voltages to 1 and from equation 14 it can be shown that all sequence voltage components at the original k nodes are eliminated except for those of the zero sequence. The time sequence condition is still applicable to these nodes and the system remains symmetrical.

In general other nodal reductions will be possible provided p can be factored by any integer p'. In this case some qth sequence voltage component q_1 where $q_1 p'=p$, will be present at nodes

$$k,\ k+p',\ k+2p'\ldots k+(q_1-1)p'$$

in equal phase since

$$\epsilon^{-jkq_1\,2\pi/p}=\epsilon^{-j(k+p')q_1\cdot 2\pi/p}\ldots\text{etc.}$$

Note that the zero sequence is also present at these nodes with equal phase, and so is the q_1th sequence component if

$$q_1 p'=2p,\ 3p\ldots\text{or }(p'-1)p$$

In order to obtain a symmetrical reduc

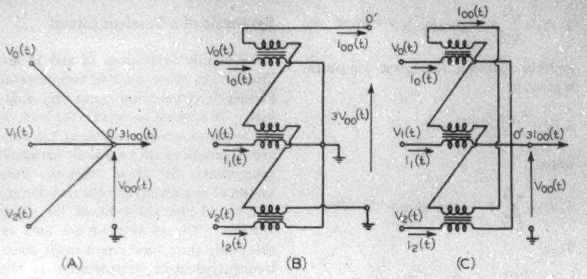

Fig. 4. Linear nodal and branch reducing networks for $p=3$, $p'=1$

A—Nodal reduction

B—Branch reduction
$I_0(t)=I_1(t)=I_2(t)=I_{00}(t)$

C—Alternative branch reduction
$I_0(t)=I_1(t)=I_2(t)=I_{00}(t)$

tion with the suppression of all other sequence voltages, all nodes having the sequence components q_1 in equal phase must be treated similarly. Where

$$q_1p'=0,\ p,\ 2p\ldots(p'-1)p \qquad (15)$$

Thus

node 0 is joined to node $0'$
node 1 is joined to node $1'$
$\vdots$
node $p'-1$ is joined to node $(p'-1)'$
node p' is joined to node $0'$
node $p'+1$ is joined to node $1'$
$\vdots$
node $p-1$ is joined to node $(p'-1)'$

This has produced a balanced p-phase set of node voltages containing sequence components given by equation 15. The reduced phase system is time sequential on both a p-phase basis and a p'-phase basis if it is understood that each new node or branch represents more than one of those of the original system. A p'-phase set of equal linear and nonlinear components can be included in this section followed by another nodal phase reduction to some factor p'' of p'. Sequence voltage components of the following p'' phase system are given on the original p-phase basis by

$$q_1p''=0,\ p,\ 2p,\ \ldots(p''-1)p$$

This treelike reduction of the original system is made possible if p can be gradually factored to eliminate a few sequences per stage.

Note that for some values of p several factoring schemes may be used, and that the reduction can be terminated at any desired set of nodes.

At each of these nodel reductions undesired sequence voltages are suppressed and in the succeeding branches currents are represented by a summation of preferred sequence currents from the original branches. A converse situation results when sequence currents of the original network are suppressed rather than voltages. Methods of performing this reduction, signified as a branch type since it reduces the number of independent branch currents, are shown in Fig. 4 for $p=3$, $p'=1$.

A modified reduction network such as shown in Fig. 4(C) using an ideal, nonsaturating, core-type trans-former is necessary when zero-sequence direct currents are to be propagated. In the general frequency multiplier circuit either nodal or branch reduction networks can be chosen to connect any two multiphase sections. Branch reductions allow elimination of sequence current components from the driving source and first section

of the general tandem configuration. It can be noted from equation 15 that fundamental frequency (first sequence) currents would always be eliminated if the first phase reduction were of branch type. Since it is normally desired to convert power from the fundamental, source frequency, to load power in higher sequence components, the first reduction must be nodal. All other possible sequence isolations for a given p-phase system can be determined empirically by performing alternative nodal or branch reduction schemes on the tandem configuration.

It is noted that the use of nonlinear elements after the first section of the general circuit of Fig. 2 can effect quantitative changes in the various sequence components but cannot isolate these in a manner different from a purely linear-phase-reducing network. In the following discussion only one p-phase of set nonlinear elements will be referred to, with succeeding p', p'', ... phase sections composed of linear elements. Qualitative results then obtained could be extended to fit the more general case. Examples of linear phase reductions are given for $p=6$ in Fig. 5.

EQUIVALENT CIRCUITS

It was indicated at the beginning that many magnetic-core frequency multiplier circuits could be used to obtain a given frequency output. Such circuits, if symmetrical, will be mathematically equivalent to a frequency multiplier with tandem connections. Their performance can be related to that of the latter, by the method of superposition in terms of sequence quantities. As in symmetrical component analysis sequence impedances will be used to represent balanced sets of linear network elements. In this case however, sequence voltages and currents are represented in the frequency domain by infinite series of discrete harmonic coefficients. Hence the expression $V_{0q}(t) = I_{0q}(t)\, Z_q$ will imply

$$V_{0q}(t) = \sum_{n=0}^{\infty} I_0(j(q+np)\omega_0) Z_q(j(q+np)\omega_0) \epsilon^{j(q+np)\omega_0 t}$$

and Z_q must be indicated explicitly by a function of frequency $Z_q(j\omega)$. Fortunately, in practice most frequency multiplier sequence impedances can be closely approximated by series combinations of resistance and inductance, so that such a function can be characterized by a single complex number $Z_q(j\omega_0)$ or $Z_q(jq\omega_0)$ for instance.

If the nonlinear element terminals are considered as balanced p-phase source terminals superposition can be used to obtain sequence impedances in the linear network as seen from these elements. Sequence networks are obtained for a single nonlinear section in the form shown in Fig. 6. In this diagram $V_{0q}(t)$ refers to the external driving source, $Vn_{0q}(t)$ refers to the sequence components of the voltages at the nonlinear element terminals.

If there is an equal, unique relationship between time-varying terminal quantities for each member of the set of nonlinear elements, there must be a one-to-one relationship between sequence voltages and currents for the p-phase set when the prescribed symmetry assumptions are met by the entire circuit. When saturating cores with multiple windings are used, the nonlinear relationship exists between mutually induced voltages or flux and the total ampere turns acting on each core. By various winding connections sequence currents are allowed to flow in different paths, but the effect on the total ampere turns will be the same if external driving forces and sequence impedances are identical. The sequence network diagram can then be used to indicate the equivalence of various linear network connections and results obtained for one circuit in terms of sequence quantities are applicable to all equivalent versions.

For the reduction networks of Fig. 5 if impedance branches were used in each branch, or nodal reduction, it is apparent that the number of independent branch impedance functions is equal to the number of reduction stages. Similarly the number of independent sequence impedances and the number of isolated combinations of sequence quantities is equal to the number of reduction stages.

The tandem circuit can be used effectively as a model for quantitative analysis of equivalent connections as some simplification usually is obtained. Note however that physically, this model will not be equivalent in all cases, because of a restraint which it places on sequence impedances. For example in Fig. 5(A) the sequence impedances are equal to

$$Z_0 = Z_p + 6Z_L$$

$$Z_1 = Z_2 = Z_3 = Z_4 = Z_5 = Z_p$$

where Z_p is the series impedance in the first stage. Hence the nonlinear elements always see a zero-sequence impedance equal to or larger than that of other sequences. Using saturating cores with mutually coupled windings this constraint is not necessarily imposed. Mathematically however, there is no difference between the two circuits and identical sequence impedances can be obtained possibly requiring a fictitious, negative branch impedance in the model. A similar situation occurs commonly, when using a T equivalent circuit for a 2-winding transformer.

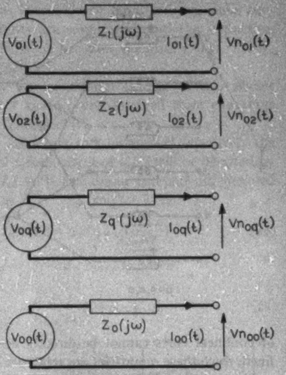

Fig. 6. Sequence networks as seen from a single set of nonlinear elements

In finding equivalent circuits one practical circuit variation deserves some further consideration. When the number of independent nonlinear elements in a single section are even, a normal p-phase driving source, if it contains only odd harmonic quantities can be obtained from $p/2$ of the phase voltages, by the use of simple transformers.

From equation 11 it is seen that for q odd

$$V_{p/2q}(t) = \epsilon^{jq\pi} V_{0q}(t)$$

$$= -V_{0q}(t)$$

Hence the odd harmonic voltages in phase $k+p/2$ are reflections of those in phase k. Rather than use transformers on the set of $p/2$ source voltages, phases $k+p/2$ can be driven directly from phase k. If a zero sequence source such as a d-c current is applied externally it must also be reversed on phases $k+p/2$. Other even sequence components generated in these phases will also be reversed so that various changes are necessary in phase-reducing networks, in order to maintain symmetrical frequency multiplier operation. Examples of such modified circuits are shown in Fig. 1(D) and in reference 3. The sequence impedances can be found for these circuits by superposition, applying modified phase, sequence components at the nonlinear element terminals.

Quantitative Circuit Analysis

The steady-state relationship between sequence voltage and currents on a set

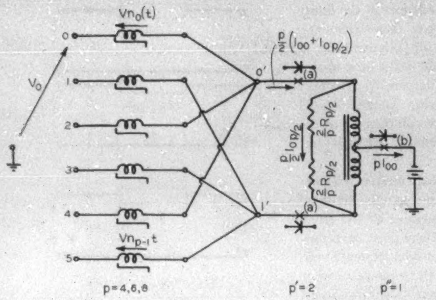

Fig. 7 (above). Example of a 6–2–1 reduced magnetic frequency multiplier

$R_{p/2} = R_{\text{load/phase}}$
$Z_{q=0}$ for $q \neq p/2$

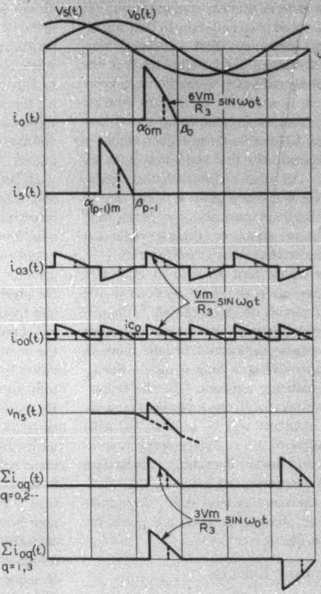

Fig. 8 (right). Waveforms for the 6–2–1 reduced frequency multiplier

of nonlinear cores cannot be directly defined, since these quantities are related to total element voltages and currents by linear superposition. Time domain relationships are defined however, and using these on the total voltage and currents appearing in a tandem frequency multiplier will give a quantitative solution in terms of sequence components. These will be obtained directly in time functional form and can then be characterized by rms, average or harmonic functional values.

SATURATING CORE FREQUENCY MULTIPLIERS

For the analysis of these saturating core circuits a piecewise linear approximation of core **B-H** loops has been found suitably accurate. Magnetic frequency multipliers operating under load provide large enough magnetic intensities on cores to render the effect of saturated reactance essentially linear. However the combined effect of this with leakage reactance and coil resistance must usually be considered to obtain accurate analytical results. Time response of the circuits under cyclic switching transients have been obtained using the Laplace transformation.[1] The equations and results in such an analysis are found by using various *s* functional impedances. From the previous study it is seen that if these impedances are related to sequence impedances the analysis will apply to a number of linearly equivalent circuits. The use of equivalence in this manner is of great advantage since the complete solution for one circuit in terms of two or three independent parameters has been found to require considerable time and effort even with the aid of a digital computer.

In order to illustrate the use of generalizations obtained in this discussion and also to indicate an important use of diodes in tandem sections of a frequency multiplier, a highly idealized multiplier circuit will now be treated quantitatively. Such an analysis has been used effectively to make comparisons between frequency multipliers on the basis of optimum performance.[2,3] The circuit chosen here uses the 6–2–1 reduction network of Fig. 5(C) and is a d-c controlled frequency multiplier.

The idealizing assumptions which are made in this analysis are:

1. The nonlinear cores are ideal having infinite unsaturated and zero saturated state reactances. Hysteresis and eddy currents are neglected.
2. Excitation is provided by an ideal, balanced, sinusoidal voltage, driving source and an ideal d-c control source. Saturating reactors are designed to obtain knee-point flux excursions, when no control current flows.
3. Windings have zero resistance and linear transformers and diodes are ideal.

In order to rate various equivalent connections it is necessary to find the rms value of isolated groups of sequence currents. For the 6–2–1 reduction all sequences currents flow in the first section, sequences $q=0$, $p/2$ flow in the second ($p'=2$) section and the zero sequence in the last. Where the circuit is inverted to operate from a 3-phase source the combined rms value of odd sequences also must be known for power-factor determination. The design of the ideal branch reducing transformer will be determined by the maximum volt-second integral of the third-sequence voltage across the load and the rms value of zero sequence current. For comparison purposes, the size of the saturating reactors can be obtained by determining their combined volt-amperage rating as a 2-winding power transformer.[2,3] A similar "rating factor" is applied to the ideal transformer. Capacitive power factor correction at the source will require knowledge of the reactive component of fundamental frequency input current. The modulus of the first output component $I_{0p/2}(jp/2\omega_0)$ will also be obtained.

In a piecewise linear analysis of this type it is found that similar modes of operation occur in circuits of different original phase order p, which have the same reduced phase sections, i.e., 6–2–1, 4–2–1, 8–2–1. In obtaining results from one analysis if the factor p is used explicitly, numerical results although different, can be directly obtained for all such circuits. The same is true in analyses which include internal reactance effects. The circuit of Fig. 7 for $p=6$ is treated in this manner.

It is noted in Fig. 7 that the d-c control source is placed in series in the zero sequence path of the tandem circuit. Since d-c power is not necessary for the operation of ideal frequency multipliers, no d-c resistance is placed in this path. Hence any desired direct current is obtained with an infinitesimal direct control voltage. The circuit operation however is entirely equivalent when a parallel zero sequence path with current limiting resistance is provided, along with a shorted final branch. Usually this parallel path will use mutually coupled windings on the saturating core. Looking into the linear circuit from the cores gives the same sequence impedances, and for a given direct control magnetomotive force, operation is identical. Chokes are usually necessary in frequency multiplier circuits to allow a low resistance d-c path in the zero sequence, along with a high harmonic-frequency impedance.[1-3]

Using the time symmetry condition all steady-state sequence quantities can be found if node and branch time functional quantities can be defined for one subperiod $T_{0/p}$. This period is conveniently taken from the angular time α_0 when core N_0 saturates.

For

$$\alpha_0 \leq \omega_0 t < \alpha_0 + \frac{2\pi}{p}$$

with N_0 saturated $2V_0$ appears across the ideal transformer and

$$p/2 i_{0p/2}(t) = \frac{2V_0(t)}{\frac{4}{p} R_{p/2}}$$

$$i_{0p/2}(t) = \frac{V_0(t)}{R_{p/2}} \tag{16}$$

For

$$V_0(t) = V_M \sin \omega_0 t$$

$$i_{0p/2}(t) = \frac{V_M}{R_{p/2}} \sin \omega_0 t \tag{17}$$

Since no net ampere-turns act on the ideal transformer

$$p/2 i_{00}(t) = p/2 i_{0p/2}(t)$$

$$i_{00}(t) = \frac{V_M}{R_{p/2}} \sin \omega_0 t \tag{18}$$

$$i_0(t) = p/2\left[i_{00}(t) + i_{0p/2}(t)\right] = p\,\frac{V_M}{R_{p/2}} \sin \omega_0 t \tag{19}$$

$$i_k(t) = 0 \text{ for } k \neq 0 \tag{20}$$

Core N_0 comes out of saturation at $\omega_0 t = \beta_0$ when $i_0(t) = 0$ during this interval. Hence β_0 is defined by $\sin \beta_0 = 0$

$$\beta_0 = \pi \tag{21}$$

For

$$\beta_0 \leq \omega_0 t < \alpha_0 + 2\pi/p \text{ all } i_{kq}(t) = 0$$

For this mode of operation, termed mode I, only one core is saturated at any given time. Equations 17–21 will define all isolated sequence components for this mode.

Mode II will occur if at some time in the period, two cores are simultaneously saturated. The initiation of mode II is indicated by the flux in the remaining cores N_k for $k \neq 0$. In the period $\alpha_0 < \omega_0 t < \alpha_0 + 2\pi/_p$, Core N_{p-1} will be the one to initiate mode II since its flux is at the saturation value at $\beta_{p-1} = \beta - 2\pi/p$. The voltage across N_{p-1} is shown in Fig. 8. For the period $\beta_{p-1} \leq \omega_0 t < \alpha_0$

$$vn_{(p-1)}(t) = V_M \sin(\omega_0 t + 2\pi/p)$$

For the period $\alpha_0 \leq \omega_0 t < \beta_0$

$$vn_{(p-1)}(t) = V_{p-1}(t) + i_{0\,p/2} R_{p/2}$$

and using equation 17

$$vn_{(p-1)}(t) = V_M[\sin(\omega_0 t + 2\pi/p) + \sin \omega_0 t)] \tag{22}$$

$$\varphi n_{(p-1)}(t) = \frac{1}{\omega_0} \int_{\beta_{p-1}}^{\omega_0 t} Vn_{(p-1)}(t)\, d\omega_0 t + \varphi_s \tag{23}$$

From Fig. 8 it is seen that $\varphi n_{(p-1)}(t)$ will reach a minimum at α_0 and then again approach φ_s dependin on the value of α_0. At the limit of mode I

$\int_{\beta_0}^{\omega_0 t} vn_{(p-1)}(t)\, d\omega_0 t$ will reach a maximum positive value of zero at a time $\omega_0 t > \alpha_0$ given by

$$vn_{(p-1)}(t) = 0$$

From equation 22 this time is $\omega_0 t = \pi - \pi/p$.

The limiting firing angle for mode I, α_{0M}, is then obtained from equation 32. Since

$$\int_{\pi-2\pi/2}^{\alpha_{0M}} \sin(\omega_0 t + 2\pi/p)\, d\omega_0 t + \int_{\alpha_{0M}}^{\pi-\pi/p} (\sin \omega_0 t + \sin(\omega_0 t + 2\pi/p)\, d\omega_0 t = 0 \tag{24}$$

which gives

$$\alpha_{0M} = \cos^{-1}(1 - 2\cos \pi/p) \tag{25}$$

Operation in mode II during the interval in which N_0 and N_{p-1} are saturated can be found by inspection of Fig. 7. The voltage $v_0(t) + v_{p-1}(t)/2$ is applied to the zero sequence path and $v_0(t) - v_{p-1}(t)/2$ to the $p/2$ sequence path. Obviously this operating condition cannot be permitted in an ideal circuit of this type since $Z_0 = 0$. However in practical cases it can be used as it is found that with sufficient zero sequence reactance more power output is attainable. If $Z_0(j\omega)$ for $\omega \neq 0$, is allowed to become very large zero-sequence currents are suppressed and the reduction network becomes essentially that of Fig. 5(B).[2]

The maximum ratings of this circuit for $\alpha_0 = \alpha_{0M}$ are obtained from equations 17–19 and 25.

Since it can be applied separately the d-c component of $i_{00}(t)$ will be denoted by I_{c0} with remaining components denoted as $i_{00}'(t)$, $I_{00}'(\text{rms})$. Then

$$I_{00}(\text{rms}) = [I_{c0}^2 + I_{00}'(\text{rms})^2]^{1/2} \tag{26}$$

$$I_{c0} = p/2\pi \int_{\pi-2\pi/p}^{\pi} i_{00}(t)\, d\omega_0 t$$

$$= \frac{V_M}{R_{p/2}} \frac{p}{2\pi} (1 + \cos \alpha_{0M}) \tag{27}$$

$$I_{00}(\text{rms}) = \frac{V_M}{R_{p/2}} \left[p/2\pi \int_{\pi-2\pi/p}^{\pi} i_{00}^2(t)\, d\omega_0 t \right]^{1/2}$$

$$= \frac{V_M}{R_{p/2}} [p(\pi - \alpha_{0M} + \tfrac{1}{2} \sin 2\alpha_{0M}/4\pi)]^{1/2} \tag{28}$$

$I_{c0}'(\text{rms})$ is found from equations 26 and 27. Since $i_{0p}/_2(t) = \pm i_{00}(t)$ depending on the interval

$$I_{0p/2}(\text{rms}) = I_{00}(\text{rms}) \tag{29}$$

using equation 19 the value of $I_0(\text{rms})$ is related to $I_{00}(\text{rms})$ by

$$I_0(\text{rms}) = \sqrt{p}\, I_{00}(\text{rms}) \tag{30}$$

Fourier Analysis of $i_c(t)$ can be used to find the active and reactive fundamental frequency components. However the active component is simply related to the power output

$I_{0x}(j\omega_0)$ referring to the rms value of the reactive component

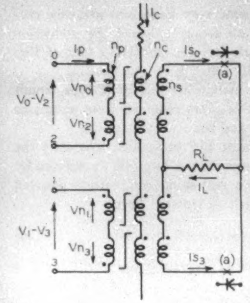
$$= -\frac{0.707}{4\pi} p \frac{V_M}{R_{p/2}} [1 - \cos 2\alpha_{0M}] \tag{31}$$

$$I_{0A}(j\omega_0) = \frac{p_{\text{out/phase}}}{0.707 V_M} = \frac{I_{0p/2}(\text{rms}^2) R_{p/2}}{0.707 V_M} \tag{32}$$

The complex value of the first harmonic output component is obtained by Fourier Analysis of $I_{0p/2}(t)$ expressed as an rms magnitude $I_0(jp/2\omega_0)$ becomes

$$\frac{V_M}{R_{p/2}} \frac{0.707}{\pi} \frac{4p}{p^2-4} \left\{ \left[(-1)^{p/2+1} + \frac{p-2}{4} \cos(p/2+1)\alpha_{0M} - \frac{p+2}{4} \cos(p/2-1)\alpha_{0M} \right] + j\left[\frac{p-2}{4} \sin(p/2+1)\alpha_{0M} - \frac{p+2}{4} \sin(p/2-1)\alpha_{0M} \right] \right\} \tag{33}$$

The rating factor[2] of the saturating cores is given by



$Vn_k(t)$ SEQUENCE COMPONENT PHASE ANGLES

k	Vn_{k1}	Vn_{k2}	Vn_{k3}	Vn_{k0}
0	→	→	→	→
1	↓	←	↑	→
2	←	→	←	→
3	↑	←	↓	→

Fig. 9 (above). Experimental circuit of the p–2–1 type, for p = 4

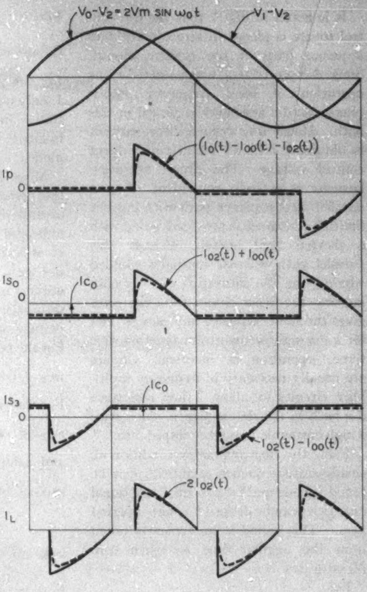


Fig. 10 (right). Predicted and observed waveforms for the experimental 2x multiplier

———Predicted results
- - - - -Experimental results

$$\text{RF (cores)}=V_M\frac{\frac{0.707}{2}I_0(\text{rms})}{p_{\text{out,phase}}} \qquad (34)$$

Note that with separate windings for various sequences this factor would be increased. If one separate winding were provided for zero sequence, and $p/2$ sequence quantities, the rms value of the remaining sequences in the primary winding (from equation 10) is given by

$$I_p(\text{rms})=[I_0{}^2(\text{rms})-I_{00}{}^2(\text{rms})-I_{0p/2}(\text{rms})]^{1/2}$$

The rating factor then becomes

$$V_M\times\frac{\frac{0.707}{2}I[_p(\text{rms})+\sqrt{I_{00}{}^2(\text{rms})+I_{0p/2}{}^2(\text{rms})}]}{p_{\text{out/phase}}}$$

on a primary turns basis.

A rating factor can also be obtained on the same output power basis for the ideal transformer. Its equivalent fundamental frequency voltage rating per phase is given by

$$\frac{1.11}{\pi}\int_{\pi-2\pi/p}^{\pi} i_{0p/2}R_{p/2}d\omega_0 t$$

$$=\frac{1.11}{\pi}V_M(1+\cos\alpha_{0M}) \qquad (35)$$

Hence

$$\text{RF (trans)}=\frac{\frac{1.11}{2\pi}V_M(1+\cos\alpha_{0M})I_{00}(\text{rms})}{p_{\text{out/phase}}} \qquad (36)$$

The method of obtaining the time function representing all combined odd sequences is shown in Fig. 8. The rms value of these is given by

$$\left[\sum_{q=1,3,5\ldots p-1} I_{0q}{}^2(\text{rms})\right]^{1/2}$$

and is seen to be equal to

$$\frac{1}{\sqrt{2}}I_0(\text{rms}) \qquad (37)$$

Using equations 26 to 37 design data for multipliers of this type with $p=12, 8, 6, 4$ are given in Table I. Results are normalized with $V_M=1.0$, $R_{p/2}=1.0$.

As an example, the operation of an experimental 4-core frequency multiplier shown in Fig. 9 will be predicted on an ideal basis. Data for this unit are as follows:

Cores. Deltamax toroidal no. *3T5690 D4* (Arnold)
$2^1/_2$ by $3^3/_4$ by $1^1/_2$ inches – 4 mill
$n_p=273$, $n_s=546$, $n_c=826$

$V_0-V_2=1.414\times120\sin\omega_0 t$
$V_1-V_3=1.414\times120\sin(\omega_0 t-\pi/2)$

$R_L=50$ ohms

Using the primary turns as a basis

$$V_0(t)=84.8\sin\omega_0 t$$

The relative directions of the sequence components of $Vn_k(t)$ are shown in Fig. 9. Applying these to the primaries a sequence at a time gives

$$i_p(t)=i_{01}(t)+i_{03}(t)$$

$$i_{s0}(t)=\frac{n_p}{n}[i_{02}(t)+i_{00}{}'(t)]$$

$$i_{s3}(t)=\frac{n_p}{n_s}[i_{02}(t)-i_{00}{}'(t)]$$

$$i_c=\frac{n_p}{n_c}I_{c0} \text{ where } \frac{n_p}{n_c}I_{c0}+\frac{n_p}{n_s}i_{00}{}'(t)=i_{00}(t)$$

$$i_L=\frac{2n_p}{n_s}i_{02}(t)$$

$$Z_2=R_L\left(\frac{N_s}{N_p}\right)^2=12.5 \text{ ohms}$$

From the equations of the preceding section the waveforms can be predicted using the relation

$$i_{01}(t)+i_{03}(t)=i_0(t)-i_{02}(t)-i_{00}(t)$$

These are shown on a primary turns basis in Fig. 10 along the observed values. Ratings are obtained using Table I.

$$I_p(\text{rms})=[I_0{}^2(\text{rms})-I_{02}{}^2(\text{rms})-I_{00}{}^2(\text{rms})]^{1/2}$$

$$=\frac{84.8}{12.5}[0.956^2-0.478^2-0.478^2]^{1/2}$$

$$=4.58A$$

$$I_s(\text{rms})=\frac{1}{2}[I_{02}{}^2(\text{rms})+I_{00}{}'(\text{rms})^2]^{1/2}$$

$$=\frac{1}{2}\frac{84.8}{12.5}[0.478^2+0.298^2]^{1/2}=1.91A$$

$$I_L(\text{rms})=I_{02}(\text{rms})=\frac{84.8}{12.5}0.478=3.24A$$

$$I_c=\frac{273}{826}I_{c0}=\frac{273}{826}\left(\frac{84.8}{12.5}\right)(0.373)=0.837A$$

Measured values are found at the

Table I. Ideal Ratings for p–2–1 Reduced Frequency Multiplier with $Z_{p/2}(j\omega)=R_{\text{load/phase}}$ and all other $Z_q=0$

$I_{0A}(j\omega_2)$	0.322	0.168	0.0985	0.0447
p_{out}/phase	0.228	0.119	0.0696	0.0316
Rating F (cores)	1.48	2.51	3.79	6.90
Rating F (trans)	0.217	0.1332	0.102	0.067

approximate limit of mode I, in Fig. 11(A) to be about 10% lower than predicted values, since primary and secondary winding impedances have been neglected. Predicted values would nevertheless be useful for approximate coil design.

The theoretical rating factor for the saturating cores of this configuration is given by

$$\frac{0.707}{2}\left\{\frac{[I_0^2-I_{02}^2-I_{00}^2]^{1/2}+[I_{02}^2+I_{00}'^2]^{1/2}+I_{c0}}{I_{02}^2}\right\}=2.49$$

This value is considerably higher than the combined value for the cores (1.48) and the transformer (0.22) of the tandem circuit. This circuit has the advantages however, of lower input power factor and separate windings for control and output quantities.

SELF-SATURATION

One disadvantage of d-c controlled frequency multipliers such as those described in this and in past articles,[1–8] is their need of substantial externally applied control magnetomotive force. This disadvantage is felt in power amplifier applications[1] since the control source must have considerable power output capacity to achieve rapid amplifier response. It is also felt in converter-power-supply applications where control current remains fixed at full output level regardless of load. As others have demonstrated[1–8] magnetic frequency multipliers behave essentially as a current source with regard to output unless at the maximum control level. Unfortunately with large control currents, removal of load does not cause any corresponding drop in rms input currents which become then mainly reactive. If the frequency multiplier is forced to supply its own d-c component, then as in the case of magnetic amplifiers, operation becomes very nearly that of a controlled voltage source with high gain, and removal of load also automatically reduces input currents to a negligible value.

In the analysis of the ideal tandem circuit of Fig. 7 it has been noted that in the steady state no finite direct voltage is necessary in the zero sequence path. Furthermore, since the cores cannot pass any negative load currents the currents in this path are always either zero or positive. Hence diodes could theoretically be instantaneously inserted in a symmetrical fashion at points A or point B of Fig. 7 without affecting circuit operation. In these locations the diodes are able to sustain direct magnetomotive force on all the cores, and the infinitesimal, direct voltage source could then be removed without affecting steady-state system behavior. In practice the cores will have finite unsaturated impedances and a very small quantity of externally applied direct current will be necessary to sustain a given level of operation. Also because of this magnetizing component, small negative currents are normally required in the p-phase section of the circuit so that insertion of diodes at this point could cause an entirely different and undesirable mode of operation.

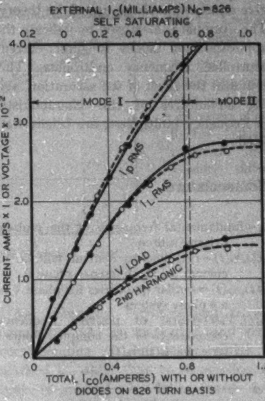

Fig. 11. Control characteristics for the 2x multiplier of Fig. 9 with and without self-saturation

——— Without self-saturation
– – – – With self-saturation

The same argument can be applied to any of the d-c controlled types of frequency multiplier. This has been proved experimentally with several basically different types such as typified by Fig. 5. It can be performed as indicated on equivalent connections such as those in Fig. 9 and also on circuits which are inverted to operate from lower phase sources. However, a strict requirement is provided in that the diodes must be placed symmetrically in the path of all zero-sequence components. In circuits having negligible zero sequence resistance no change is observed in the mode of operation, and results such as those of Table I can be used for rating purposes. With circuits having this property the steady state reverse voltage appearing on the diodes is usually only a small fraction of the line voltage, although with transients, peaks of this order do appear.

In Fig. 11 the control characteristics of the experimental unit of Fig. 9 are compared with and without self-saturation. Only the mode I type of operation has been included in the graphs although mode II operation is possible in both cases. The slight offset at the zero control point in Fig. 11(B) is caused by mismatches, or slight unbalances in the circuit. Changing the line voltage causes slight variations in this offset, however, the effect is not nearly as great as that observed in conventional magnetic amplifiers. The transient response of the device has been observed to be similar to that of a frequency multiplier without diodes operated at no load.[1]

Summary

A generalized steady-state theory of symmetrical frequency multiplier operation has been presented. This has provided principles for the synthesis of circuits and also a basis on which to obtain quantitative results applicable to various multipliers with equivalent connections. Considerable simplification in analysis is obtained by using a circuit model for a specific analysis.

A particular idealized frequency multiplier has been quantitatively analyzed to give an example of the use of the theory. The example is also used to indicate the application of diodes to direct-current controlled, frequency multipliers. This produces the effect of self saturation, and the advantages of this characteristic in frequency multipliers, are briefly outlined.

Nomenclature

ω_0 = fundamental frequency of the p-phase driving source
$i_0(t)$, $v_0(t)$ = real line to neutral voltage or current on the reference phase 0
$i_k(t)$, $v_k(t)$ = similar quantities for phase k or a p phase system
$I_k(t)$, $V_k(t)$ = total of positive frequency components of the complex Fourier series for $i_k(t)$, $v_k(t)$
$I_{0q}(t)$, $V_{0q}(t)$ = component functions of $I_k(t)$ $V_k(t)$ given by summation of the positive frequency harmonic components with $\omega=(q+np)\omega_0$
$i_{0q}(t)$, $v_{0q}(t)$ = real value of $I_{0q}(t)$, $V_{0q}(t)$
$I_{0q}(j\omega)$, $V_{0q}(j\omega)$ = complex harmonic spectrum of $i_{0q}(t)$, $v_{0q}(t)$ containing frequency components for $\omega=(q+np)\omega_0$
$I_{c0}=I_{00}(j0)$
I_{0q}, or I_{0q}(rms) = rms value of the real, time function $i_{0q}(t)$
Z_q or $R_q=Z_q(j\omega)$ linear driving source sequence impedance as seen from a p-phase set of nonlinear elements
I_{00}'(rms) = combined rms value of all zero-sequence components except the direct current
$I_{0x}(j\omega_0)$ = reactive component of fundamental frequency source currents
$I_{0A}(j\omega_0)$ = active component of fundamental frequency source currents
RF (cores) = rating factor of the cores
RF (trans) = rating factor of the center-tapped transformer or its volt-ampere rating as a fundamental frequency transformer
N_k = nonlinear element in phase k
$Vn_k(t)$ = total terminal voltage across N_k

Locking Range of an Oscillator for Different Nonlinearities

B. R. NAG
NONMEMBER AIEE

Synopsis: Dependence of the locking range of an oscillator on the character of the stabilizing nonlinearity is studied in this paper and it is shown that a lower order nonlinearity provides a wider range.

LOCKED oscillators are used in various fields of communication engineering for synchronizing frequencies of oscillators belonging to a common system. A desirable property of the oscillators is that the locking range for a fixed amplitude of the locking signal should be large. The locking range is mainly determined by the nature of the nonlinearity in the oscillator. In most of the theoretical studies, the oscillator nonlinearity is assumed to be cubic. It is the purpose of this paper to study the dependence of the locking range on the character of the nonlinearity. Theoretical derivations are based on van der Pol's method of approximation.[1] Experimental results for checking the theoretical derivations have been obtained with the help of an electronic differential analyzer.

Theoretical Derivation of Locking Range

The oscillator is considered to be described by a second-order equation which may be written as:

$$\ddot{x}-a\dot{x}+\mu f(\dot{x})+\omega_0^2\, x=E \sin \omega t \qquad (1)$$

where a is the initial negative damping coefficient, $\mu f(\dot{x})$ is the nonlinearity, and $E \sin\ \omega t$ is the locking signal.

The general solution of equation 1 consists of the forced oscillation of frequency ω, free oscillation of frequency ω_0 and the oscillations of harmonic and combination frequencies. If ω is close to ω_0, free oscillation is suppressed and the oscillator executes oscillation of forcing frequency only and is said to be locked. If a and μ are small, the harmonics of the forced oscillation have little effect and in the first order of approximation may be neglected. When study of the locked behavior of the oscillator is the objective, the solution is assumed to be of the form:

$$x=A \sin(\omega t+\phi) \qquad (2)$$

A and ϕ are determined by E, a, μ, ω and the functional form of $f(\dot{x})$. It is noted that since the damping coefficient is nonlinear, though the solution may be periodic in the steady state, in the transient conditions A and ϕ vary with time. But the variation is slow so that $\ddot{A}$, $\dot{A}\dot{\phi}$, $\ddot{\phi}$, $a\dot{A}$, $a\dot{\phi}$, $\mu\dot{A}$, and $\mu\dot{\phi}$ are negligible in comparison with A and ϕ.

Differentiating equation 2:

$$\dot{x}=\omega A \cos(\omega t+\phi)+\dot{A} \sin(\omega t+\phi)+A\dot{\phi} \cos(\omega t+\phi) \qquad (3)$$

Differentiating again and neglecting the small-order terms:

$$\ddot{x}=-\omega^2 A \sin(\omega t+\phi)+2\omega\dot{A} \cos(\omega t+\phi)-2\omega A\dot{\phi} \sin(\omega t+\phi) \qquad (4)$$

Substituting in equation 1 x, $\dot{x}$, and $\ddot{x}$ from equations 2, 3, and 4 respectively, and keeping only the terms of fundamental frequency contributed by $\mu f(\dot{x})$, one obtains:

$$(\omega_0^2-\omega^2)\, A \sin(\omega t+\phi) -\omega a A \cos(\omega t+\phi)+a_1 \cos(\omega t+\phi)+b_1 \sin(\omega t+\phi)+2\omega\dot{A} \cos(\omega t+\phi)-2\omega A\dot{\phi} \sin(\omega t+\phi)=E \sin(\omega t+\phi) \cos \phi-E \cos(\omega t+\phi) \sin \phi \qquad (5)$$

where a_1 and b_1 are the coefficients of $\cos(\omega t+\phi)$ and $\sin(\omega t+\phi)$ respectively, in the Fourier expansion for $\mu f[\omega A \cos(\omega t+\phi)]$.

On equating the coefficients of sine and cosine terms on the two sides of equation 5 one obtains:

$$2\omega\dot{A}=-E \sin \phi+\omega A a-a_1 \qquad (6A)$$

$$2\omega A\dot{\phi}=-E \cos \phi+[(\omega_0^2-\omega^2)/\omega]\, \omega A+b_1 \qquad (6B)$$

In the absence of the forcing signal, the amplitude of free oscillation is obtained from equation 6(A) on putting $\dot{A}=E=0$. Let the amplitude of free oscillation be called ρ_0. Also, at this stage, normalize the amplitude of the locking signal, detuning, and the amplitude of the locked

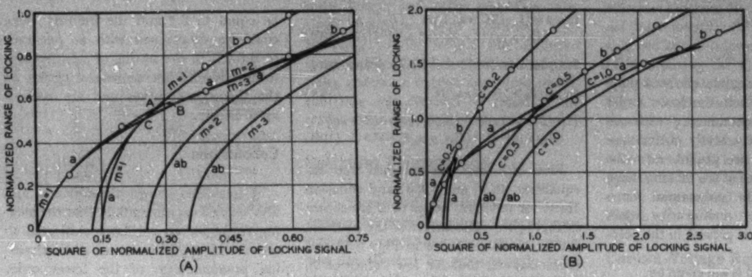

Fig. 1. Locking ranges

A—For polynomial-type nonlinearity, different values of m

B—For dead-zone-type nonlinearity, different values of C

oscillation, and call them F, δ and ρ, respectively. F, δ and ρ are defined as:

$$F=E/a\rho_0,\ \delta=(\omega_0^2-\omega^2)/a\omega,\ \rho=\omega A/\rho_0$$

Equations 6(A) and 6(B) in terms of these normalized quantities may be written as:

$$2\dot{\rho}=a[-F\ \sin\ \phi+\rho-a_1/a\rho_0] \tag{7A}$$

$$2\rho\dot{\phi}=a[-F\cos\ \phi+\delta\rho+b_1/a\rho_0] \tag{7B}$$

In the locked condition of the oscillator $\dot{\rho}=\dot{\phi}=0$. On putting $\dot{\rho}=\dot{\phi}=0$ in equations 7(A) and 7(B) and combining them, one obtains.

$$F^2=(\rho-a_1/a\rho_0)^2+(\delta\rho+b_1/a\rho_0)^2 \tag{8A}$$

$$\tan\ \phi=(\rho-a_1/a\rho_0)/(\delta\rho+b_1/a\rho_0) \tag{8B}$$

Equations 8(A) and 8(B) give, respectively, the amplitude and phase of the locked oscillation.

However, in order that the oscillator may remain locked, it is necessary that the equilibrium represented by $\dot{\rho}=\dot{\phi}=0$ should be stable. The stability is ensured if at the equilibrium values of ρ and ϕ (reference 2):

$$\frac{\partial\dot{\rho}}{\partial\rho}+\frac{\partial\dot{\phi}}{\partial\phi}<0 \tag{9A}$$

$$\frac{\partial\dot{\rho}\partial\dot{\phi}}{\partial\rho\partial\phi}\times-\frac{\partial\dot{\rho}}{\partial\phi}\times\frac{\partial\dot{\phi}}{\partial\rho}>0 \tag{9B}$$

In view of equations 7(A) and 7(B) and on using the equilibrium condition, inequalities 9(A) and 9(B) reduced to:

$$2-\frac{\partial}{\partial\rho}(a_1/a\rho_0)-a_1/a\rho\rho_0<0 \tag{10A}$$

$$\left[1-\frac{\partial}{\partial\rho}(a_1/a\rho_0)\right][1-a_1/a\rho\rho_0]+[\delta+b_1/a\rho\rho_0]$$
$$[\delta+b_1/a\rho\rho_0+\rho\frac{\partial}{\partial\rho}(b_1/a\rho\rho_0)]>0 \tag{10B}$$

For a fixed value of F, there is a maximum value of δ up to which the two inequalities are satisfied. This maximum value of δ, called δ (max), defines the range of detuning up to which the oscillator remains locked and is called the locking range of the oscillator. The locking range for a particular value of the locking signal may be obtained on reducing the two inequalities to two equations and solving each for δ simultaneously with equation 8(A). For some values of F, two values of δ (max) are obtained from inequality 10(B) in addition to a third one given by inequality 10(A). In most of these cases the largest of the three values gives the actual range of locking since the other two correspond to conditions of oscillation which are not permissible.[3,4]

The general equations deduced will now be used to determine the locking range for some special nonlinearities.

Locking Range for Polynomial-Type Nonlinearity

Let the nonlinearity be of the polynomial type given by:

$$\mu f(\dot{x})=k(\dot{x})^{2m+1}$$

In this case a_1 and b_1 are given by:

$$a_1=k(m)\ (\omega A)^{2m+1},\ b_1=0 \tag{11}$$

where $k(m)$ is a constant depending on m.

On substituting this value of a_1 in equation 7(A), ρ_0 is found to be given by:

$$\rho_0=[a/k(m)]^{1/2m}$$

Thus, a_1 may be written in terms of ρ as:

$$a_1=a\rho_0(\rho)^{2m+1}$$

On substituting for a_1 and b_1 in equations 8(A) and 8(B), ρ and ϕ in the locked condition are found to be given by:

$$F^2=\rho^2[(1-\rho^{2m})^2+\delta^2] \tag{12A}$$

$$\tan\phi=(1-\rho^{2m})/\delta \tag{12B}$$

Inequalities 10(A) and 10(B) also reduce to

$$\rho^{2m}>1/(m+1) \tag{13A}$$

$$(1-\rho^{2m})^2-2m\ (1-\rho^{2m})\ \rho^{2m}+\delta^2>0 \tag{13B}$$

The plot of δ (max) against F^2 for different values of m as obtained from the inequalities 13(A) and 13(B) in combination with equation 12(A) are shown in Fig. 1(A). The plot corresponding to inequality 13(A) is marked b and that corresponding to inequality 13(B) is marked a, while that corresponding to both is marked ab. It is noted that δ (max) as given by the plot marked a is larger than that given by the plot marked b or ab up to A (Fig. 1[A]). At A both the inequalities are just satisfied. The corresponding value of F^2 is obtained on solving simultaneously equation 12(A) and the equations derived from the inequalities and is found to be given by $(2m^2)/(m+1)^{(2+1/m)}$. The value of δ (max) as given by the plot marked a is slightly lower than that given by the plot marked b in the range between A and B (Fig. 1[A]). The value of F^2 corresponding to point B is obtained on considering that the two solutions for δ (max) as obtained from inequality 13(B) are identical at B. It is given by $(2m^2)(m+1)^2/(2m+1)^3$. In view of the discussion presented earlier, it follows that the locking range is given by the plot marked a for values of F^2 up to A and by the plot marked b for values of F^2 on the upper side of B. It should be noted that in the range extending between A and B, the locking range may be given by either of the plots depending on the direction of variation of δ.[3,4] However, the indeterminate zone is very small in extent and also the locking range as given by the two plots do not differ much.

On comparing the plots for different values of m in the light of the discussion, it is observed that the locking range is independent of the order of the nonlinearity for low values of F (normalized amplitude of the locking signal), while for higher values of F the lowest order nonlinearity gives the widest range.

Locking Range for Dead-Zone-Type Nonlinearity

In this section a dead-zone type of nonlinearity is considered, for which $f(\dot{x})$ may be written as:

$$\begin{aligned}\mu f(\dot{x})&=C(\dot{x}-E_b),\ \dot{x}>E_b\\&=0\quad -E_b<\dot{x}<E_b\\&=C(\dot{x}+E_b),\ \dot{x}<-E_b\end{aligned}\tag{14}$$

$\mu f(\dot{x})$ may be approximated by a polynomial in $\dot{x}$, in which the lower order terms increase in prominence with decrease in C. Hence a study of this nonlinearity provides an insight into the nature of dependence of the locking range on the order of the polynomial for a polynomial type of nonlinearity when more than one term is present in the polynomial.

In this case, a_1 and b_1 are given by:

$$a_1=\frac{2C}{\pi}\omega A\,[\cos^{-1}E_b/(\omega A)-(E_b/\omega A)\,\{1-(E_b/\omega A)^2\}^{1/2}]\tag{15A}$$

$$b_1=0\tag{15B}$$

The amplitude of free oscillation ρ_0 is given by:

$$\cos^{-1}E_b/\rho_0-(E_b/\rho_0)\,\{1-(E_b/\rho_0)^2\}^{1/2}=\pi a/2C\tag{16}$$

In terms of ρ and ρ_0, a_1 may be written as:

$$a_1=(2C/\pi)\rho\,\rho_0[\cos^{-1}(E_b/\rho\,\rho_0)-(E_b/\rho\,\rho_0)\,\{1-(E_b/\rho\,\rho_0)^2\}^{1/2}]\tag{17}$$

In this case, equations 8(A) and 8(B) reduce to:

$$F^2={}^2[1-(2C/\pi a)\,\{\cos^{-1}(E_b/\rho\,\rho_0)-(E_b/\rho\,\rho_0)\,(1-E_b^2/\rho^2\,\rho_0^2)^{1/2}\}]\tag{18A}$$

$$\tan\phi=[1-(2C/\pi a)\,\{\cos^{-1}(E_b/\rho\,\rho_0)-(E_b/\rho\,\rho_0)\,(1-E_b^2/\rho^2\,\rho_0^2)^{1/2}\}]/\delta\tag{18B}$$

Inequalities 10(A) and 10(B) reduce to:

$$(\rho\,\rho_0)/E_b>1/\cos(\pi a/2C)\tag{19A}$$

$$[1-(2C/\pi a)\cos^{-1}(E_b/\rho\,\rho_0)]^2-(2C/\pi a)^2(E_b/\rho\,\rho_0)^2\,[1-(E_b/\rho\,\rho_0)^2]+\delta^2>0\tag{19B}$$

Plots of δ (max) as obtained from inequalities 19(A) and 19(B) and equation 18(A) for different values of C are shown in Fig. 1(B). The nature of the plots are similar to those shown in Fig. 1(A) and it is observed that for low values of F, the locking range is almost independent of C while for higher values it increases with decrease in C. One may, therefore, conclude that even for a polynomial-type nonlinearity including more than one term, the locking range increases with greater predominance of the lower order terms.

Experimental Verification

The locking range for different nonlinearities considered has been obtained with the help of a differential analyzer. The limiting value of δ up to which the oscillation is locked was determined by observing the oscillator output on an oscilloscope. Appearance of the amplitude variation indicated unlocked condition. The initial damping was chosen to be equal to 0.1 and the limiting value could be determined with an accuracy of ±0.001 in the setting of ω_0^2. Experimental results are shown by circles on the theoretical curves and are seen to agree closely.

Conclusions

It has been shown theoretically and also verified experimentally that the locking range for an oscillator subjected to an external signal increases with increasing predominance of the lower order terms in the nonlinearity. For small amplitude signals, however, the locking range is not much influenced by the character of the nonlinearity.

Current–Voltage Relationships in Negative Pulsed Corona

J. B. THOMAS
MEMBER AIEE

T. R. WILLIAMS
NONMEMBER AIEE

SOME INTERESTING properties of negative pulse corona have been noted by several investigators.[1,2] Among these properties are sparkover voltages and pulse currents considerably above d-c values. Such properties are desirable for those applications, such as electrostatic precipitation, where maximum corona loss may be sought. A more detailed study of negative pulse corona is therefore pertinent.

This paper presents the current–voltage relationships of negative pulse corona for a wide range of pulse lengths and repetition rates and for various values of load capacitance. In all cases a fixed cylindrical electrode structure was employed.

Apparatus and Procedure

A schematic diagram of the experimental equipment is shown in Fig. 1. The corona fixture consisted of a vertical aluminum discharge tube 12 in. (inches) long and 0.5 in. inside diameter and a coaxial nichrome wire 14 in. long and 0.010 in. in diameter. The wire was held taut by weights which were as heavy as the elastic limit of the wire permitted. The tube and wire were supported by insulators appropriately arranged to allow accurate centering of the wire in the coaxial tube. The ends of the tube were flared to prevent field concentrations.

The average current flow to the discharge tube was measured by a d-c milliammeter connected between the tube and ground as shown. Both the average and peak voltage across the corona gap were measured with appropriate meters.

The pulse generator was a conventional hard tube pulser with a pulse length continuously variable from 1 μsec (microsecond) to 50 μsec. Typical output waveforms for these two extreme cases are shown in Fig. 2(A) and Fig. 2(B). The pulse repetition rate could be varied from as low a value as desired to a rate corresponding to a duty cycle of approximately 0.25.

Paper 60-102, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted November 4, 1959; made available for printing December 9, 1959.

Fig. 1. Diagram of apparatus

Measurements were made both with and without a series blocking diode between the pulse generator and the corona cell. When the diode was not present, the corona gap voltage was the pulse generator output voltage as in Fig. 2(A) and Fig. 2(B). With the diode in place, the gap voltage waveform was a function of the capacitance C between the discharge wire and ground. Typical waveforms are shown in Fig. 2(C) and Fig. 2(D). The capacitance C had an irreducible minimum due to stray capacitance and that of the measuring equipment but was varied above this minimum by adding an adjustable capacitor connected from the discharge wire to ground as shown. The total capacitance C was one of the parameters in the current–voltage relationships.

The usual precautions were taken to condition the discharge wire and obtain reproducible data. Since the corona characteristics were quite sensitive to pulse length and pulse repetition rate, these quantities were monitored continuously. Pulse length was adjusted from oscilloscope observations of the pulse generator output and pulse repetition rate was checked by counting the pulses on an electronic counter.

Sparkover Characteristics

As mentioned previously, sparkover voltages for negative pulse corona are considerably higher than negative d-c values and are affected by pulse length, pulse repetition rate, and load capacitance. Some typical data are shown in Fig. 3. Here sparkover voltages are shown for two duty cycles, 0.01 and 0.1, for three load conditions. For convenience the d-c sparkover value is shown as a horizontal line.

In all cases, as load capacitance increases, sparkover voltage decreases as the d-c case is more closely approximated. Also, as pulse length decreases for a constant duty cycle, sparkover voltage tends to decrease as the load capacitance becomes a more effective filter.

Another interesting quantity is the product $V_s\,I_m$, where V_s is the sparkover voltage and I_m is the average d-c current obtained just before sparkover. This product is a measure of the maximum obtainable corona loss. It is convenient to plot this quantity as is done in Fig. 4, where $V_s\,I_m$ has been plotted versus the parameter T_o/T_D. Here T_o is the off time or time betweeen pulses and T_D is a nominal fall time obtained as follows. The corona cell was assumed to have a constant resistance R of one megohm, and T_D was taken to be the product of R and the load capacitance C. For the case where no blocking diode was employed, 30 $\mu\mu f$ (micromicrofarad) has been arbitrarily assigned as the value of C for the purpose of normalizing the data so that it falls approximately along a single curve as in Fig. 4. As the ratio T_o/T_D decreases, the product $V_s\,I_m$ increases as the d-c case is approached. It should be noted that the d-c value of $V_s\,I_m$ is 81.4 volt-amperes and appears to be the asymptotic value of the curve represented by the points of Fig. 4.

Current-Voltage Relationships

The current-voltage characteristics of the pulse corona are difficult to present concisely since there are three major parameters affecting these characteristics: pulse length, pulse repetition rate, and load capacitance. However, Figs. 5(A) and 5(B) show some of the most interesting features of these characteristics.

If the pulse length is long, the data can be approximately normalized for each load condition. This situation is shown in Fig. 5(A) where the current–voltage curves for 50-μsec pulses have been plotted. Two load conditions are presented: the case where no blocking diode is employed, and the case where the load capacitance is approximately 383 $\mu\mu f$. For each of these two cases, data are given for four duty cycles. For convenience in comparison, the negative d-c characteristic has been added to the figure. It should be noted that the ordinate is not average current but average current divided by duty cycle. The abscissa is the height of the voltage pulses. For low load capacitance, the data for different duty cycles normalize along a single curve which is approximately the d-c characteristic ex-

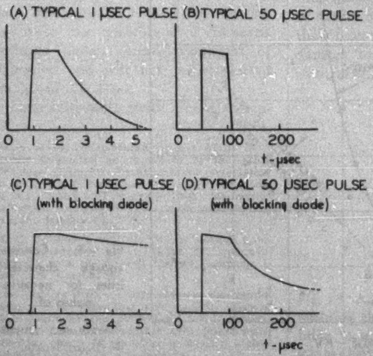

Fig. 2 (left). Typical voltage waveforms

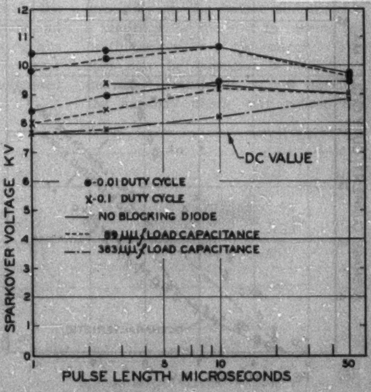

Fig. 3 (right). A comparison of negative pulse and d-c sparkover values

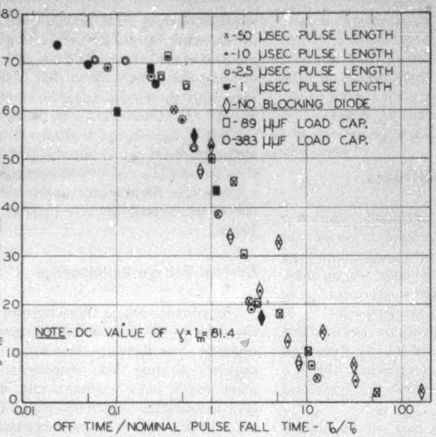

Fig. 4. Negative pulse corona power loss

cept that the range has been extended as a result of the higher pulse sparkover voltages. As the load capacitance increases the curve shifts and the normalization is not as complete, although the data for different duty cycles still lie approximately along the same curve.

For short pulse lengths, on the other hand, such normalization as described above is not possible. A typical situation is shown in Fig. 5(B) where data for 1-µsec pulses are presented. In this figure, average current is plotted directly versus peak voltage. The same two load conditions are considered as in Fig. 5(A). For the short pulses, the time between pulses becomes small as the duty cycle is increased so that a given load capacitance acts as a more effective filter. Consequently, for high duty cycles and high load capacitance, the situation approaches the d-c case as shown.

For pulse lengths between the extremes of 50 µsec and 1 µsec, the characteristics show a gradual shift from those of Fig. 5(A) to those of Fig. 5(B).

For pulse lengths above 50 µsec, the current–voltage relationship approaches more and more closely the d-c case, i.e. the current/duty cycle versus voltage curves approximate the d-c curves. Sparkover voltages are higher than for the d-c case however, as suggested by Fig. 3, and there are the usual advantages of pulse energization as far as voltage stability is concerned. Energization techniques for pulse lengths of 100 µsec and above have been studied previously.[3]

It should be noted that the study reported herein was restricted to short gap (1/2 in.) corona fields. For the larger electrode spacings of 3 to 6 inches encountered in some applications, further investigation is indicated.

Conclusions

With negative pulse energization it is possible to obtain corona losses of the same order as for the d-c case. This can be accomplished even with relatively low duty cycles. At the same time peak voltages considerably in excess of the d-c sparkover value can be maintained.

In addition to the above, pulse energization permits the selection of a wide range

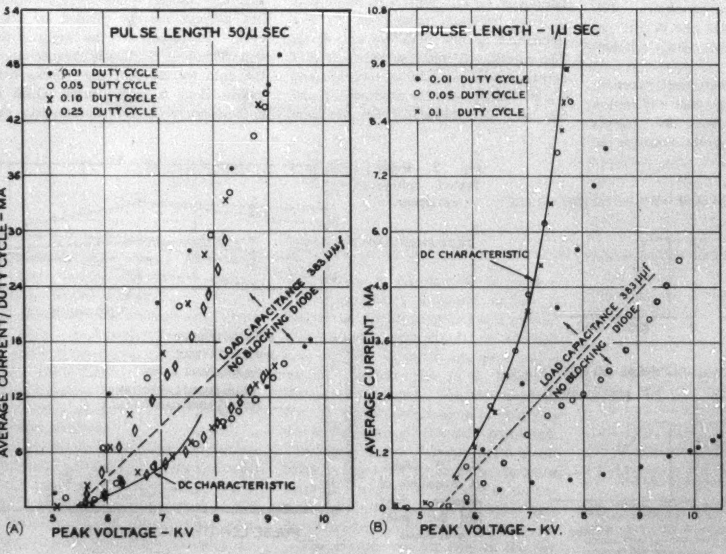

Fig. 5. Current-voltage characteristics for negative pulses of:

A—50-µsec length
B—1-µsec length

of current–voltage characteristics for a given corona cell electrode structure. Characteristics can be changed by varying pulse length, pulse repetition rate, and load capacitance.

Voltage Transients Due to Arc Extinction

H. C. STEINER
FELLOW AIEE

R. W. STRECKER
ASSOCIATE MEMBER AIEE

HIGH TRANSIENT VOLTAGES may be developed in equipment associated with gas conduction tubes when there is a sudden cessation or change in the magnitude of the current that is being conducted through the tube. The conditions for the occurrence of this phenomenon have received considerable attention from those working in the field of gas conduction tubes as well as those who have applied such devices. Three conditions of operation of gas conduction devices have been recognized as contributing or being capable of creating the rapid rate of current change that is necessary to generate the high voltages observed: 1. cathode-spot extinction, 2. arc extinction, or gas "starvation" as it is sometimes called, and 3. the pinch effect. The pinch effect occurs when the current through the discharge reaches a sufficient magnitude to cause the conduction electrons to be pressed into a tight spiral because of the force of the self-induced magnetic field on the electron trajectory. This phenomenon is receiving considerable attention in the controlled thermal nuclear work that is currently being undertaken. Of the three, the pinch effect has not been demonstrated to be a contributing factor in the generation of transient voltages under normal conditions of operation and will not be considered further in this paper.

Langmuir, Mott-Smith, Tonks, Compton, and Fetz have studied and reported[1–5] on the physical factors involved in arc discharges at low pressures. Tonks, in a paper[6] presented before the Electrochemical Society in 1937, discussed the theory and phenomenon when a low pressure arc is "overloaded," and the resulting sudden change in current "creates surges of many thousands of volts." Hull,[7] in his development of hot cathode, grid-controlled, gas-filled-thyratron tubes, found the same high-voltage surges that had been found earlier in mercury-pool rectifying devices. Hull and Elder[8] as a result of their investigation of the phenomenon established certain quantitative data of permissible arc-current density as a function of gas density. Hansell[9, 10] and McArthur[11] have used the gas-starvation phenomenon as a nonlinear element for the generation of high-frequency currents.

It is the intent of this paper to review, briefly, the physical factors involved in the cathode-spot extinction and gas-starvation phenomena, to indicate the conditions under which such phenomena are likely to occur, to discuss the probable voltage generated, the factors within the tube which tend to limit the voltage and to outline some of the protective circuits that have been employed to prevent damage to transformers or associated equipment.

Arc Extinction Mechanisms

Cathode Spot Extinction

If one establishes an arc in a glass-enclosed mercury-pool tube that is operating at room temperature, one finds as the current is reduced that the arc becomes unstable and conduction ceases. At 3 amperes, for example, the arc seldom goes out. At 2 amperes, conduction ceases more or less frequently. At one ampere, it is very difficult to maintain the arc. If one substitutes metal for the glass wall of the mercury tube, the current for arc stability increases from the 3-ampere limit of the glass tube to 4 to 5 amperes for metal tubes of the same diameter. A further increase in current is required as the area of the container is increased. The explanation for the increased current was provided by Dr. K. H. Kingdon.[12] Fig. 1 shows the auxiliary anode current required for reasonable arc stability as a function of the operating temperature of a steel ignitron tube approximately 8 inches in diameter. The current to such an anode is composed of electrons which come from cathode spots on the mercury pool and the plasma, and from positive ion charges that are collected on the surface of the pool, the enclosing metallic envelope and any shields that are connected to the cathode. Free cathode spots on the mercury surface travel erratically on the surface and there is a tendency for the spot to burrow beneath the surface of the mercury. The spot may be quenched by collapsing mercury. Transiently, at low currents, the auxiliary anode may collect the

Paper 60-76, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted February 6, 1959; made available for printing January 11, 1960.

H. C. Steiner is with the General Electric Company, Schenectady, N. Y.; and R. W. Strecker, formerly with the General Electric Company, is now at St. Charles, Ill.

The authors wish to acknowledge the careful reviews of the paper that were made by many of their associates and particularly the discussions with Mr. J. D. Cobine and Mr. A. O. Jensen which aided so greatly in the effort to develop a clear physical concept of the phenomena.

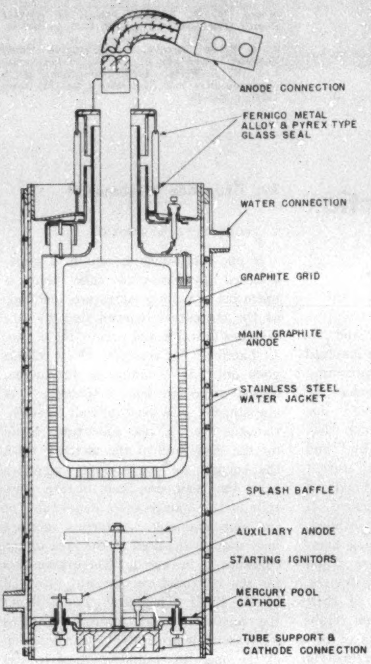

Fig. 2 (left). Cross section of a 400-ampere ignitron showing the general design

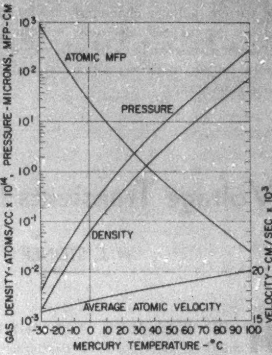

Fig. 3 (right). Properties of saturated mercury vapor[13,14]

required current from the plasma and this may extinguish the spot. Cathode-spot extinction is rapid, of the order of 10^{-8} seconds, and the auxiliary anode voltage would rise rapidly to high values if it were not possible to obtain a gradually decreasing supply of electrons from the decaying plasma or to re-establish new cathode spots. The arc-drop voltage under low temperature conditions is very oscillatory as indicated in the sketch of the observed waveshape. The oscillations disappear and the voltage becomes stable when the current is increased as with main anode conduction.

The circuit voltages generated from the foregoing changes in tube current are not of major concern. If the conditions of operation of the tube are such that cathode spots are established on the side walls of the tube, the arc may be stable or unstable. If the cathode spot forms on a mercury droplet on the wall and the droplet evaporates, thereby allowing the arc to run onto the metal, cathode-spot instability may occur at a higher current and result in higher surge voltages. Cathode spots may be formed on the side wall of the tube by extraneous magnetic fields forcing the arc into contact with the tube wall. Also, operation at very low temperatures and with the corresponding gas densities increases the arc drop and the probability of cathode-spot formation on the walls particularly if the tube is subjected to sudden high-current demands. Such spots may also form in hot cathode tubes if the available thermionic emission is insufficient to supply the current demand. In such cases, however, there is less likelihood of severe voltage surges developing because the mass of the parts in such tubes is usually small and the necessary temperature conditions are rapidly established to supply the required emission.

ARC STARVATION

The ability of arc to establish a normal plasma is dependent, as one factor, on the density of the available gas. As the gas density is lowered, the arc drop tends to increase. At very low pressures the gas density becomes insufficient to provide the molecules that are needed for ionization. The available ions are insufficient to neutralize the electron space charge and conduction changes rapidly from that of a gas discharge to that of a high-vacuum device. The effect is accentuated in tubes having grids or constrictions in the arc path. The current reduction as conduction changes from a gas discharge to high vacuum is very rapid, and transiently, voltages of the order of many thousands of volts may be generated in inductances associated with the current change. The general phenomenon has been termed "arc starvation."

Tests of an early model sealed ignitron tube will illustrate the characteristics of the phenomena. Fig. 2 shows the general design of the tube. The design employed a grid around the anode and the grid holes were of the order of a centimeter in diameter and a centimeter in length. When the tube was tested under low temperature conditions, rather violent voltage surges were found for cooling water temperatures in the range of 10–20 C (degrees centigrade). Below this range there was no conduction, while above it there was normal plasma conduction. The properties of saturated mercury vapor pertinent to this problem are shown in Fig. 3. Since the test loads were applied suddenly, the properties indicated correspond reasonably well to the conditions existing within the tube at the start of each test. At −20 C, which corresponds to a vapor pressure of 0.018 micron, the ignitor would fire satisfactorily, but the main anode, the grid and the small auxiliary holding anode which was approximately 2 inches from the ignitor would not conduct. As the temperature was increased to −10 C the main anode and grid still would not conduct but the holding anode would start. The discharge voltage trace was very oscillatory and the arc drop high, and the arc tended to go

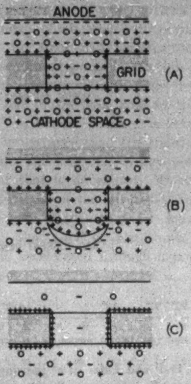

Fig. 4. Idealized sketch of the space conditions in the grid section of a gas tube showing gaseous atoms, ions and electrons in

A—Normal plasma
B—Plasma at reduced gas density in which a second sheath has formed
C—Transient high-vacuum conduction at very low gas densities

out frequently. At 3 C, the holding anode conducted and conduction started to the grid, but there was no measurable current conduction to the anode. At approximately 10 C, which corresponds to a vapor pressure of approximately 0.5 micron, conduction was established to the anode but conduction was erratic and voltage transients sufficient to break down protective gaps occurred. At 20 C, which corresponds to a vapor pressure of 1.2 microns, operation was stable over a current range of from a few amperes to several hundred amperes.

Although the general description of the phenomenon is straightforward, the physical changes involved are exceedingly complex. Figs. 4(A), (B), and (C) have been prepared to visually interpret three steps in the process of arc extinction. The cross sections show an enlarged view of one grid hole and the molecular, ion and electron entities that exist in the space. Normal conditions of conduction are shown in Fig. 4(A), the beginning of the surge conditions in (B), and the probable conditions at the end when the current has been reduced essentially to that of a high-vacuum tube in (C). These changes occur very rapidly, probably, as indicated later, in the order of 10^{-6} to 10^{-8} seconds.

Under normal conditions of arc conduction, Fig. 4(A), there are sufficient gas molecules in the space to provide the necessary positive ions for neutralization of any space charge because of the electrons conducted. The potential gradients in the plasma are low, probably of the order of a tenth of a volt per centimeter, and the ions drift slowly toward the cathode. Ions are lost to the grid and to the enclosing walls or enclosing shields if these are connected to the cathode. The plasma drop increases slightly to provide the additional ions needed to make up the losses. There will be a positive ion sheath around the grid if the grid is slightly negative with respect to the plasma and probably a very thin electron sheath at the anode. The thermal energy of the gaseous molecules is sufficient to maintain a reasonably uniform atomic distribution throughout the space, including the grid holes and the grid-to-anode region. The degree of ionization is low, probably of the order of a few per cent.

In Fig. 4(B) the gas density has been lowered to the point where insufficient positive ions are formed and the potential gradient through the plasma along the anode-to-cathode axis is increasing. As the arc drop increases to approximately 40 volts the energy of the electrons is increased and their efficiency of ionization increases. As the arc voltages increase above 40 volts, however, the efficiency of ionization decreases rapidly, and the beginning of the transient period is probably reached. At or prior to this time there is formed a double sheath[6] at the cathode side of the grid. There will be a concentration of positive ions on the anode side of this sheath and a concentration of electrons at the cathode side of the sheath as the arc attempts to establish conditions that will provide the needed supply of electrons. The drop through the plasma in the grid hole and in the grid-to-anode region further accelerates ions in the direction of the cathode and toward the grid surfaces. One further phenomenon occurs which probably accentuates the runaway conditions. As pointed out by Tonks, the electrons that are drawn across the cathode sheath provide a force of sufficient magnitude on the gas molecules within the grid hole to further deplete the density of the gas in that region. Very rapidly, then, the plasma disintegrates and the condition shown in Fig. 4(C) is obtained.

Fig. 4(C) is intended to represent the conditions of minimum current flow. At the instant of minimum current flow, positive ion sheaths cover the grid, the residual positive ions in the space on the cathode side of the grid have redistributed themselves so that the double sheath

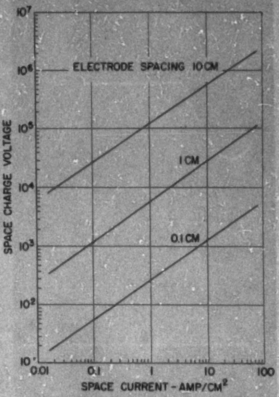

Fig. 5. Plot of the space-charge voltage between parallel plane electrodes, Childs-Langmuir equation[4]

$$J = 2.33 \times 10^{-6} \frac{V^{3/2}}{X^2} \text{ amperes/cm}^2$$

has disappeared, and the major part of the voltage that is applied between the anode and cathode exists between the grid and anode. Only a very small current would be conducted because of the high voltage drop that exists in high-vacuum conduction for relatively low current densities. Fig. 5 shows the calculated space charge for parallel plane electrodes separated by distances of the order of magnitudes that might be encountered in gas conduction tubes. These conditions exist only momentarily. Gas begins to flow back to re-establish equilibrium conditions. If the tube has a thermionic cathode, electron emission begins again, the plasma is re-established and the extinction cycle can begin again. This conduction-extinction-conduction cycle is shown in the oscilloscope traces of Fig. 6. These traces show the arc-drop voltage and current conducted in a xenon-filled thyratron operating with 1. normal gas pressure and 2. with the gas pressure reduced to near the surge limit. The tube was conducting as a half-wave rectifier from a 60-cycle source and the load current was resistance limited. Traces (A) and (B) of Fig. 6 show the arc-drop voltage and the anode current at the supply frequency. Trace (C) has been expanded to approximately 10 μsec (microseconds) per division to show the oscillations at the peak of the current wave for the low pressure condition and the absence of such oscillation for normal pressure. The extreme rapidity with

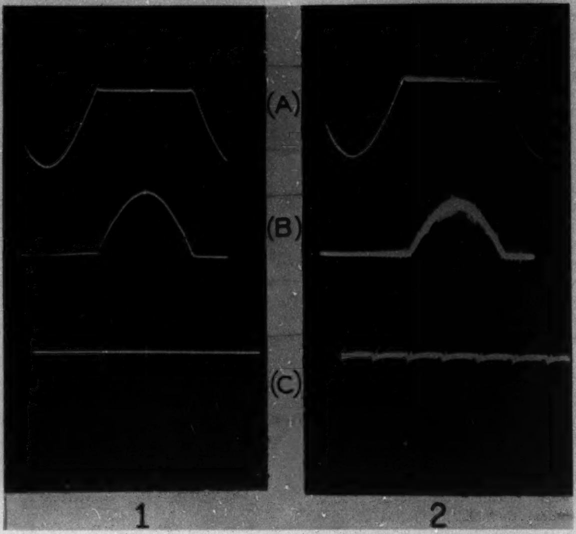

Fig. 6. Oscilloscope traces for 1. normal gas pressure and 2. low gas pressure in an inert-gas-filled thyratron showing

A—Arc voltage
B—Current at 60-cycle sweep frequency
C—Peak current at an expanded scale of 10 μsec per division

which the extinction and recovery takes place is indicated clearly in the expanded trace. If the device were a pool tube, it is probable that the cathode spots on the mercury pool have ceased and new cathode spots would have to be established in order to re-establish full current conduction through the tube.

The magnitude of the current that can be conducted through a grid as a function of mercury vapor pressure is indicated in Fig. 7. The data reproduced are from Figs. 6 and 7 of the Hull and Elder article.[8] The curves show the surge current for a large developmental thyratron and the corresponding current density through the grids for this and a smaller tube. Fig. 8 shows the remarkable increase in current capacity that occurs in an inert gas-filled thyratron when the gas density is increased just slightly above the critical surge value.

Voltage Generated

The voltage generated or, more properly, the voltage developed across the tube is, as indicated previously, directly proportional to the rate of change in current through circuit inductances and the tube. The magnitude of this voltage, if not restrained or limited, would be

$$e=-L\frac{di}{dt} \tag{1}$$

where

e = voltage developed
L = the inductance in henrys of the tube, the connecting leads, the leakage reactance of the transformer, and the reactance of the load circuit
$\frac{di}{dt}$ = the rate of current change in amperes per second, which for the purposes considered may be represented as finite changes ΔI and Δt

The voltage developed will be in such a direction as to attempt to maintain current flow through the tube, that is, the anode will become positive with respect to the cathode. The inductance L would be more properly represented by a transmission line since distributed capacities in the transformer and probably in the load circuit would tend to limit the L to only the end turns of the transformer windings. More or less of the load circuit would be involved, depending on the load wiring and the type of load. Primarily, however, the major factor is the rapid rate of current change and an evaluation of this will permit an evaluation of the voltage developed.

As indicated previously, there is probably a balance between the thermal diffusion of the gas into the grid-anode region and the drift velocity of the positive ions out of the region. As long as sufficient molecules exist in the grid holes to maintain a normal plasma, the plasma voltage gradient is relatively low. When there is a deficiency of gaseous molecules the voltage gradient increases and the velocity of the positive ions increases. With increased plasma voltage more ions are lost to the grid and to the double sheath when such sheaths are formed. One measure of the time of current extinction, therefore, would be the time that is required for an ion to travel from

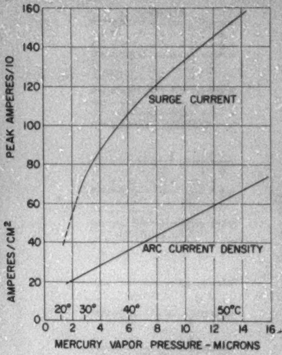

Fig. 7. Hull and Elder data[8] showing peak surge-current limit in a large thyratron and the maximum current carrying capacity for mercury vapor as function of pressure

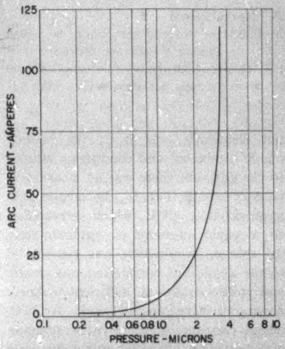

Fig. 8. Surge current limits in a xenon-filled thyratron showing the rapid increase in capacity as the critical gas pressure is exceeded

Vol.
Pt. 1
1960

the top of the grid to the bottom under the influence of whatever voltage gradient exists. For thick grids perhaps the more important factor would be the time an ion requires to traverse the distance from the center line of the grid hole to the grid wall. The actual distance is relatively of less importance than the speed of the ion under the influence of any potential gradient that is developed. If we consider the mass of the ion to be the same as the mass of the atom, the maximum velocity that such an ion could attain in being accelerated through a potential difference of V volts would be

$$1/2\, mv^2 = eV$$

where

m = mass of the ion in grams (3.33×10^{-22} for Hg)
v = velocity in cms per second
e = charge on the ion (4.767×10^{-10} esu)
V = potential difference in esu volts, or $V/300$ in practical volts

A mercury ion accelerated through a potential of one practical volt would attain a velocity of approximately 10^5 cm/sec (centimeters/second). A potential difference of 100 volts would increase this velocity 10 fold or to 10^6 cm/sec. These velocities would give times of the order of 10 μsec and 1 μsec respectively for a mercury ion to traverse a distance of 1 cm. Since the potential difference may be many fold the values discussed and the critical dimensions less than one centimeter, extinction times of the order of 0.1–1.0 μsec seem realistic. The fast oscilloscope trace, Fig. 6(C), of the current through a tube that is operating in the critical gas density range shows current cessations that are very rapid and of this order of magnitude.

As a first approximation of the voltage developed, we might consider only the commutating reactance of the transformers. For a 300-kw 275-volt rectifier, the commutating reactance per phase would be of the order of 10 microhenrys, and for a 5-kw 275-volt rectifier of the order of 1,500 microhenrys. If the entire inductance were involved in the transient and if there were no restraining forces, the voltage developed in the 300-kw unit for a current change of 10 amperes in a time interval of a quarter of a μsec would be approximately 400 volts. For a current change of 100 amperes and the same time interval, approximately 4,000 volts would be developed. For the 5-kw rectifier, current changes of one and 10 amperes in the same time interval would result in voltages of 6,000 and 60,000 respectively. These equations serve primarily to indicate that appreciable voltages may be developed. Quite obviously, the levels attained represent the unrestrained system and it is very doubtful that the actual inductance involved encompasses more than the first few turns of the transformer winding and a small part of the associated loads.

The results of tests made to determine the magnitude of the surge voltages "generated" indicate voltages within the range estimated. Generally, such tests are made by operating the tubes at very low gas pressures (10 C, for example, for mercury vapor tubes) and suddenly applying load. The test circuits usually include an air-core inductance in the anode lead to insure that the maximum voltage is developed. Suitable filters are placed across the power source and load. Voltages may be determined approximately from Lichtenberg figures[13] or more precisely from oscilloscope measurements. The maximum voltages developed under such conditions correspond rather well with the maximum voltage that a given design of tube will withstand. For example, it is relatively easy to design gas tubes for 10,000 volts, more difficult for 15–20,000 volts, and considerably more difficult in the 20–40,000 volt range. The highest test voltage measured—55 kv—within the authors' knowledge, was attained on a multigrid high voltage ignitron (*GL-6228/GL-506*) which has a rating of 20 kv forward and inverse and which withstands normally a potential test of approximately 50 kv. Voltages within the range of five to 25 kv are more representative of the majority of industrial tubes when operated under test conditions that would be expected to result in surges. The distribution of the magnitude of the surge voltages generated in a series of tests follows a normal distribution curve. Such a distribution is shown in Fig. 9 for two separate series of tests conducted on two types of tubes. If the calculated curve has been more precisely matched with the test data it would indicate that surge voltages approximately 20% greater than the maximum test voltage E found would be developed occasionally if a great many trials were run.

VOLTAGE LIMITS

There are several factors within the tubes themselves as well as in the external circuit that tend to limit the voltage developed. In the transformer, there is distributed capacity between the windings and ground and, in addition, there may be gaps, lightning arresters, or nonlinear resistors as protection for the transformer itself. From the tube standpoint, the conduction as a high-vacuum tube provides some slight limitation on the voltage that might be developed across the tube. More important is the likelihood of formation of new cathode spots on elements that are in the anode region. The ions under the conditions postulated have high energies and it becomes relatively easy to form new cathode spots. This is particularly true at the higher current levels where cathode spots may form on the inside of the grid and conduction then tends to become two arcs in series with the grid acting as anode with respect to the normal cathode of the tube and as cathode with respect to the anode. Finally, if there is no ionization present in the tube, there is still the probability of breakdown due to field emission. Experience indicates that very high vacuums must be attained and the tubes must be very "clean"[12] to sustain voltages in the 20–100-kv range.

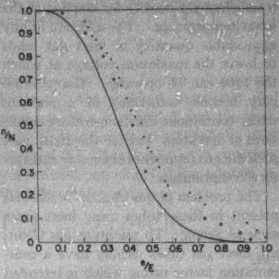

Fig. 9. Distribution of surge voltages in high-current low temperature (approximately 10 C) tests of two designs of mercury-vapor tubes compared with a Maxwellian distribution function[13]

—— Maxwellian distribution function

CONTROL METHODS

From the tube standpoint, the ratings and specifications are intended to define the range of operation without surging. Operation of the tube within the specified temperature limits for ambient or condensed mercury provides a high degree of insurance that voltage surges will not be developed for normal current demands or for fault currents. It is particularly important in the thermionic-cathode mercury-vapor tubes that normal vapor conditions be established since the vapor density changes so markedly with very small changes in temperature. Efforts to decrease the permissible lower operating temperature usually take the form of opening the grid structure or adding an inert gas (such as argon) to provide a sufficient gas density for starting at the lower temperature. The addition of any appreciable quantity of inert gas tends to lower the maximum voltage at which the tube can be operated. Gas cleanup may become something of a problem under continuous low-temperature conditions of operation, but for the most part such designs represent reasonably satisfactory compromises.

The problem of gas cleanup is likewise present in those tubes using inert gases such as xenon. To minimize gas cleanup, inert gas tubes usually have a commutation factor rating which is intended to permit full utilization of the tube capabilities. The commutation factor rating defines the circuit requirements in terms of the product of the rate of current decay (di/dt) at the end of the conduction cycle and the inverse voltage (de/dt) initially applied. High factors increase the rate of cleanup since the residual ions present in the space at the end of conduction attain higher energies with higher inverse voltages. These higher energy ions increase the sputtering and the rate of gas cleanup. Rapid gas cleanup may also occur near the end of the cathode life when the arc drop increases. A discussion of cleanup is beyond the scope of this paper except to recognize the phenomena and to indicate that satisfactory tube performance can be obtained by a combination of the design, materials, and processing and limiting the commutation factor. In general, other malfunctions tend to insure that the tube is removed from service before excessively high voltage surges develop.

From the equipment viewpoint, the application of gaps in conjunction with nonlinear resistors should provide adequate protection against the occasional possibility of high-voltage surges. Resistor-capacitor filters across the tubes or transformers should also provide effective attenuation. Such filters should be nonoscillatory with respect to the expected inductance. The capacitor should be capable of absorbing most of the energy stored in the inductance within its voltage rating. The initial surge voltage will be determined by the *IR* drop across the resistor.

Conclusions

This brief survey of the problems associated with arc extinction indicates that high transient voltages can be developed across vapor or gas-filled electron tubes when such tubes operate below their design gas densities. The sudden reduction in current, which creates the transient voltage, is dependent primarily on the gas density and tube geometry and not on the type of gas or vapor. Considerable testing has led to the conclusion that surging does not occur under normal gas densities or vapor temperatures. Gas cleanup in inert-gas tubes must be considered as an ultimate end of life possibility, but considerable field experience indicates that change in other characteristics is more likely to terminate the useful service period than is surging. Additional research and investigation are needed to clearly define these very interesting and complex phenomena.

The use of surge-voltage limiters should be considered, particularly for any essential service type of equipment. Without such limiters, voltage breakdown in the tube most probably determines the maximum voltage that can be developed. Standards for guidance would be desirable.

Generalized Brillouin Flow

GORDON KENT
NONMEMBER AIEE

THE 1945 PAPER by Brillouin[1] presented an exact solution to the problem of space charge flow of electrons in a magnetic field. As is well known, this solution demonstrates the possibility of an electron beam of cylindrical or rectangular cross section in which the repelling forces due to the space charge are exactly balanced by the magnetic field forces so that the beam maintains its shape for an indefinite length. The many electron tubes which have been designed to make use of this type of flow as well as the large number of research papers published on problems associated with Brillouin flow constitutes substantial evidence of the impact on the electron tube industry of the Brillouin paper.

Although the many difficulties encountered in the use of Brillouin flow have in recent years made the less elegant but simpler method of confined flow-focusing more practical,[2] Brillouin's paper remains interesting as one of the early contributions to the cataloging of exact solutions to the electron flow problem. Since this problem is of such monumental difficulty that solutions of any degree of generality are elusive, the listing of exact solutions, starting with those of Langmuir and extending to the elegant contributions of Kirstein,[3–6] is equivalent to a series of snapshots from

---

Paper 60-31, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted July 14, 1959; made available for printing November 18, 1959.

GORDON KENT is with Syracuse University, Syracuse, N. Y.

This work was done with the support of the National Science Foundation, research grant (*NSFG6314*).

which one may hope to acquire sufficient understanding to permit the development of solutions of increased generality. The solution presented here is of interest more as an addition to the list of exact solutions than as a result of great practical importance, although its implications for the focusing of beams of finite rectangular cross section are perhaps useful.

Many of the recent discoveries of new electron flow solutions are nascent in the approach recommended by Spangenberg in 1941.[7] In essence, Spangenberg makes use of a velocity potential to obtain a single partial differential equation representing the electromagnetic and the electrodynamic problems simultaneously. The Brillouin paper, in contrast, considers the two problems separately, seeking, ultimately, a set of self-consistent solutions. When the problem attacked by Brillouin is formulated along the line suggested by Spangenberg, the possibility of a somewhat general solution is immediately evident. As is shown subsequently, the Brillouin cylindrical and semi-infinite rectangular beams are special cases.

Derivation of Basic Equation

If it is assumed that the electrons originate with zero initial velocity from a cathode at which the normal component of the magnetic field vanishes, the generalized momentum is an irrotational field quantity so that

$$\mathbf{P}=\nabla W \tag{1}$$

It is also assumed, though not of necessity, that the velocity of the electrons is a single-valued function of the spacial co-ordinates and, further, that all field quantities are explicitly independent of time. In accordance with equation 1, the velocity is given by

$$\mathbf{v}=(1/m)\,(\nabla W+e\mathbf{A}) \tag{2}$$

where $\mathbf{A}$ is the vector potential from which the magnetic field is derived by the relation

$$\mathbf{B}=\nabla x\mathbf{A} \tag{3}$$

and e is the magnitude of the electron charge. With the velocity represented by equation 2, the energy equation takes the form

$$\Phi=\frac{1}{2em}\,(\Delta W+e\mathbf{A})^2 \tag{4}$$

where Φ is the electrostatic potential measured with respect to the cathode, and m is the electron mass. In accordance with equation 4, Poisson's equation becomes

$$\rho=(\epsilon_0/2em)\nabla^2\,[(\nabla W+e\mathbf{A})^2] \tag{5}$$

Finally, the continuity condition requires that the product of the left-hand sides of equations 2 and 5 be a solenoidal vector or, symbolically, that

$$\nabla\{(\Delta W+e\mathbf{A})^{\prime}\,[(\nabla W+e\mathbf{A})^2]\}=0 \tag{6}$$

In this derivation it has been assumed that $(v/c)^2<<1$ so that the magnetic field due to the electron motion is of no consequence and the applied magnetic field may be set independently of the motion. The vector $\mathbf{A}$ which appears in equation 6 is any vector consistent with equation 3, and to remove this ambiguity it will be assumed that $\mathbf{A}$ has zero divergence. With $\mathbf{A}$ determined, equation 6 is a fourth-order third-degree partial differential equation for the function W. Once W is determined, all other quantities of interest can be calculated from expressions 1 through 5.

Motion in Axial Magnetic Field

An axial (z-directed) magnetic field of strength B_0 is derivable from the solenoidal vector potential

$$\mathbf{A}=\frac{1}{2}\,B_0(-\hat{x}y+\hat{y}x) \tag{7}$$

where the circumflex indicates unit base vectors. There is little to be gained by substituting equation 7 in equation 6 to obtain a differential equation involving W and the co-ordinates only, because the resulting expression is cumbersome despite the simplifications that result from the fact that $\mathbf{A}$ is solenoidal and in the transverse plane and that

$$\nabla^2(e\mathbf{A})^2=e^2B_0^2 \tag{8}$$

Nevertheless, these properties of $\mathbf{A}$ lead directly to the observation that a function W which makes the charge density a constant, and at the same time is a solution of Laplace's equation, is also a solution of equation 6. Alternately, if the charge density depends on z only and W satisfies the further conditions that

$$\frac{\partial^2 W}{\partial_x{}^2}+\frac{\partial^2 W}{\partial_y{}^2}=0$$

$$\frac{\partial^2 W}{\partial_z{}^2}\,\rho+\frac{\partial W}{\partial_z}\,\frac{\partial\rho}{\partial_z}=0 \tag{9}$$

then W is a solution of equation 6 describing a more general motion.

To construct a solution satisfying equation 9, it is possible to put

$$W=m[\Omega xy+f[z]) \tag{10}$$

This assumption leads to the charge density

$$\rho=(\epsilon_0 m/2e)\left\{4(\Omega+\omega_L{}^2)+\frac{d^2}{dz^2}\left[\left(\frac{df}{dz}\right)^2\right]\right\} \tag{11}$$

where ω_L is the Larmor frequency. Evidently, the required functional dependence of ρ is provided and the first part of equation 9 is satisfied by the choice of W. The second part of equation 9 is satisfied providing $f(z)$ is a solution of the differential equation

$$\left\{4(\Omega^2+\omega_L{}^2)+\frac{d^2}{dz^2}\left[\left(\frac{df}{dz}\right)^2\right]\right\}\frac{df}{dz}=(2eJ_0/\epsilon_0 m) \tag{12}$$

where J_0, a constant, is the axial component of current density. Since a solution of the problem does not require the function $f(z)$ but only its first derivative, which is the z-component of the velocity, it is convenient to put $df/dz=s(z)$. In terms of the new variable, the first integral of equation 12 is

$$C_1=(\omega_L{}^2+\Omega^2)s^2+\frac{1}{2}\,s^2\left(\frac{ds}{dz}\right)^2-\left(\frac{eJ_0}{\epsilon_0 m}\right)s \tag{13}$$

Before obtaining the second integral of equation 12, it is enlightening to examine the significance of the integration constant C_1, and to classify the different kinds of solutions accordingly. The requirement that the term $s^2(ds/dz)^2$ be positive or zero in equation 13, leads to a greatest lower bound on C_1,

$$C_1\geqq-\frac{1}{4\omega^2}\left(\frac{eJ_0}{\epsilon_0 m}\right)^2=C_{\min} \tag{14}$$

and to greatest lower and least upper bounds on s,

$$\left.\begin{matrix}\dfrac{1}{2\omega^2}\left(\dfrac{eJ_0}{\epsilon_0 m}\right)\left[1-\sqrt{1+4\omega^2C_1/\left(\dfrac{eJ_0}{\epsilon_0 m}\right)^2}\,\right]\\ 0\\ \dfrac{1}{2\omega^2}\left(\dfrac{eJ_0}{\epsilon_0 m}\right)\left[1+\sqrt{1+4\omega^2C_1/\left(\dfrac{eJ_0}{\epsilon_0 m}\right)^2}\,\right]\end{matrix}\right\}\leqq s\leqq \tag{15}$$

where the greater of the two terms on the left of equation 15 applies. In the two previous expressions the substitution $\omega^2=(\omega_L{}^2+\Omega^2)$ has been made. In addition, a combination of equations 12 and 13 shows

$$\frac{d^2s}{dz^2}=-\frac{1}{s^3}\left[\left(\frac{eJ_0}{\epsilon_0 m}\right)s+2C_1\right] \tag{16}$$

Although equations 13 and 16 reveal that (ds/dz) and (d^2s/dz^2) become singular as s approaches zero, equation 12 remains satisfied, and s may assume the value zero. Such a point, however, cannot be a relative minimum.

It is now possible to classify solutions as follows:

1. If $C_1=0$, d^2s/dz^2 is negative so that s

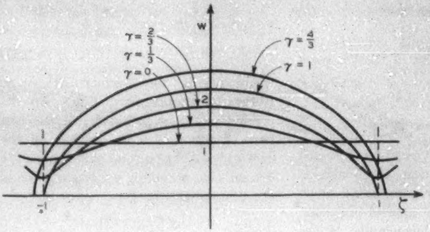

Fig. 1. Normalized velocity plotted against normalized distance with varying parameter γ

may have a relative maximum equal to the least upper bound in equation 15, and s may vanish.

2. If $C_{1\min}<C_1<0$, s may have relative minima and relative maxima given by equation 15, but s cannot vanish.

3. If $C_1=C_{1\min}$, s must be constant. In fact, $s=0$, or $s=eJ_0/2\epsilon_0 m\omega^2$ In the event that J_0 vanishes, still another solution is possible, but this is of no interest here.

In the foregoing discussion, only positive or zero values of s have been considered. Since the equations for s are reversible in z, all the remarks apply equally when s is a negative semidefinite function. The only difference in the analysis is the change of sign of J_0.

For solution 1 as well as solution 2 the point at which s is a maximum may be fixed at $z=0$ without loss of generlaity. The second integral of equation 12 then takes the form

$$|Z|=\frac{1}{\omega\sqrt{2}}\left\{\sqrt{(s_2-s)(s-s_1)}+\left(\frac{s_1+s_2}{2}\right)\times \sin^{-1}\frac{2\sqrt{(s_2-s)(s-s_1)}}{s_2-s_1}\right\} \qquad (17)$$

where

$$s_2;\ s_1=\frac{1}{2\omega^2}\left(\frac{eJ_0}{\epsilon_0 m}\right)\left[1\pm\sqrt{1+4\omega^2C_1\left(\frac{eJ_0}{\epsilon_0 m}\right)^2}\right]$$

For class 1, s vanishes when

$$Z=\pm\frac{1}{\omega\sqrt{2}}\left[\sqrt{-s_1s_2}+\frac{1}{2}(s_1+s_2)\times \sin^{-1}\left(\frac{2\sqrt{-s_1s_2}}{s_2-s_1}\right)\right] \qquad (18)$$

and for class 2, s takes the minimum value s_1 at

$$Z=\pm\frac{\pi}{\omega\sqrt{2}}\left(\frac{s_1+s_2}{2}\right) \qquad (19)$$

The ambiguity inherent in the appearance of the inverse sine function in expressions 17 and 18 is removed by the rule that for s in the interval $s_2=s={}^1/_2(s_1+s_2)$, the inverse sign takes values in $(0,{}^1/_2\pi)$, but for $s<{}^1/_2(s_1+s_2)$, the inverse sign is in $({}^1/_2\pi,\pi)$. In the case of class 2 solutions, s is a periodic function of z with period of $\pi/\pi\sqrt{2}(s_1+s_2)$, and with due caution all branches of the inverse function are applicable.

A graphical representation of the dependence of s on z is most readily obtained through the introduction of the following dimensionless variables:

$$w=(2\omega^2\epsilon_0 m/eJ_0)s$$

$$\zeta=(2\sqrt{2}\omega^2\epsilon_0 m/eJ_0)z$$

$$\gamma=\sqrt{1+(4\omega^2C_1)/(eJ_0/\epsilon_0\epsilon_0 m)^2}$$

In these terms, equation 17 becomes

$$\zeta=\frac{1}{\pi}\left[\sqrt{\gamma^2-(1-w)^2}+\sin^{-1}\sqrt{\gamma^2-(1-w)^2/\gamma)}\right] \qquad (20)$$

which evidently lends itself to the parametric representation

$$\pi\zeta=\theta+\gamma\sin\theta$$

$$w=1+\gamma\cos\theta \qquad (21)$$

Expression 21 describes a 1-parameter family of cycloids, as shown in Fig. 1. As C_1 increases from C_{1min}, γ increases from zero. When $\gamma<1$, the cycloids are curtate; and when $\gamma>1$, they are prolate. The ordinary cycloid results from putting $\gamma=1$, or equivalenty, $C_1=0$.

The complete vector velocity, obtainable from equations 2 and 7 is

$$v=\hat{x}(\Omega=\omega_L)y+\hat{y}(\Omega+\omega_L)x+\hat{z}s(z) \qquad (22)$$

From this expression it is apparent that the projections of the trajectories on the x-y plane are conic sections whose characteristics depend on the relative magnitudes of Ω and ω_L. When $\omega_L<\Omega$, the projected trajectories are hyperbolas with the common asymptotes

$$y=\pm\left(\frac{\Omega+\omega_L}{\Omega-\omega_L}\right)x \qquad (23)$$

and when $\omega_L>\Omega$, they are a one parameter family of congruent ellipses, with eccentricity

$$e^2=\left(\frac{2\Omega}{\omega_L-\Omega}\right) \qquad (24)$$

Of particular interest are the limiting cases $\Omega=0$ and $\Omega=\omega_L$. In the former, the projections are circles, and in the latter, they are straight lines.

The particular case in which s is the constant, $(eJ_0/2\epsilon_0 m\omega^2)$, and the trajectories project as ellipses constitutes a generalized Brillouin beam. As Ω takes its limiting values, the Brillouin sheet beam or cylindrical beam result. For the general case, the current density and charge density take values intermediate between the corresponding values for the limiting cases.

Potential Outside a Finite Beam

In this discussion it is assumed that $\omega_L>\Omega$, and that the beam is inside an elliptic cylindrical surface whose major and minor axes are prescribed. In addition, it is possible to specify the normalizing velocity of expression 20 and the current density. The potential inside the beam is then conveniently written in the normalized form

$$\phi=A(u^2+v^2/\beta^2)+w^2 \qquad (25)$$

where

$\beta=(b/a)^2$
$u=(x/a)$
$v=(y/a)$
$A=(eJ_0a^2/\epsilon_0 mv_n^3)(\beta^2/\beta^2+1)$
$w=s/v_n$
$a=$ minor axis of ellipse

From equation 25 it appears that the traces of the equipotential surfaces on planes normal to the z-axis are congruent ellipses with eccentricity equal to the square of the eccentricity of the trajectory ellipses.

That the finite beam described can be maintained, the potential and its normal derivative must be continuous across the beam edge, and outside the beam the potential must satisfy Laplace's equation. The analytic statement of this boundary value problem is most simply made in terms of the co-ordinates of the elliptic cylinder so that the beam boundary is described by a co-ordinate surface. The co-ordinate transformations are the following:

$$x=a\sqrt{\beta-1}\sinh\xi\sin\eta$$

$$y=a\sqrt{\beta-1}\cosh\xi\cos\eta \qquad (26)$$

$$z=z$$

The domain exterior to the beam is $\xi_0\xi\leqq<\infty$ and $0\leqq\eta\leqq 2\pi$. The beam boundary is described by the co-ordinate surface $\xi={}_0\xi$, where

$$\xi=\cosh^{-1}\sqrt{\beta/(\beta-1)} \qquad (27)$$

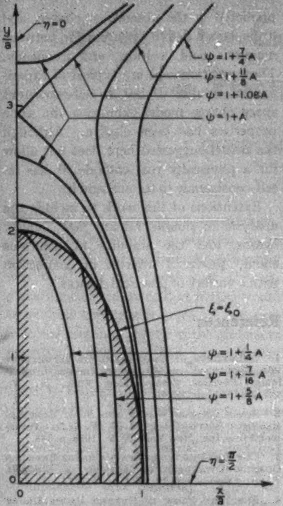

Fig. 2. Equipotentials for elliptical Brillouin beam with $(b/a)^2 = 4$

In terms of the new co-ordinates, expression 25 reads

$$\phi = A(\beta-1)\,[\sinh^2\xi\,\sin^2\eta + (1/\beta^2)\times \cosh^2\xi\,\cos^2\eta] + w^2 \qquad (28)$$

From equation 28 and its derivative with respect to ξ, the potential and its normal derivative on the beam boundary are obtained in the forms

$$\phi(\xi_0,\eta,z) = \frac{A}{2}\left(\frac{\beta+1}{\beta}\right) + w^2 - \frac{A}{2}\left(\frac{\beta-1}{\beta}\right)\cos 2\eta \qquad (29)$$

and

$$\left.\frac{\partial\phi}{\partial n}\right|_{\xi=\xi_0} = \frac{A\sqrt{\beta}(\beta^2+1)}{\beta^2}\left[1 - \left(\frac{\beta^2-1}{\beta^2+1}\right)\cos 2\eta\right] \qquad (30)$$

It is now required to find a solution in the exterior domain of Laplace's equation in the form

$$\frac{2}{a^2(\beta-1)(\cosh 2\xi - \cos 2\eta)}\left(\frac{\partial^2\psi}{\partial\xi^2} + \frac{\partial^2\psi}{\partial\eta^2}\right) + \frac{\partial^2\psi}{\partial z^2} = 0 \qquad (31)$$

whose value and normal derivative converge to expressions 29 and 30 respectively on the beam boundary.

The Cauchy problem as stated possesses a unique solution, but little is gained by writing it down. The solution is obtained by virtue of the separability of equation 31, and it is expressible in terms of a double infinite sum involving Mathieu functions of the $ce_{2m}(\eta)$ type, the associate Mathieu functions of the first and second kind, and cosine functions. The constants are related to those appearing in equations 29 and 30 and to the Fourier coefficients of the function $w^2(z)$, but the task of determining these constants is hopelessly complicated.

More enlightening than the general solution are the solutions for some particular cases. These suggest properties of the general solution, and are of some practical interest in themselves.

Potential of Generalized Brillouin Beam

If the axial velocity of the beam is constant, the normalized potential need have no z dependence, and equation 31 reduces to the 2-dimensional Laplace equation. In accord with equations 29 and 30, its solution is

$$\psi = 1 + \frac{A}{2}\left(\frac{\beta+1}{\beta}\right) + A\left(\frac{\beta^2+1}{\beta\sqrt{\beta}}\right)(\xi-\xi_0) - \frac{A}{2}\left(\frac{\beta-1}{\beta}\right)\left[(\cosh 2(\xi-\xi_0) + \left(\frac{\beta+1}{\sqrt{\beta}}\right)\sinh(\xi-\xi_0)\right]\cos 2\eta \qquad (32)$$

Several equipotentials for a beam of eccentricity $\sqrt{3}/2$, $(\beta=4)$, are shown in Fig. 2. Near the beam, the equipotentials are very similar to ellipses with the same eccentricity as the elliptical equipotentials in the interior of the beam. At greater distances from the beam, the equipotentials are no longer closed curves. All the curves of this class must ultimately become asymptotic to the lines $y = \pm x$. The potential at the saddle point shown is only a small amount greater than the potential on the beam edge where it cuts the x-axis.

From the potential plots it is apparent that a variety of electrode shapes and potentials for the maintenance of such a beam are possible, and the electrolytic tank should yield design shapes which can be readily machined. For the very long ellipse, which approaches the Brillouin sheet beam, it appears that electrodes at more than one potential are a necessity if the boundary conditions at the end of the beam are to be satisfied.

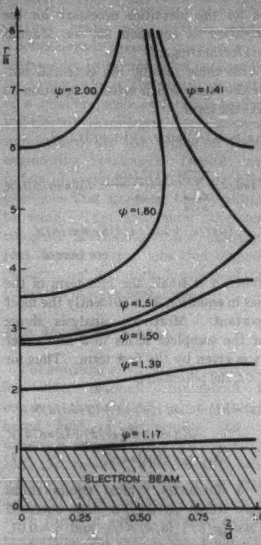

Fig. 3. Equipotentials for circular periodic beam with $(a/d) = 1/4$, $\gamma = 0.01$, and $A = (\pi/8)^2$

Potential of Circular Beam with Varying Axial Velocity

If the cross section of the beam is circular, considerable simplification of the general problem is achieved. (This case is discussed from a different point of view by Dow.[8]) It is appropriate to express the potential in terms of circular cylindrical co-ordinates so that by separation of variables a solution is obtained in the form of a sum over Bessel and trigonometric functions. The solution must satisfy the boundary conditions

$$\psi(a,z) = A + w^2(z) \qquad (33)$$

$$\left.\frac{\partial\psi}{\partial r}\right|_{r=a} = \frac{2A}{a}$$

Before writing the expression for the potential, it is necessary to determine the Fourier coefficients of the function $w^2(z)$. This may be done with an elegant result for the curtate cycloid of Fig. 1, although the problem is of considerable difficulty for the prolate case. With the assumption that $\gamma < 1$ and that

$$w^2 = \frac{1}{2}a_0 + \sum_{n=0}^{\infty} a_n \cos\frac{n\pi z}{d} \qquad (34)$$

it follows that

$$a_n = \frac{2}{\pi}\int_0^{\pi}(1+\gamma\cos\theta)^3\cos(n\theta + \gamma n\sin\theta)\,d\theta$$

$$a_0 = (2+3\gamma^2) \qquad (35)$$

$$a_n = -(-1)^n\frac{4}{n^3}J_n(n\gamma)$$

For the notation on Bessel functions

and for the identities necessary for the derivation of equation 35, see Magnus and Oberhettinger.[9]

With these results, the potential outside the beam which satisfies equation 33 takes the form

$$\psi(r,z)=A(1+2\log r/a)+1+(3/2)\gamma^2$$
$$-(4\pi a/d)\sum_{n=0}^{\infty}\frac{(-1)^n J_n(n\gamma)}{n}K_1(n\pi a/d)I_0\times$$
$$(n\pi r/d)+I_1(n\pi a/d)K_0(n\pi r/d)\times$$
$$\cos(n\pi z/d) \quad (36)$$

When γ is small, the first term of the series in equation 36 is evidently the most important. Moreover, analysis shows that the complete series to a first order in γ is given by the first term. Thus for $\gamma<<1$, the potential is

$$\psi(r,z)=A(1+2\log r/a)+1+(2\gamma\pi a/d)\times$$
$$[K_1(\pi a/d)I_0(\pi r/d)+I_1(\pi a/d)\times$$
$$K_0(\pi r/d)]\cos(\pi_n/d) \quad (37)$$

Fig. 3 illustrates typical equipotential surface traces on the r-z plane obtained for $A=(\pi/8)^2$, $(a/d)={}^1/_4$, and $\gamma=0.01$. The small value of γ is chosen to show the existence of equipotentials bounded with respect to r. For a larger γ, the curves which are nearly semicircular would be closer to the beam. For larger potentials than those shown, the equipotential curves approach a rectangular shape. It appears that the design of electrodes to produce this type of beam should be a simple problem even if it is desired to incorporate such electrodes into a slow-wave structure.

Conclusions

The exact solutions presented which are characterized by $\gamma<1$ are descriptive of regions containing no cathode, for there is no point at which the velocity vanishes. Nevertheless, the launching of a beam with elliptical cross section and periodically varying axial velocity should be possible by employing the techniques developed for the production of the circular Brillouin beam. When $\gamma=1$, the region may contain an even number of points at which the velocities vanish, and these may be considered as real or virtual point cathodes. Unfortunately, the solutions yield no surface of vanishing velocity and hence no model of a physically realizable cathode.

Although the generalized Brillouin beam possesses no distinguishing practical advantages over the circular Brillouin beam, it appears that the problem of producing a sheet beam might be approached to advantage in terms of the elliptical beam with large eccentricity. Since the sheet beam in practice cannot be semi-infinite, the elliptical model is in this respect a more realistic one.

A theoretical question which Brillouin's paper leaves unanswered is whether or not the circular beam is a particular solution of the general problem whose properties are dependent on the highly symmetrical cross-sectional shape. A similar question has been raised concerning the TE_{01} mode in a circular waveguide, and in this case it is well known that a distortion of the boundary into an ellipse eliminates the mode altogether. In the case of the circular Brillouin beam, however, the analysis presented here shows that it belongs to a 1-parameter family of solutions and is not a singular case.

Another possible application of these results is to the Barkhausen-Kurz oscillator. In recent work on this complicated device, much effort has been spent in attempting to find a satisfactory space charge model of the beam. The solution presented above with $\gamma=1$ and $\beta=1$ has the possibility of being a good space charge model, because it predicts a reduction in the frequency below that predicted in the absence of charge, and it displays a definite relationship between magnetic field, voltage, and frequency. These relationships are typical of experimental results,[10,11] but a self-consistent space charge model exhibiting the same properties has been elusive. Although the model suggested here does not allow for a physically real cathode, it has its self-consistency to recommend it.

Extensions of this work to include the analysis of double stream flow, hollow beams, and the stability of solutions should prove of interest in connection with a variety of practical devices.

Education for Expanding Horizons in Electric Power

GORDON S. BROWN
FELLOW AIEE

TO RECALL the undergraduate education of the writer's generation is to see evidence that engineering education was based on the belief that the engineering curriculum of that period would serve him throughout most of his professional lifetime. Many of the professors teaching at that time had a firm idea of what their students needed to know in order to engage in careers in the professional world. This seemed appropriate, for these professors had in no small degree conceived most of the world of electrical technology of about that era. It looked sophisticated and enduring. They accepted the principle of a curriculum largely based on contemporary practice, and assumed that the engineering profession would merely build the mechanisms of society, often to a conventional pattern, and keep them running. This doctrine stemmed from the assumption that technology would not change appreciably during an engineer's professional career.

Today the problem for the engineering degree-granting college is different. The last two decades or more have witnessed great productivity in science with the uncovering of tremendous amounts of wholly new knowledge about the physical world. In our turbulent technological scene, engineering proliferates with accelerating tempo in many fields, each with a broad range of work function, each undergoing rapid technological change. The changing technology presents educators with an ever-widening spectrum of problems. With each successive college commencement, it becomes increasingly difficult as well as increasingly unwise to equip graduates with specialized know-how skills related to contemporary engineering practice. Not only will tomorrow's engineer need to know more than his counterpart of a few decades ago, but he needs to be prepared to learn more during his professional lifetime. And what he must learn will often be quite different from what he was taught in college.

Within the young and rapidly changing field of electrical engineering is a wide variety of work function. The majority of graduates work for industry and not for a client. Matters of public safety, of equipment cost, etc., are important, but the yardstick by which their importance is measured is a function of determining who is the customer. Where the customer is a branch of the military, as is often the case, the yardstick for performance and cost of devices and systems is often calibrated in terms of national survival rather than by a 6% return on investment, and change is often encouraged for change's sake. Modern science exerts a dominant role in all engineering, and especially in defense engineering. Much engineering is done prior to a demonstration of practical feasibility.

The contrast in criteria that set engineering values in: 1. the design of a multimegawatt generating station for a public utility, and 2. a multikilowatt generating plant for a large vehicle to operate in outer space, puts the picture into focus. The first system may be typified as stationary, coal-, oil-, or gas-burning for a uniform environment, requiring 100% reliability, low capital cost, and low maintenance. Each new plant must be superior to its predecessor because of a number of circumstances, but it comes into existence largely through an orderly integration and some extension of the known art of the day. The second system, on the other hand, presumably must have negligible weight and size, must use electromagnetic radiation as its source of energy, withstand large accelerations, and operate for limited time in environments never yet encountered by man. Furthermore, its design must be compatible with the changing needs of many interlocking requirements set by specialists in nagivation, guidance, aerodynamics, etc.

The engineers who are to create this system encounter many problems for which there is little prior art to supply many of the answers. They must lean heavily on fundamentals of science and on their ability to apply them.

At present, there is the gradual substitution of fission fuel for fossil fuel, with its attendant highly technical problem of protection of personnel and equipment against radiation. The future shows promise of wholly new techniques for converting heat into electric energy. Thermoelectric power conversion by thermopiles using advanced semiconductor technology, or thermionic generators on a grandiose scale, or fuel cells as chemical-electric converters, or thermofusion energy, are live topics on today's engineering campuses. Digital computers of amazing capability are taking over jobs that engineers once performed by hand. They and many other technological developments are exerting a vast impact on the jobs that engineers perform, on the work function of vast categories of professional men.

The Academic Scene

The academic environments in engineering differ markedly throughout the country; they also differ even within the broad field of engineering. To cite merely a few differences, some institutions are oriented toward research, others toward applied engineering or manufacturing. The big differences in the work function among different fields of engineering and even within fields, exert considerable influence on educational policy.

As engineering as a vocation and as a profession has evolved, a system has been devised of 2- to 3-year technical institutes, 4- to 5-year baccalaureate-degree-granting engineering colleges, a system for on-the-job education of graduate engineers in industry, and an expanding program of graduate education in engineering colleges. The doctor's degree is becoming a prerequisite for leadership in many engineering areas.

Since it appears certain that the 4-year program of undergraduate education in engineering in most colleges and universities will be adhered to for quite a while, engineering curriculums are allocating less time to a treatment of contemporary engineering practice and more time to broad basic science and to the engineering of science.[1–3] As professors concern themselves with this limited task while continuing to point their interests toward engineering, they find the available time for undergraduate education much too short for the job that industry and society expect of them. On all sides one sees a reassessment of the content of curriculums and the methodology for giving an en-

Paper 60-17, recommended by the AIEE Education Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 4, 1960. Manuscript submitted July 6, 1959; made available for printing October 7, 1959.

GORDON S. BROWN is with the Massachusetts Institute of Technology, Cambridge, Mass.

during, purposeful education to future engineers.

The problem before engineering educators involves being sensitive to the expanding body of scientific knowledge and to the wide spectrum of work function in industry. Educators must continually update the scientific or technical content of their programs of instruction. Likewise, industrial leaders must keep abreast of the changes that occur in college environments as, year by year, the professors' interests change with the unfolding of new knowledge, and as curriculums, in the updating process, become more broadly based in the sciences. Updating can no longer be achieved merely by adding new material to an existing curriculum. The problem is not what to add but what to drop in order to make room for change. Often the procedure is misunderstood, as evidenced by the comment of a British educator who recently visited the writer's office. He had noted the preponderance of electronics, and was most disturbed that the teaching of electric power engineering had nearly disappeared from the American campus. He had not observed, however, that everything electrical is a manifestation of charge carriers, that a broadly based program called electronics can embrace power or, more properly, electric energy processing; and that electric power itself is emerging in new, more modern, forms.

It appears, therefore, that the solution at the undergraduate level is to bring about, continually, fresh course syntheses that have wider applicability within the criterion of knowledge that will be negotiable at par in many allied fields for a reasonably long time. Specialization is being moved to the graduate level. But the guideposts for doing this are varied and often appear contradictory.

Guideposts to an Engineering Curriculum

That engineering is the exploitation of science for the betterment of man is widely accepted. In other words, engineering is applying science or practicing the quantitative organization of natural phenomena. But in its creative aspects it comprises the ability to relate seemingly unrelated events of nature in quantitative ways in devising useful configurations of matter, elements, devices, or systems. Engineering must also quantitatively classify the recorded observations of science in ways that will provide a prediction of the quality and quantity of the outcome of designs not yet concluded,[4] in order that achievement may result from suggestions, that the possibility of new applications shall be enhanced and the validity of theories extended to include a continually widening scope. One may say that doing engineering is practicing the art of the organized forcing of technological change.

But not all persons whose careers are in engineering are endowed with identical talents. Because of the wide diversity among people, the wide diversity of activity within engineering, and the limited scope of most engineers' activities, it is helpful to classify broadly the work functions of engineers. There are about as many work functions as there are people but to point up some meaningful aspects of activity in relation to education, one may try to classify engineering practice in three categories, knowing well that the specific kinds of competence sought are a blend of an engineer's natural gifts, what he learns in college, and what he learns on the job or just by living longer and observing the world around him. Though oversimplified, the following is submitted to identify broadly three categories of work function.

1. IMAGINATIVE INSIGHT

In this category belong the persons who have talent for detecting deficiencies in the capabilities of existing engineering devices or systems, and who can conceive from abstractions or from the whole body of science, wholly new superior devices and systems. These can relate quite abstract and seemingly unrelated concepts in useful ways. They are composers rather than arrangers. Their work is predominantly intellectual and varied. These are the engineers who, having perceived, for example, the need for increased capability in computation, can conceive and point the way to the giant digital machines long before the first one is built; or who, from an assessment of the dwindling fossil fuel supply, perceive the possibility of, and point the way to, nuclear power or the direct conversion of cheap heat into usable electricity by thermoelectric generators, or who can synthesize from abstract science the techniques by which man may tame the energy of thermofusion. The power industry needs these men within its fold.

2. CREATIVE INVENTION

In category 2 are the persons who can devise and build systems of engineering works by an orderly, creative, ingenious arrangement of the knowledge of the day. These men are more creative arrangers or inventors than composers. They work at a less abstract level than do the men in the first category; they are sensitive in a quantitative way to engineering feasibility, and to economics. They need a high degree of competence in the areas of mathematics, physics, and related sciences, for they must understand both how and why machines work, and perform complicated analyses. They design and build complicated engineering works and in a great many instances they are doing something new. Within their area of work, they may perform at the same level of creative achievement, but their achievement will be of a different character from that of the engineers in category 1. Without these persons the contributions of the engineers of category 1 would be slow in coming into physical actuality.

3. PRACTICAL SKILLS

Persons who are expert in assembling, operating, and maintaining complicated machines and engineering works from drawings, descriptions, and from experience are in this category. These are not second-rate citizens. In tomorrow's era of technology they will be needed in great numbers. They find it difficult to move ahead with the stream with less than 2 years of study beyond high school. The environment in which they learn, however, can appropriately be adjusted to teaching them the how in addition to the why of contemporary engineering practice, devices, and systems.

For the engineers of either category 1 or 2, the Bachelor's degree should be only a beginning. During their professional lifetime, these men will witness great change and will be required to learn a great deal of technology not even visualized during their college careers. Their careers will be influenced by the fact that never is a machine devised which, within a few years, is not called upon to perform at a higher level of capability than its creators built into it. Throughout the undergraduate program of these men, the emphasis should be on providing a sound training in basic science and in applying scientific method to the solution of tomorrow's problems rather than yesterday's, and on developing qualities of character and mind typical of the industrial leader. The curriculum should be pointed toward graduate work; for many, toward the doctorate. The environment should be charged with creativity. The knowledge acquired should be intellectually open-ended so that it will be negotiable at par in many fields for a long time to come. On the other hand, it may be appropriate to offer for the engineer in category 3, a Bachelor's degree program in a technical school and to regard it as terminal. His continued education will occur largely on the job.

The Field

The relative need for persons in these categories of work function varies in different fields and in different societies. In many societies the person in category 3 is the most valuable and most in demand. But regardless of where a person gets his education, there is no denying that he should be given the opportunity to develop to the highest intellectual level that his talents will allow. Unfortunately, our educational system does not find it easy to do this.

Some Specifics of Engineering Curriculums

Speaking specifically with respect to technical competence, and perhaps paradoxically, specialized professional competence in the newest fields is secure only when it is based on a sound fundamental training in the oldest of our disciplines, namely, physics, mathematics, and chemistry. In the newest fields, it should be emphasized again, within the 40-year professional lifetime that is ahead of today's college student, there will be many changes. Many new fields will emerge and demand their services.[6]

Hence, it is not surprising that in planning engineering curriculums, increased emphasis is being given to these old disciplines, and to building upon them new syntheses of a body of knowledge called engineering science. These engineering sciences couple the classic scientific subjects with new engineering frontiers. Education's new role is to illustrate the *engineering of science.* Indeed, it is this frontier coupling, or interaction in engineering, which must be made clear to students who want to become engineers and not scientists. The teaching of mechanics and dynamics in the broad sense; thermodynamics and statistical mechanics, mass momentum and heat transfer, electrical science of a kind that treats electric and magnetic field and circuit phenomena at an advanced level as related to energy and information processing; and microscopic properties of matter in relation to materials in engineering should be made relevant to tomorrow's engineering. No two colleges, nor for that matter any two departments of the same school, are approaching the future in an identical way. This seems proper in view of the wide differences among engineering fields and among academic environments. But the trend toward engineering science[3] in lieu of specialization for an undergraduate degree, has been noticeable long enough to indicate that for many institutions the development is beyond the point of no return.

As the increased relative importance of engineering science has stimulated college faculties to remake their course structures, there has been a widespread search for guideposts. Initially, the reassessment is limited to studies within departments; but pressure to do this on interdepartmental and interdisciplinary bases is increasing. Many educators question the wisdom of preserving an undergraduate program that is organized along conventional lines of electrical, mechanical, chemical, aeronautical, or metallurgical engineering, etc. The careers of many engineers prove to be no respecters of such categorization.[5] The existence of large digital computers as commonplace engineering tools has had a major influence on current engineering practice.[6] The boundaries between established departments on academic campuses are becoming more permeable, but professional society structures, the Engineers' Council for Professional Development accreditation practices,[7] licensing practices for engineers, etc., are so well entrenched and are such important parts of our heritage, that change is going to be evolutionary rather than revolutionary.

The criterion that "the knowledge should be negotiable at par in a wide range of allied fields for a significant period of time" should be a dominant factor in establishing guideposts. For an electrical engineer, another guidepost is found in the statement that everything that is characterized as electrical is a manifestation of the phenomena of charge carriers, their associated fields, and how they interact with materials.[8] To inject purpose into a program of study, it is helpful to say that electrical engineers exploit this nucleus or model of natural phenomena to perform useful functions in everyday living, either to process energy for energy's sake, or to process information so that humans can communicate. The processing of energy relates to man's desire to substitute machine for human muscle by providing the giant motors, machines, and power systems that control wheels of industry and also provide light and heat. The processing of information embraces techniques for establishing communications between man and man, between man and machine, and between machine and machine. Radar, radio, and wire telephony, measurement, electronics, computation, and control are the fields where information processing is applied.

First-rate competence in engineering practice is made more secure when an engineer is quite knowledgable in both broad areas. The above concept of electrical technology is being implemented by curriculums and teaching programs in American colleges in several forms. Behind the names of courses, one can observe emphasis on such open-ended topics and concepts as Electric Circuit Theory; Electronic Devices and Circuits; Information-Handling Systems; Electromagnetic Theory; Electrical Energy Conversion, Transmission and Radiation; and Modern Physics and Materials.

In many colleges, the sophomore and junior year work is substantially in science and electrical science. In the final year, students take various electives that couple the earlier study with areas of application. Here, hopefully, they come to grips with some of the new engineering frontiers.

Speaking strictly of the writer's own institution, the Massachusetts Institute of Technology has abandoned an option structure that was attempting to provide specialization by field, such as power, communications, computation, radar, etc. and is veering toward an option structure that shows signs of compatibility with categories 1 and 2 of work function, for they exist throughout all fields. For about 25 years, the Cooperative Course in Electrical Engineering, Course VI-A has been offered as one option. Recently, an Electrical Science and Engineering option, Course VI-B was initiated. The latter option is intended to provide the maximum opportunity for early development of the person whose eventual academic level is the doctorate and whose eventual work function would fit category 1. The program in Courses VI and VI-A fit students who may be oriented toward either categories 1 or 2.

In the evolution of this program, new areas of instruction have come into being and new laboratory facilities have evolved.

A graduate of the Department a decade ago will recognize in today's program little of what he studied, but it is hoped he may now see presented what he wishes he had studied. This is especially true of the graduate who has made his career in the electric power field. Alumni and educators from industry who know of the program in detail have given it a vote of confidence.

The Coupling of Industry and Education

As technology has advanced during the last decade, the newer fields have often appeared more glamorous than the older ones. For perfectly valid reasons, the research interests of engineering professors are in the newer fields. In fact, many of these fields were spawned by these research interests. As a consequence, the communications links between the older and well established fields and the new challenging activities on college campuses often become strained. In many instances, they have become disconnected.

This situation is not good. The field of power generation in the public utility area, while long established, continues to enlarge. It needs to recruit able young men to take care of growth, to stimulate its technological advance, and to replace the engineers who, after long years of productive service, have reached retirement age. It needs its proportionate share of first-rate minds in both categories 1 and 2.

The writer believes that ways must be found to restore this communication link, and that restoration will best be accomplished by activating open-ended on-campus research in energy-processing and related areas, rather than merely in electric power, in ways that capture the interest of both engineers in industry and engineering college professors.

It does not appear possible to establish research on engineering campuses around topics that relate closely to contemporary industrial practice. Faculty research is of questionable academic caliber unless it is basic, open-ended, and has with respect to its effect on industry, a lead time of several years. Some new horizons need to be explored, and this may be the time to do it.

For example, throughout all industry a major deterrent to advancement is the limited capability of existing materials. Basic research in the area of molecular engineering to achieve new materials and improvements in existing materials would be most fruitful.

Within the broad field of the direct conversion of heat into electric energy, there are many problems whose solution would yield useful engineering developments within 5 to 10 years. Specifically, the exploitation of solid-state technology, plasma dynamics, and magnetohydrodynamics to provide new machines to furnish electric power are good examples. Research in these areas should be flexible and imaginative, for no one living can visualize the technology of 10 years hence. The record clearly shows that the future will be different, that it will surprise us, and that the public utility industry will need what ever the future may bring.

The advent of the large digital computer[6] opens a wide vista for gainful research in the power area. Automatic monitoring of load generation and distribution presents a challenge. Contemporary digital computers possess a capability that so vastly exceeds the capability of network analyzers of merely a decade ago, that the methods for representing complete electrical generating systems on computers for stability and power-flow problems merit reassessment. It is no longer necessary to use oversimplified mathematical models of boilers, turbines, speed governers, generators, and voltage regulators.

As technologies for the direct conversion of heat into d-c energy reach the engineering phase, the following needs are apparent: 1. The invention and engineering of new machines to utilize energy in the form of kiloamperes at a few volts, in contrast with a few amperes at high voltage as used today. 2. Ingenious ways to convert large blocks of energy from direct current to alternating current, perhaps by devising ways to exploit modern silicon diodes and modern switching transistors. 3. Better and cheaper ways to convert from alternating energy into direct energy, and vice versa.

The long-term values of on-campus research in which a student participates need wider recognition. This does not imply that a student should be trained only for a job in research and development but, rather, to enhance the probability of developing his talents of creativity and versatility or originality. Even if he is not destined for a career in research and development, this may be a wise choice, for, increasingly, management leaders are being selected from personnel within this category.

The electric utility industry has yet to find a way to allocate funds to college professors for research of a professor's own choosing that is compatible with an academic career. The older procedure of contracting with colleges for programmatic work that is more engineering than research, and monitoring it from the central office, does not meet with the enthusiasm that is necessary. Young, imaginative students, enthusiastic about a career in the public utility field, do not favor the prospect of monitoring engineering which is practiced elsewhere. The result is that there is a poor impedance match between the industry and the campus that often results in many highly desirable students looking elsewhere for employment and hence overlooking a wonderful opportunity for an exciting career.

Conclusions

The persistent substitution of machine for human muscle forecasts continuing programs to construct electric generating and distribution plants to keep ahead of demand. With increased load comes a demand for increased size of plant with increased performance. Greater numbers of engineers are required to build bigger and better plants on a shortened time scale and to incorporate new technological developments. Concurrent with these trends is an exfoliation of engineering into many new highly technical and challenging fields that compete for engineers.

These situations tax the technical and administrative skills of the practicing engineer, and of the professor who is to educate tomorrow's engineer. Since engineering colleges are restricted, in the main, to the 4-year undergraduate program, they are adjusting to the challenge by presenting students a more integrated body of fundamental knowledge, at the sacrifice of the specialized knowledge characteristic of the past. Many graduates of a modern 4-year curriculum are capable of a career in any one of several industries. When an employer first talks with a new 4-year graduate, he is less likely to find a specialist ready for his industry than did his predecessor a decade or so ago; this is especially true of employers in the electric power industry.

Industry needs to keep abreast of the changing technical content of modern engineering curriculums, and of the changing educational environment, in order to communicate fluently with tomorrow's graduate. It needs to appreciate the vital role of on-campus research and graduate study in keeping our educational institutions as places of learning, rather than merely places for teaching. The importance of recruiting top-flight young minds into all segments of industry on a balanced basis needs attention. The importance of aiding practicing engineers to obtain refresher instruction in an organized manner every 5 years or so is increasing. The key to the much needed communication between the leaders in the electric power industry and the professors on engineering college campuses is to initiate more open-ended programs of on-campus research under direct industry sponsorship.

◆

Discussion

V. F. Estcourt (Pacific Gas and Electric Company, San Francisco, Calif.): We note with interest that this more recent presentation of the paper (first presented in 1958) contains a number of significant revisions. The author is to be congratulated for this thoughtful review of a number of important educational fundamentals of methods for bringing about a closer relationship between industry and education.

We agree that the communication links between the older and well-established fields and the challenging activities on college campuses often become strained, and in many instances disconnected. In recommending ways for the restoration of this communication link, emphasis is placed upon the activation of "...open-ended on-campus research in energy-processing and related areas, rather than merely in electric power, in ways that can capture the interest of both engineers in industry and engineering college professors," and the author concludes that faculty research is of questionable academic caliber unless it is basic. Certainly we must agree that faculty research around topics that are too closely related to contemporary industrial practice is not only unattractive to teachers of engineering but, because such topics normally lie outside the field of engineering teaching, activity in this area would be largely unproductive of constructive results.

Throughout the paper, the need for basic research is emphasized as the key to communication between leaders in the electric power industry and the professors of engineering college campuses. This is good to the extent that it will bring significant advances in the art, or justifiable economic returns in the short or the long range. But the author stops there and fails to mention other desirable links. To this extent it becomes difficult to see the major problem in its proper perspective.

It is natural that research efforts by power engineers are predominantly in the field of applied rather than more fundamental research. This does not mean that the power industry lacks interest in this field, but merely that educational institutions, special research organizations, and large manufacturers usually provide a more suitable climate for the successful conduct of this type of activity. On the other hand, it should be pointed out that a most intimate relationship exists between the engineers of a good many utilities and the major power equipment manufacturers, and the two groups are constantly teaming up in co-operative research efforts.

The engineering scene in the power industry has been changing rapidly, but engineering teachers in some instances appear still to be thinking in terms of situations which existed 10 or 15 years ago. A great amount of applied research and development is continually going on in, or in relation to, existing power plants, as well as in connection with radically new designs, and the outlook is for further spectacular advances in the art, partly as a result of such activities. A large modern thermal power plant (conventional or nuclear) is in a certain sense one of the best equipped and most challenging research laboratories available for advanced engineering study. We suspect that many teachers of engineering would be surprised if they realized the full extent and significance of high-level research which goes on in connection with some of the large modern power plants. Utilities have perhaps been lax in bringing their story to engineering faculties, and a recent paper by this discusser represents an effort to establish a closer understanding between engineering colleges and the power industry.[1]

In the section "Guideposts to an Engineering Curriculum," in category 1, the author states that the kind of individual required is one "who can conceive from abstractions or from the whole body of science, wholly new superior devices and systems." This recognizes a fundamental objective in certain fields of engineering science, and is especially applicable where it involves the transition from one technological plateau to another. On the other hand, to certain types of intellects, each such plateau appears to a large extent as a distinct and static situation in the sense that it cannot be extended or improved in any significant amount unless it is completely displaced by other "wholly new and superior devices or systems." What must be understood is that, in many instances, each plateau of a major technological advance contains within it much of a dynamic nature which makes possible further expansion or development of radically new concepts leading to a significant technological advance, or sometimes a series of less pretentious advances which, in the aggregate, represent a major transition to a wholly superior device or system. Therefore, we must also recognize those individuals who have a feeling for the dynamic possibilities inherent in a given device or system, and who have the intellectual qualifications to develop radically new applications rather than wholly abandon one device or system for an entirely different one. Frequently these two approaches require substantially different types of intellect and motivation. Broadly speaking, this distinction emphasizes one of the differences between a scientist and an engineer.

The significance of this point of view is sometimes overlooked. Existing devices or systems are too often regarded by the abstract thinker as inherently static in the sense that all of the engineering has already been completed and wrapped up in a package which provides no room for further creative and significant technological contributions. It would appear that the author's thinking is in this channel when he states, in the section "The Coupling of Industry and Education," that young imaginative students, "enthusiastic about a career in the public utility field, do not favor the prospect of monitoring engineering which is practiced elsewhere." Doubtless, such situations may exist in varying degrees both in the utility field and in other heavy industries. Since jobs requiring the highest level of academic achievement may be limited in these industries to approximately 25% to 40% of the engineering payroll, mistakes are sometimes made in the allocation of personnel by not recognizing the need for a proper balance of skills. Academic quality and over-all quality are not necessarily synonymous, and this must be taken into consideration in the assignment of engineering personnel.

There is another side to the problem. It is something of an anomaly that, as engineering curriculums become more concentrated in the study of the fundamental sciences, the end result in industry is a very large increase in the number of specialists, which appears to be out of proportion to the inherent need with respect to problems definitely requiring such specialization in depth. Thus, although it might reasonably be assumed that the broader knowledge of fundamentals acquired by today's engineering students would develop the ability to encompass larger areas of engineering, the reverse is frequently the case. This is partly because of overemphasis upon rigorous logical processes of abstract thought and mathematical formalism which tend to place the world of reality out of focus. As Prof. Keenan has aptly observed in an unpublished paper, "Many young people who will ultimately be competent, even brilliant, members of the profession would find that such a program would inhibit rather than stimulate their creative talents." It would appear that educators in the field of engineering have an important obligation to guard against the danger of leading engineering students into areas of intellectual irresponsibility with too little regard for worth-while objectives in the field of application.

We can certainly agree with the author's timely admonition that "Industry needs to keep abreast of the changing technical content of modern engineering curriculums, and of the changing educational environment, in order to communicate fluently with tomorrow's graduate." We are aware that efforts by industry in this direction have sometimes left much to be desired. However, it is also reasonable to expect that engineering professors will continue to maintain adequate communication with industry in order to retain close familiarity with its technological advances and progressively unfolding objectives. Thus the challenging outlets for brilliant minds may be better understood by educational institutions. A number of engineering colleges have been eminently successful in maintaining realistic contacts with what the better power companies are doing in application and development, but by no means has this always been the case.

Brilliant scientists are understandably in demand for much needed basic research which frequently demands unusual ability in the area of creative abstraction. However, there appears to be too much of a tendency to think of brilliant engineers as scientists and the less brilliant ones as engineers. As I have stated, "We must get away from the idea, expressed or implied, that an engineer is essentially a scientist with some practical experience in the design of hardware, as a result of which he has acquired judgment in the execution of his assignments. This is a very dull and unrealistic concept of an engineer, but unfortunately it represents a viewpoint which is not uncommon in the field of education."[2]

In conclusion, we endorse wholeheartedly the suggestion that basic research can be made a natural and worth-while communication link between industry and engineering colleges. As the author observes, "This does not imply that a student is being trained only for a job in research and development." On the other hand, if no other links with industry are created in the mind of the student, it suggests a lack of something of profound importance either in the engineering curriculum or in the point of view presented to the student.

It is our hope that this discussion of the author's fine presentation, offered from the viewpoint of an engineer and technical manager in the power field, will be accepted as a contribution to his expressed objective of establishing a stronger "coupling of industry and education."

Gordon S. Brown: I am indebted to Mr. Estcourt for his provocative comments on my paper, and agree with many of them. But I believe that there is still a breakdown in communications and that the discussion has not provided a solution.

I am well aware that there is good team play between the public utilities and the major equipment manufacturers, but I am pleading for interplay between the utilities and the college campus. Many of my colleagues have close association with public utility problems but find it difficult to bring much back to the classroom or laboratory in a way that makes it a growing part of academic life.

My emphasis on basic research, with due recognition of the "humpty-dumpty" nature of the word basic, is to make it possible for the professor and his students to do work that conceivably could lead to self-generating ideas. Mr. Estcourt appears to be critical of my Category I engineer, but I believe firmly that unless professors and selected students can work at the kind of problem characterized by this category of work function, the self-generated idea is unlikely to arise. It is the open-ended, self-generated idea that is ideally suited to being followed up in a college environment.

I do not deplore design in the broad sense, but I know of no way to accomplish public-utility contemporary design under authentic circumstances in a college environment. On the other hand, I strongly support the introduction of students in mature ways into design problems. It so happens that in almost all research problems in engineering there are abundant design problems that students can tackle, and which reflect bona fide situations.

Perhaps the crux of the issue is found in my interpretation of the role of a university or technical college in today's society. I believe that not only should it teach well the knowledge of the day but also it should provide an environment where the ideas and issues of tomorrow are being uncovered. Here it must give a strong emphasis to learning rather than teaching. It is not enough for professors to be abreast of contemporary public utility practice and problems; they should be forging ahead into new problems. Likewise, it is not enough to equip students with the knowledge of the day; they need the basic knowledge from which will spring the developments of the future. They should be given the attitude of mind that will tend to bring these developments into reality. If they are going to be leaders they will be the instigators of change in the interests of improvement in technology and our society in general. The engineer is the person who has shaped our past and he will shape our future.

As I stated in the paper, electric energy is a vital element of our industrial system. Electric power engineers of the future will not be limited to hydro or fossil fuels as the basic source. New sources, and new forms for the processing of energy are clearly in the offing. Now is the time to be educating a future generation of public utility engineers in anticipation of these new forms, for, if this is done wisely and well, today's students, by their efforts as practicing engineers, will bring into reality what is now over the horizon. As they do engineering they will be participating in the organized forcing of technological change. Perhaps we have here the means for man to achieve the future that today he wishes were already a reality.

Development and Application of Time-Division Multiplexing Telemetering Equipment for Data Transmission on an Electric Power System

C. P. ALMON, JR.
FELLOW AIEE

JOHN DONELSON, JR.
ASSOCIATE MEMBER AIEE

Synopsis: In the fall of 1957 the Tennessee Valley Authority (TVA) began preliminary work toward increasing the number of telemeter readings by use of existing telemeter circuits with a minimum of modifications and additions. The additional channels were used to provide the power-system dispatchers with data that were normally received by telephone. The initial objective was to transmit the load readings of five hydroelectric plants and their total from the Nashville Load Dispatching Office to the Chattanooga Load Dispatching Office. High-speed data transmission was not a requirement in this case, since no automatic controls were involved and the readings were to be used for informative purposes. In view of the foregoing requirement, studies indicated that distant readings could be transmitted to a remote central location, from which time-division multiplexing telemetering equipment could be employed for data transmission, thus reducing the cost of communication channel facilities. Investigations indicated that no suitable equipment was available for this purpose that would work with existing facilities and that would provide the necessary functions. TVA devised experimental equipment to transmit six hydro plant readings over one impulse channel from the Nashville Load Dispatching Office to the Chattanooga Load Dispatching Office. Later the hydro plant readings were replaced by six substation load readings that are used in a computer for system economic loading purposes. This equipment has operated over a 1-tone channel of a microwave system about 130 miles in length for more than $1^1/_2$ years and the operation has been satisfactory.

THE OPERATING AREA of the TVA covers approximately 80,000 square miles, comprising portions of the states of Kentucky, Virginia, North Carolina, Georgia, Alabama, and Mississippi and most of the state of Tennessee. The rapid growth of power generation and the distribution of electicity through this area have led to a need for transmitting more quantities from distant areas to the central dispatching office in Chattanooga for system operation and economic loading purposes.

In TVA's automatic load-frequency control system numerous interchange readings with other companies are transmitted direct by high-speed telemetering over carrier channels. The interconnecting companies' megawatt load readings are totalized in Chattanooga and compared with a schedule; and the deviation from schedule is transmitted to the appropriate generating station, which automatically adjusts its output to compensate for the deviations from schedule. It is of great importance that time delays be reduced to a minimum in this control operation.

There are other readings in which high-speed response is not required, such as those needed for general dispatching information and economic loading. With a reduction in the speed of data transmission the telemetering channels could be reduced by applying the principles of time-division multiplexing. With this system, kilowatt load information gathered from various locations at a distant subcenter could be sequentially scanned and transmitted over one narrow-band telemeter channel.

It was found that suitable equipment that would work with existing equipment and that would transmit the desired quantities was not available. Since the output from the receivers at the Nashville Load Dispatching Office was in millivolts proportional to power, direct application of these quantities into an electronic scanning device did not appear to be feasible at that time. Several methods of transmitting the megawatt readings were considered; however, studies indicated that impulse duration transmission was best suited for the purpose, since an existing Leeds & Northrup 2.4-second Speedomax impulse telemeter transmitter could be incorporated easily into the transmission system.

After it was decided to use impulse lengths proportional to power readings, other considerations were: the methods of scanning the local inputs, the synchronizing circuit for the transmitter and receiver, a comparator circuit to convert impulses into an electrical quantity, and a means of synchronizing the comparator circuit with the memory circuits that hold the readings constant until the next comparison is made. Fig. 1 is a block diagram of the systems operation.

The Transmitter Unit

Six quantities were initially selected for retransmission, and the inputs for these quantities were derived from retransmitting slide wires that were already in use in a totalizing circuit. Two telephone-type rotary switches were chosen for the transmitter unit—one operates as a scanner and the other as a timer for synchronizing. A 22-point 5-bank switch

Paper 60-245, recommended by the AIEE Telemetering Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted November 4, 1959; made available for printing December 17, 1959.

C. P. ALMON, JR. and JOHN DONELSON, JR. are with the Tennessee Valley Authority, Chattanooga, Tenn.

The authors wish to acknowledge the assistance by Mr. Fairfax, Mr. Gostin, and Mr. Huff of the Tennessee Valley Authority.

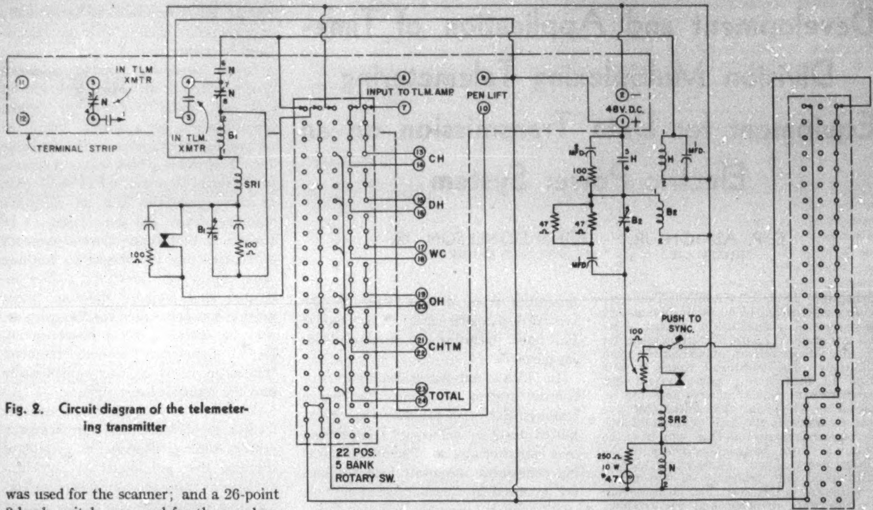

Fig. 2. Circuit diagram of the telemetering transmitter

was used for the scanner; and a 26-point 3-bank switch was used for the synchronizer timer. These switches were available and could be adapted to TVA's needs. Three positions are assigned for each reading. Postion *1* in each group is connected at the transmitting end only and is used to allow time for the transmitter recorder to achieve a balance. Postion *2* transmits 91% of the change since the last scanning. Position *3* transmits 99% of the change.

The start, or leading edge, of the time-duration impulse causes the scanner to move one position. The scanner switch also controls the pen lift of the transmitter recorder so that a dot is made for each quantity being recorded, operating very much in the same way as a multiple point temperature recorder. Each revolution of the scanner switch advances the timer synchronizing switch one position. After 20 revolutions of the scanner switch, the synchronizing switch repositions the scanner switch to the no. *1* position and suspends transmission to the receiver end for synchronizing purposes. During this interruption the scanner switch remains on position *1*.

It is necessary to scan the quantities only one time per sweep of the rotary switch. Since ordinary load changes are very small during that period of time and since one sweep will give 91% and the second sweep 99% of the load change, one scan per input quantity would be entirely satisfactory.

A manual pushbutton is provided for near instantaneous synchronizing of the transmitter and receiver. This switch is used for testing purposes and maintenance.

Fig. 2 shows the circuit diagram of the transmitter. The front and rear views of the transmitter are shown in Fig. 3.

The Receiver

The receiver is composed of a comparator circuit; a 22-position 5-bank telephone-type scanner switch; a synchronizing circuit with a local impulse device; memory circuits; indicating meters; and dropping resistors for use as millivolt potentials for recorders.

The comparator circuit is a resistor capacitor circuit in which the charge on a capacitor is proportional to the time duration or length of the impulse. The capacitor used is of a high-grade type with a very low dielectric-absorption characteristic. The RC (resistance-capacitance) time constant of the circuit is much longer than the longest impulse.

A 22-position telephone-type rotary switch, the same as used in the transmitter, scans the memory circuits. Three successive positions are assigned to each reading, with the second and third points in each group being used to connect the comparator circuit with the memory circuits.

The synchronizing circuit consists of a signal failure device that operates when two signal impulses are suspended; and this device synchronizes a cam impulse de-

vice that is driven by a local synchronous motor, which takes advantage of the interconnected 60-cycle system and supplies impulses for stepping the local scanner switch.

The memory circuits are composed of twin triode vacuum tubes having capacitors shunted across the input grids. These triodes have cathode dropping resistors and operate on the linear portion of the curve so that the plate current is proportional to the grid voltage. The cathode voltage with respect to negative is compared with a reference voltage. A milliammeter for indicating megawatts and a dropping resistor for potentiometer use are connected between the cathode voltage and the reference voltage. When the cathode voltage and the reference voltage have the same value, the indicated megawatt on the milliammeter is zero. If a left-scale instrument is used, these voltages are adjusted to be equal for zero indication. If zero-center operation is used, the cathode voltage is adjusted to equal a reference voltage at midrange. This type of memory circuit will hold an almost steady output for several minutes. A secondary emission from the grid tends to increase the charge on the capacitor in a positive direction, which would result in an increased indicated megawatt usage. This effect is nullified by the choice of capacitors that have dissipation factors about equal to the secondary emission of the grid circuits.

In the operation of the initial receiver circuit the start, or leading edge, of the received impulse from the transmitter over the communication channels was used to step the scanner switch directly. During communication disturbances false impulses would cause the local scanner switch to get out of synchronism with the transmitter scanner switch. The local synchronously driven impulse device previously mentioned was contrived to take advantage of the interconnected 60-cycle system and to prevent false impulses from causing a loss of synchronization between the two switches. Once the transmitter and receiver are in synchronism, they will remain so indefinitely unless disturbed. If the receiver or transmitter is interrupted, it will be automatically resynchronized within a preset 15-minute interval.

Synchronization of the local impulse device (shown in the lower portion of Fig. 5) is accomplished by the suspension of signal impulses from the transmitter. The suspension of two impulses will cause the synchronizing device to operate and return the local scanning switch to position no. *1*. Contacts in the synchro-

nizing device also operate a relay which locks in a notch of the motor-driven cam and stops this cam from rotating by means of a slipping clutch. When the leading edge of the first impulse is again received from the transmitter, the synchronizing device unlocks the cam, which starts rotating. The local impulse device steps the scanning switch to position no. *2*. At the same time the scanning switch in the transmitter is stepping to position no. *2*, after which both switches remain in synchronism.

During the operation of the receiver the capacitor in the comparator circuit is charged through a resistor, and the value of the charge is proportional to the length of impulse received from the transmitter. At the end of the impulse the comparator circuit is switched to the scanning switch. There are three successive positions on the switch assigned to each reading; and the first position in a group is not connected, since the transmitter recorder may not have reached a balance and any unbalance would cause a false reading in a memory circuit. The second and third points of the scanning switch in a group are connected successively to a memory circuit. Since the comparator capacitor is 10 times as large as the capacitor used in the memory circuit, 91% of the load change since the last scan will be recorded on the second contact of a particular group, and 99% of the change will be recorded on the third position of the group For instance, if a receiver position were reading 0 and there was a 100-megawatt load change, the memory circuit would read 91 megawatts on the second position of the group and 99 megawatts on the third position of the group. A successive scan would cause 100 megawatts to be read.

After each comparison with a memory circuit the capacitor in the comparator circuit is discharged. When the grid voltage in the memory circuit is increased in a positive direction, the cathode voltage becomes higher than the reference voltage as previously explained, and causes current to flow through a milliammeter and a dropping resistor, thus indicating an increase in load.

During any synchronizing operations the impulse circuit to the scanning switch from the comparator circuit is open; hence, although the switch may pass over contacts of the memory circuits, there are no spikes or false readings made in the memory circuits.

Fig. 4 shows the circuit diagram of the receiver. Fig. 5 shows a view of the receiver with local impulse device at the bottom. Fig. 6 shows a view of the megawatt indicating meters on the dispatching instrument board.

Fig. 7 shows a comparison of the same megawatt load curves that were transmitted simultaneously from Nashville to Chattanooga. The upper curve was made by means of 2.4-second-cycle impulse telemetering equipment over a carrier telemeter channel. The lower curve was made by multiplex telemetering equipment and was 1 of 6 quantities transmitted. The comparison shows that there is no loss of essential information in the latter curve.

Conclusions

1. The 2.4-second scanning period of the circuit is relatively slow, but it has been entirely satisfactory and is much faster than is required for the present purposes.

2. Each quantity is scanned at an interval of $45^{6}/_{10}$ seconds. By speeding up or reducing the balancing of time on the Leeds & Northrup potentiometer transmitter, the same circuit can transmit 19 quantities in the same length of time as is now being used to transmit 6.

3. The use of the system described has been very effective and reliable in transmitting megawatt readings of generating plant output and substation power usage from the remote center to the power system dispatchers' office in Chattanooga.

4. In addition to the present use the multiplexing system can be applied to transmit incremental-cost data on a far-flung system, where the distances from the dispatching center to the various plants are relatively large. With this system a single transmitter can transmit to a number of receivers located at the various plants over a single-frequency, narrow-band carrier channel; and only the receiver points applying to a particular station will appear at that station. For instance, the bus costs or lambda, divided by the penalty factor for each station, could be successively transmitted; and, with auction-type bidding for the system incremental load, each station could match its incremental cost with the incremental bus cost.

A New Impulse Metering System

C. J. SNYDER
ASSOCIATE MEMBER AIEE

C. A. BOOKER, JR.
NONMEMBER AIEE

THE INCREASING number of power loads in the 100-mw (megawatt) and higher ranges with the attendant problems of metering and totalizing several supply sources has disclosed the inability of much of the present impulse-operated metering equipment to render the dependable, accurate, and maintenance-free service required.

This is in part due to the relatively low activity of such apparatus which has not justified extensive design improvement.

Recent developments, however, have made possible a new concept of impulse metering which features high impulse rates and accuracies. The purpose of this paper is to describe the development and the principles of operation of the new units now available to meet this high level of performance.

Performance Requirements

In impulse metering systems the accuracy with which demand values may be obtained is dependent upon the maximum number of impulses that can be accepted by a receiver or recorder, the number of circuits totalized, and the number of impulse totalizing steps involved which may harbor impulse storage errors. The obvious requirement for high accuracy is the capability for high impulse rates wherein each impulse represents a minimum kwhr (kilowatt-hour) or similar value so that storage errors in the meter contact devices and elsewhere are minimized.

The fundamental limit on impulse rates is the acceptance capacity of the terminal recorder in impulses per demand interval. The present trend is toward a full scale or printing capacity of 1,000

Paper 60-64, recommended by the AIEE Indicating and Integrating Instruments Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted November 2, 1959; made available for printing November 24, 1959.

C. J. SNYDER and C. A. BOOKER, JR. are with the Westinghouse Electric Corporation, Mr. Snyder at Raleigh, N. C., and Mr. Booker at Cheswick, Pa.

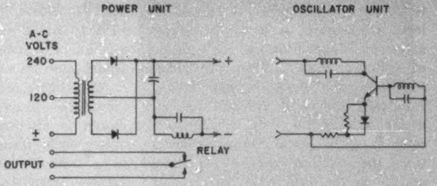

Fig. 2 (above). Impulse device schematic

impulses per interval. The ultimate accuracy of a recorder with 1,000 impulses per interval capacity is, of course, no better than ±0.1% at full scale. Such a recorder would normally be operated between 50% and 75% of full scale to provide adequate overload margin and the accuracy would therefore be more probably in the ±0.2% area. Since greater accuracy is certain to be desired in the future any new impulse system should readily handle about 5,000 impulses in a 15-minute demand period and have an inherent capability for even higher rates if required.

Another requirement is that of dependability, which is particularly important in the case of billing major revenue loads or interchange of power. This factor has in the past tended to restrict the use of electronic equipment and favor mechanical devices.

Any new system also should be compatible as far as practical with existing impulse equipment. In addition, the equipment should not be so expensive as to limit its use to those premium installations where the alternative totalizing methods of either paralleled current transformer secondaries or multistator meters cannot be used.

Design Principles

Recent developments, particularly in transistors and logic circuitry, provide the means for the generation and totalization of impulses with static equipment. These devices, along with newly available mechanical components, such as the stepping motor, make possible a system featuring high performance and reliability with low maintenance.

Impulse Generation

Every impulse metering system originates with some type of impulse-sending device driven by the watthour meter or equivalent.

The contact devices heretofore used were difficult to adjust because of the necessity of balancing contact pressure against permissible friction load and because the maintenance needed to provide clean electrical contacts within the meter required continuous attention by experienced personnel.

The concept of a truly modern impulse system has been greatly advanced by the development of the oscillator impulse device shown in Fig. 1. The two principal components of this impulse sender are a pickup head containing a transistorized oscillator appropriately mounted in the meter, and an externally mounted power and relay unit. Fig. 2 shows the schematic circuit diagram of the oscillator and power supply.

The former cams driven by gearing from the meter moving element are replaced by a nonmagnetic segmented disk or vane.

The unit employs a germanium transistor in a special relaxation oscillator circuit. When an open section of the vane moves into position between the coils the oscillator draws a normal current of about 3 milliamperes from the power supply and through the relay coil, closing the normally open contacts. Movement of a solid segment of the vane between the coils reduces the mutual coupling between them so that the oscillator supply current drops to a fraction of a milliampere, thus releasing the relay armature to its normally closed position. The oscillator, which operates at approximately 100 kc is sealed within a molded phenolic head. Single-pole double-throw contacts on the relay provide one complete cycle of operation for each vane point on the disk. This impulse unit is capable of operating at rates up to 300 impulses per minute with negligible friction load on the meter. It may be used with existing impulse equipment of either the 2-wire or 3-

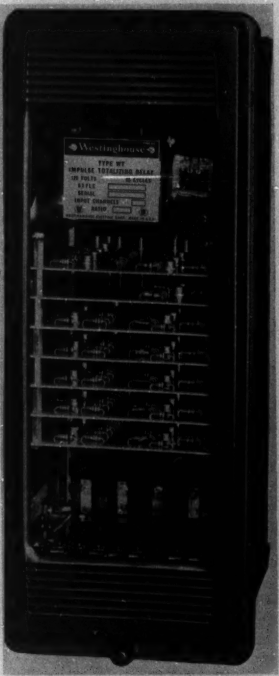

Fig. 3. Impulse totalizing relay

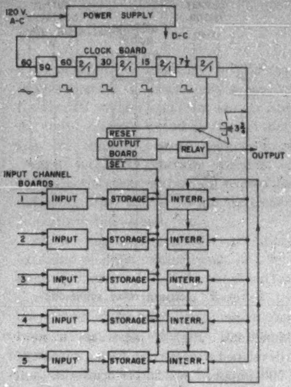

Fig. 4. Block diagram of 5-channel impulse totalizing relay

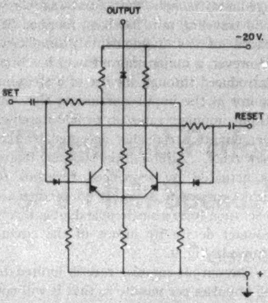

Fig. 5. Typical transistor flip-flop

wire type. Plug-in components facilitate servicing by general field personnel.

Impulse Totalization

The great majority of impulse metering applications involve the totalization of several supply sources or feeders on a single demand receiver. For this prime function it was desirable that the new impulse totalizing relay use static logic or switching components to replace the complex mechanical gadgetry.

Investigation was made into the use of both magnetic core and transistorized noncoincident impulse totalizing systems. The transistorized impulse totalizing relay, shown in Fig. 3, was developed as a result of economic and space considerations.

Units accommodating from 2- to 7-meter input channels are made up by installing a corresponding number of channel boards.

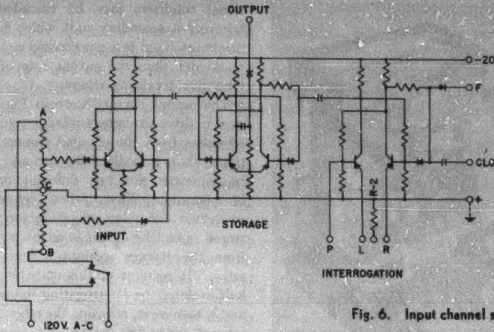

Fig. 6. Input channel schematic

Fig. 4 is a block diagram of a 5-channel impulse totalizing relay. It is seen that there are five channel boards, one for each meter input; an output board and a "clock" board.

The small blocks represent individual function circuits. Nearly all of these circuits consist of two transistors connected as a long-tailed pair with feedback giving a bistable circuit or "flip-flop." A typical unit is shown in Fig. 5 in which capacitive coupling and diode gating have been used for the interconnections between the functional units. This type of circuit may be made to operate with a high degree of reliability in spite of wide variations in component values, supply voltage, and ambient temperature. As long as sufficient drive is supplied to the ON transistor and sufficient bias to the OFF transistor, the circuit will remain in the state in which it has been placed. The diode gating assures reliable switching by steering the pulses to the proper input.

These circuits may be combined in a number of ways to perform many useful functions. For example, the channel board which is shown in Fig. 6 contains three of these to perform the three functions of input, storage, and interrogation. The left-hand pair of transistors comprise the input circuit. The two input terminals are alternately connected to a 120-volt a-c source through a set of contacts in the associated watthour meter.

The input circuit acts as a slave to the watthour meter contacts, reproducing the contact position. With each complete cycle of contact operation the input circuit delivers a "set" pulse to the storage circuit which retains the information until it receives a "reset" pulse from the interrogation circuit. If the storage circuit has been set it will deliver a pulse to the output when it is reset and will then be ready to receive a new pulse. By regularly and sequentially interrogating the storage circuits a string of noncoincident pulses is generated with one output pulse for each input pulse if the input pulse rate does not exceed the interrogation rate.

The interrogation circuits of all channel boards are interconnected to form a ring counter. In a ring counter one of the stages will differ in state from all the others and, by suitably driving the counter, the unique state may be caused to progress from stage to stage. As it progresses, the storage sections are interrogated or "scanned" in sequence. Re-

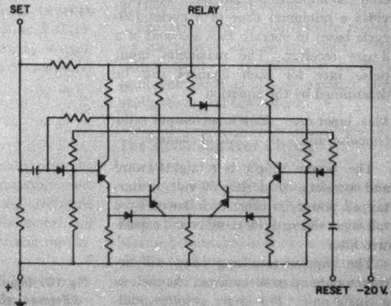

Fig. 7. Output circuit schematic

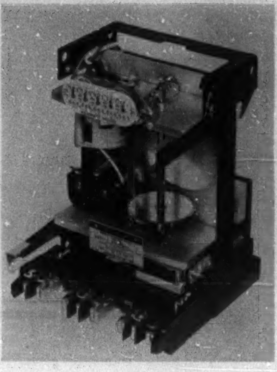

Fig. 8. Impulse storage relay

ferring to Fig. 6 it will be noted that a resistor *R-2* is terminated between the two terminals *L* and *R* of the interrogation circuit. To set up the unique state of one counter stage this resistor is connected to *L* on one board while on all other boards it is connected to *R*. The "ring" is established by connecting from *F* of each circuit to *P* of the following board.

The pulses used to drive the ring counter are obtained from a clock board which contains a pulse squaring stage fed by 60 cycles from the power transformer, and a chain of four binary divider stages. The ultimate output is a square wave with a frequency of 3.75 cycles per second. Higher frequencies are also available from intermediate stages of the divider and are used as will be described later. When the 3.75-cycle frequency is used to drive the ring counter one storage section is interrogated every 16 cycles (60-cycle base).

The response of presently available demand recorders dictated that the maximum impulse output rate should not exceed 225 impulses per minute. This provides a minimum time of 8 cycles (60-cycle base) to operate each solenoid of a 3-wire receiver. The maximum input pulse rate for each channel can be determined by the equation

$$\frac{\text{Max. input rate}}{\text{(Impulse/min.)}} = \frac{225 \times \text{input/output ratio}}{\text{No. of channels}}$$

The power supply is straightforward and consists of a 120/50-volt center-tapped power transformer followed by a full-wave silicon diode rectifier and capacitive filter.

The impulse totalizing relay will accommodate up to seven input channels as a single unit. For larger systems additional totalizers may be cascaded by selecting a secondary unit which has a maximum input rate per channel equal to or greater than the output rate of the preceding totalizing relays.

The output circuit shown in Fig. 7 is used to drive the output relay in response to pulses from the channel storage sections. It is a modified flip-flop and may be connected for two different modes of operation. First, when connected to deliver one relay operation for each stored pulse, the circuit is set by a pulse from the storage sections, closing the relay. It remains in this state for one half cycle of the interrogating frequency and is then reset, releasing the relay, by a squared wave 180 degrees out of phase with the interrogating frequency.

For the second mode of operation the output circuit is set and reset in sequence by pulses from the storage sections. Thus, two input pulses are required to deliver one output impulse, causing the relay to have a 2 to 1 input/output ratio. To maintain an 8-cycle (60-cycle base) relay closure the storage sections are interrogated by the $7^1/_2$-cycle frequency from the clock.

A 4 to 1 input/output ratio is made available by adding an additional binary stage to feed the output circuit. This permits interrogation at 15 cycles for the same chosen output rate.

Impulse Storage

Occasionally need will arise for storing impulses during periods when transmission channels are in use for communication, relaying, or other higher priority

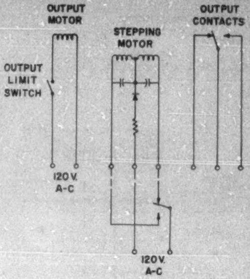

Fig. 9. Storage relay schematic

functions. Fig. 8 illustrates a newly developed storage relay with a capacity of 500 impulses which performs this function and retransmits the stored impulses on demand.

The general principle of previous storage units; namely, that of a storage screw and traveling nut, has been retained because of its fundamental simplicity. However, a major improvement has been introduced through the use of a stepping motor as the impulse actuating element. Input impulses rates up to 500 impulses per minute are readily accepted by this new relay. Although the stepping motor is actuated by sequenced reversals of direct current it is readily adapted to a-c operation from a single-pole double-throw contact device by means of the circuit shown in Fig. 9.

The output impulse rate is limited to 45 impulses per minute so that it will not exceed the maximum continuous input rate of several existing demand receivers.

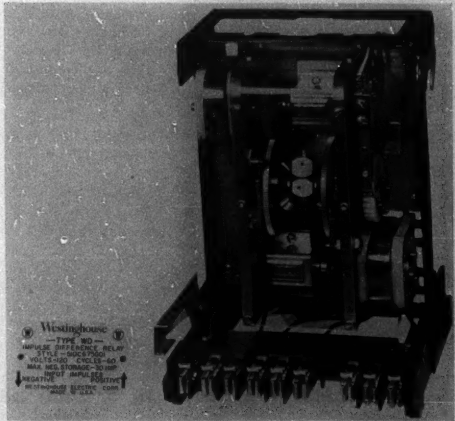

Fig. 10. Impulse difference relay

Net Totalization

In addition to totalizing several impulse sources it is occasionally necessary to subtract a minor load from a larger one. A typical example would be the subtraction of station service power from several totalized generator circuits to obtain net station output. The impulse difference relay in Fig. 10 was developed to perform such a function.

Positive impulses received by the upper left-hand stepping motor result in a forward movement of the differential output shaft. Negative impulses received by the lower right-hand stepping motor cause a backward motion of the output shaft.

The net movement of the differential output shaft is thus proportional to the net difference between the positive and negative impulses.

The output contacts and cam are driven by a pawl responsive to forward movement of the differential but with sufficient freedom of reverse movement to permit the storage of 30 negative impulses.

In this unit also the previously used mechanical differential has been employed because of its basic simplicity. The major improvement in performance comes from the utilization of stepping motors to drive opposing sides of the precision differential. A rate of 500 impulses per minute is acceptable to either the positive or negative inputs.

In applying an impulse difference relay it is imperative that the major, or positive, circuit impulse rate always exceed that of the minor, or negative, circuit. The storage capacity of 30 impulses is provided to allow for brief periods when negative impulses received may temporarily exceed the incoming positive impulses.

Summary

A series of new impulse metering devices is now available which will allow impulse rates to be increased tenfold with a comparable increase in accuracy. The units are adaptable for use with other types of impulse equipment presently in service, or they can be used for completely new high rate installations.

Provisions have been made for even higher impulse rates with minor modifications. For example, the totalizer clock board is equipped with taps for building 1 to 1 or 2 to 1 ratio units with an output rate of 1,800 impulses per minute should such totalizers be desired. Utilization of this potential performance would require demand recorders of much higher speed than any now available. It may be assumed that the output relay of the totalizer would be replaced by a power transistor stage capable of directly driving such recorders. The goal of a completely static totalizing system would then be realized by the utilization of the current change of the oscillator impulse device to drive the input circuit of the totalizing relay.

Design and Performance Characteristics of a High-Speed Wide-Chart Recorder

JOHN C. GARRIGUS
ASSOCIATE MEMBER AIEE

DURING the past decade, the requirements for null balance instruments have greatly changed. Dynamic testing applications have increased the need for accurate, high-speed measuring devices. Specifications such as a span of 50 millivolts and full-scale response time of 5 seconds are supplemented with requirements for a span of 1.0 millivolt and a full-scale response time of less than 0.5 second. Such instruments are important in the fields of rocket or jet engine testing, wind tunnel measurements, automatic machine tool positioning control, and analog-to-digital readout systems using high-speed card punch or print-out operations.

This paper describes the electrical and mechanical considerations required for the design of a high-performance wide-chart recorder. The pertinent characteristics of the input and measuring circuits, amplifier, motor, and feedback network are discussed. The effects of an *R-C* (resistance capacitance) low-pass filter upon the step, ramp, and frequency characteristics are considered.

Principles of Operation

The system consists basically of a potentiometer circuit, d-c to a-c converter, input and isolation transformer, electronic amplifier, servomotor, tachometer and feedback network, and recording mechanism, as shown in Fig. 1.

The potentiometer circuit measures an emf (electromotive force) by comparing it with a reference emf. The "error" or difference signal between the measured and reference emf is converted from d-c to a-c by the "chopper" converter. This signal is then amplified by an input transformer and electronic amplifier to a power level sufficient to drive a servo motor. The motor drives the recording pen mechanism and the contact on the potentiometer slide wire in a direction to decrease the error signal to zero. At balance the position of the contact on the slide wire is a measure of the input emf.

To increase the stability of the system, damping is introduced by means of an a-c induction tachometer coupled to the motor shaft. As the motor drives to balance, the a-c signal from the tachometer is fed to the amplifier through a coupling network. This signal is opposite in phase to the error signal.

The servo motor is geared to the recording mechanism and output shaft. The output shaft is available for auxiliary equipment such as alarms, controls, and analog-to-digital converters.

The Potentiometer Circuit

A typical potentiometer circuit for high-speed recording is shown in Fig. 2(A). This "divider" type of circuit has several advantages over the conventional circuit for low-range and multirange recording. Any thermal voltage generated at the sliding contact is reduced by the factor

Paper 60-113, recommended by the AIEE Recording and Controlling Instrumentation Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N.Y., January 31–February 5, 1960. Manuscript submitted November 23, 1959; made available for printing November 27, 1959.

JOHN C. GARRIGUS is with The Bristol Company, Waterbury, Conn.

The author wishes to acknowledge the contributions of D. A. Narducci, Jr., and J. A. Wiencko of the Bristol Company, who have provided editorial and technical assistance, and to H. Brady of Space Technology Laboratories (formerly of The Bristol Company), who was responsible for a portion of the development and design of the instrument.

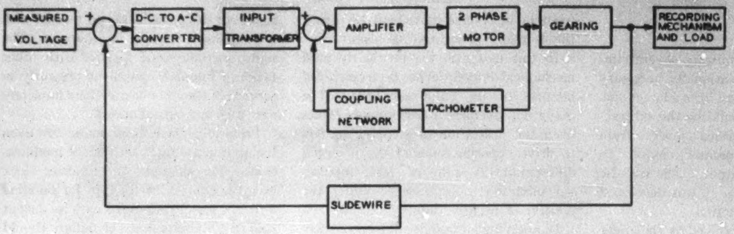

Fig. 1. Basic high-speed recording system

$$\frac{R_{M1}}{R_{M1}+R_{M2}+R_G+R_{SW}+R_D} \qquad (1)$$

on range 1. R_E and $R_F >> R_{SW}$ and R_D. By making this ratio low, contact thermal emf are made negligible.

In a multirange instrument, step or continuous span change is accomplished by changing the amount of the divider resistance included in the input circuit. Fig. 2(A) illustrates the switching arrangement.

In high-speed recording instruments, slide-wire contact bounce seriously affects instrument performance. When the contact leaves the wire, the reference voltage is removed from the balancing circuit. The error voltage then consists of the measured quantity. If the direction of pen travel is toward zero scale position, the response will be overdamped, if toward the maximum scale position, the response will be underdamped. To overcome this action, a capacitor C_0 is added as shown in Fig. 2(B). During normal motion, C_0 maintains the same voltage as E_{SW}. If the contact momentarily opens from points 3 or 4 because of wire irregularity, C_0 maintains voltage E_{SW} until the contact again closes.

The capacitor is small so that normal operation is not affected. However, it is large enough so that the discharge in R_{load}, during a momentary opening of the contact, Fig. 2(C), does not appreciably change the capacitor voltage from the value of E_{SW}. Typical component values are $R_{SW}=150$ ohms, $R_{load}=34{,}000$ ohms, $C_0=1.0$ microfarad.

Detector Circuit

The circuit consists of an electromechanical chopper and an input transformer. The d-c error signal impressed across the chopper input is converted to a square wave a-c signal of power frequency. This signal is then increased by the transformer and fed into the electronic amplifier. The secondary of the transformer is tuned for 60 cps (cycles per second). This provides for minimum phase shift through the input transformer when resistance is inserted in the bridge or input circuit.

Amplifier and Output Circuitry

The amplifier consists basically of four *R-C* coupled voltage-amplifying stages and a power output stage; see Fig. 3. The coupling networks are designed for small phase shift at the carrier frequency and for stability at low frequencies.

The input resistance of the amplifier is 4.7 megohms. The over-all input transformer and amplifier voltage gain is approximately 100×10^6 to detect measured quantities less than 1.0 microvolt. Under maximum stall-torque conditions the output tube delivers 9 watts to the control field of the balance motor.

The control field of the motor is coupled to the amplifier by means of a transformer and series capacitor. The transformer is used to remove the d-c plate current from the control field to minimize motor temperature rise and the capacitor in series tunes the load for maximum power transfer.

For phasing purposes a capacitor is used in series with the reference field of the motor. This capacitor also increases the reference field voltage, thereby increasing the motor speed and torque.

Gain Compensation Network

In multiple-range instruments it is necessary to have constant system gain in order to provide uniform dynamic performance for all ranges. This is usually accomplished by adding resistance in series with the input circuit to maintain the same current sensitivity in the detector circuit. The series resistance increases proportionally with the instrument span. When an *R-C* filter is required in the input circuit, this method cannot be used as the change in resistance affects the filter damping.

Fig. 4 shows a circuit for maintaining constant gain and constant filter resistance in multirange instruments. An auxiliary gain circuit is used to supplement the main gain control, keeping the voltage at the grid of the second-stage constant. This is accomplished by dividing the output voltage of the main control. The instrument is first adjusted for optimum response on the lowest span by R_4. With the span switch indexed to position 2, R_{4A} is adjusted to give the same response. The remaining spans are set similarly. Once all the auxiliary controls are set, the main gain control will affect all ranges similarly.

To keep the filter resistance constant, resistors R_{Y1} and R_{Y2} are added on the lower spans. On each span the resistance must equal

$$\frac{(R_{M1}+R_{M2}+R_{M3})(R_G+R_{SW}+R_D)}{R_{M1}+R_{M2}+R_{M3}+R_G+R_{SW}+R_D} \qquad (2)$$

where R_F and $R_D >> R_{SW}$ and R_D. Then for span 1

$$R_{Y1}=\frac{(R_{M1}+R_{M2}+R_{M3})(R_G+R_{SW}+R_D)}{R_{M1}+R_{M2}+R_{M3}+R_G+R_{SW}+R_D}-R_{M1} \qquad (3)$$

When the span is switched, the resistance R_{S1}, R_{S2}, or R_{S3} is also switched to maintain a constant current sensitivity for the standardizing circuit.

Discrimination Against Line-Frequency Interference

In the basic recorder, line-frequency interference signals that appear as transverse pickup in the input circuitry are converted in the chopper to second and fourth harmonic components. These components are then attenuated in the amplifier by the parallel-T network and *R-C* filter sections at the grids of the second, third, and fourth voltage stages.[1,2] This combination of filters attenuates to the extent that 60-cps spurious signal of 15% of the recorder span does not affect recorder performance.

When the phase of the interference is approximately 90 degrees from line, the major portion of the amplified signal appears in the form

$$\frac{8}{3\pi}\sin 2\omega t+\frac{16}{15\pi}\sin 4\omega t \qquad (4)$$

The second harmonic amplitude is 85% and the fourth harmonic amplitude is 34% of the line-frequency interference.

To reject the second harmonic component, a 120-cps parallel-T filter is designed with a rejection ratio of greater than 500 to 1; the 60 cps is attenuated approximately 5 to 1. This gives a 120-cps to 60-cps rejection ratio of 100 to 1. Tuning is accomplished by adjusting R_9 and R_{29}, Fig. 3, for minimum signal transfer of 120 cps. The fourth harmonic component is attenuated by the *R-C* sections at the grids of the second, third, and fourth stages.

Feedback Circuitry

The damping circuit consists of an a-c induction tachometer and feedback network; see Fig. 3.

The tachometer produces an output voltage proportional to the motor speed.

Fig. 4. **Gain compensation for multiple-range instruments**

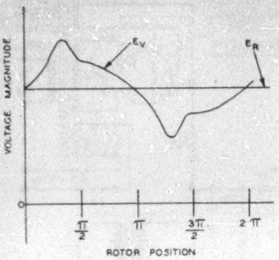

Fig. 5 (left). Tachometer zero-speed residual voltage

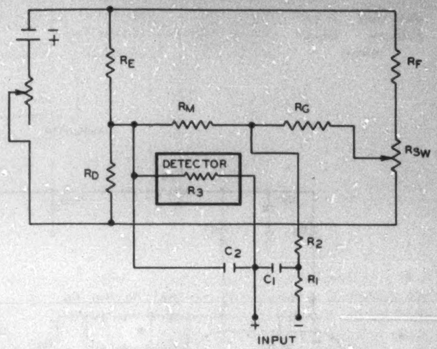

Fig. 6 (right). Divider-type bridge with R-C input filter

The signal from the tachometer is fed to a feedback network which serves two functions: 1. It compensates for the fixed fundamental frequency residual voltage from the tachometer. 2. It provides a matching network from the tachometer to the amplifier circuit. The feedback signal is phased 180 degrees from the error signal at the grid of the third stage for optimum damping.

The tachometer excitation is supplied from a regulating network to insure optimum operation over line voltage changes of 107 to 127 volts.[1] This regulating network consists of a resistor R_{30} and varistor V. The compensating network for the fixed residual voltage is also obtained from this supply.

A damping control R_{34} is provided for adjusting the dynamic performance of the system as desired.

In addition to the tachometer output voltage, which is proportional to the shaft speed, two residual voltages of fundamental frequency exist at zero speed. These voltages E_R and E_V, shown in Fig. 5, affect the damping characteristics.

E_R, which is independent of rotor position, is caused by an unsymmetrical magnetic circuit, and nonuniformity or irregularities of the pole surfaces. It is compensated for by an opposing voltage in the feedback network, adjusted by R_{31}.

E_V, which is a function of rotor position, is caused by variation in resistance of the squirrel-cage rotor segments, or eccentricity of the rotor on the shaft. Since this characteristic cannot be readily compensated for, only tachometers having a negligible E_V characteristic are selected for this use.

Mechanical Design

In the mechanical design obvious precautions are taken to minimize the inertial and frictional loading. Consideration was given to the design of a lightweight recording mechanism, minimum inertia of the output gear, and use of ball-bearing pulleys for the recording mechanism.

To insure adequate speed and acceleration without sacrificing output torque, optimum gearing between motor pinion and output gear is necessary.[3] Assuming negligible motor and load friction, the optimum gear ratio for maximum acceleration to a step signal is

$$\frac{N_2}{N_1}=\sqrt{\frac{J_2}{J_1}} \tag{5}$$

where J_1 and J_2 are inertia of the motor and load respectively; N_1 and N_2 are the number of teeth or diameter of the motor pinion gear and output gear respectively. For this recorder the calculated gear ratio is 7.2 to 1. Experimental testing showed a ratio of 6 to 1, a 20% variation from the calculated value.

To eliminate backlash in the system, a cause of instability, a split, spring-loaded pinion is used.

Particular care is necessary in the placement of the system components. Stray magnetic fields from the power transformer, output transformer, tachometer, and auxiliary equipment must not couple into the low-level circuits, or the result will be offset, dead band, and instability.

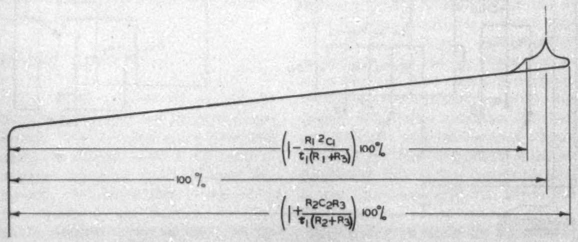
Input Circuit Filtering

In some applications it is necessary to suppress large interference voltages that are superposed on the measured quantity. A number of filter configurations have been designed consisting of resistive, capacitive, and inductive components to form low-pass or band-rejection networks. Although attenuating the unwanted frequencies, a filter will affect the instrument performance in one or more of the following ways: 1. an increase of system time lag; 2. a decrease of dynamic performance; 3. an effective lowering span of the recorder by attentuating the d-c error signal by the ratio of

$$\frac{R_3}{R_S+R_F+R_M+R_3} \tag{6}$$

where R_3 is the detector resistance, R_S is the external circuit resistance, R_F is the sum of the filter resistances, and R_M is the bridge resistance.

Resistive and capacitive components are preferred to inductive components. Although the inductive elements attenuate low frequencies with less time lag, they require tight tolerances and considerable shielding for optimum perform-



$\left(1-\frac{R_1{}^2C_1}{t_1(R_1+R_3)}\right)100\%$
100 %
$\left(1+\frac{R_2C_2R_3}{t_1(R_2+R_3)}\right)100\%$

Fig. 7. Response for a 100% step input signal illustrating lag and lead characteristics

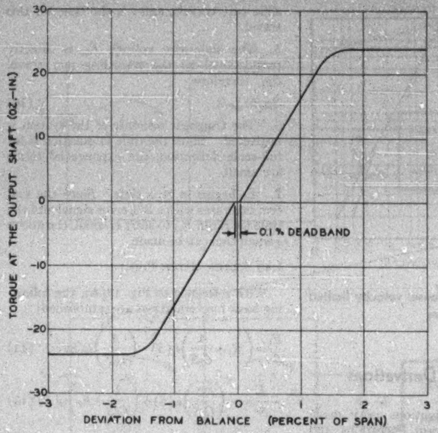


Fig. 8. Static torque characteristic

ance, particularly in low-range high-speed instruments.

One type of filter used consists of *R-C* low-pass stages arranged to give maximum attenuation, with small time lag, and does not affect the recorder performance. Such a filter is shown in Fig. 6. It consists of lag and lead sections. R_1 and C_1 comprise the lag section; R_2 and C_2 comprise the lead section.

The lag section makes the recorder damp or "hitch" at approximately

$$\left(1-\frac{R_1^2C_1}{t_1(R_1+R_3)}\right)100\% \tag{7}$$

of a full-scale step response signal, as shown in the Appendix and illustrated in Fig. 7.

The lead section makes the recorder overshoot by approximately

$$\left(1+\frac{R_2R_3C_2}{t_1(R_2+R_3)}\right)100\% \tag{8}$$

of a full-scale step response signal, where

R_1 = filter lag resistance
R_2 = filter lead resistance (bridge resistance $R_M << R_2$ and can be neglected)
R_3 = detector circuit resistance
C_1 = filter lag capacitance
C_2 = filter lead capacitance
t_1 = slope of system response for full-scale response without filter (time for 100% step response)

When the lag and lead characteristics are combined, a filter is provided that will not affect the recorder damping characteristics. In the Appendix it is shown that such a filter must satisfy the equation

$$(R_1+R_2)R_3\left(\frac{C_2}{C_1}\right)=R_1^2 \tag{9}$$

From equation 9 it is noted only the ratio of C_2/C_1 is important for optimum dynamic response, and not the magnitudes.

Static Characteristics

Performance criteria such as accuracy linearity, dead band, repeatability, rejection of transverse and longitudinal interference, and effects of ambient temperature changes are terms which define the static characteristics of this type of instrument. These terms are defined in reference 1.

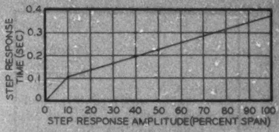

Fig. 10. Step response characteristic

Fig. 8 shows the output torque as a function of the deviation from balance. The system saturates when the deviation is 2%, and provides a maximum torque of 24 ounce-inches. The dead band is less than 0.1%.

Dynamic Characteristics

Important characteristics for an instrument of this type are the step, ramp, and frequency responses. Step response time is the time for the end device to come to rest in its new position after an abrupt change to a new constant value has occurred in the measured quantity.[1] Fig. 9 shows a response to a full-scale step input signal. Total time to balance (where balance is defined as coming to rest within the accuracy rating of the instrument) is approximately 0.37 second, of which 0.06 second is required for acceleration and 0.06 second for deceleration. The response time for step-input signals from zero to 100% is shown in Fig. 10. The slope from zero to 10% indicates the region in which the system is accelerating. Above 10% the system is velocity-limited.

By proper use of the damping control, inertial loads up to 25 ounce-inches can be applied[2] to the output shaft without affecting the step response time.

Ramp response time is the time lag, expressed in seconds, between the measured quantity and the equivalent positioning of the end device, when the measured quantity is varying at a constant rate.[1]

The ramp response time can be affected by variations in the following parameters: motor voltage constant, amplifier gain, damping constant, and input filter time constant.

The graph of time lag in seconds versus ramp velocity in per cent per second with and without an *R-C* input filter is shown in Fig. 11. The lag decreases with increasing velocity of the ramp input because of motor voltage constant, ampli-

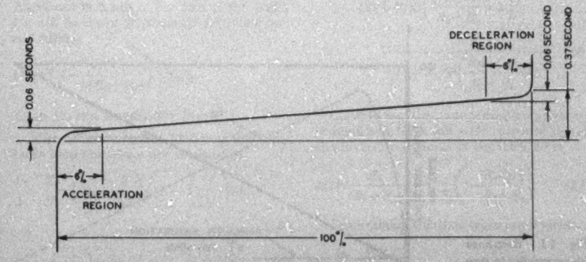

Fig. 9. Response to a 100% signal illustrating acceleration and deceleration region

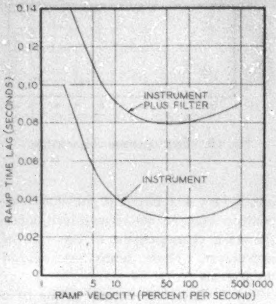

Fig. 11. Ramp response time

fier gain, and damping constant, until the saturation velocity is reached. Above the saturation velocity the system cannot follow as the amplifier and motor saturate, and the time lag increases.[5]

The introduction of an input filter increases the response time by the lag section filter time constant R_1C_1. From Fig. 11, the experimental results indicate an increase of about 0.05 second.

Frequency response is the dynamic response of an instrument when the measured quantity is varied sinusoidally over a band of frequencies.[1] Frequency response curves for a 100% peak-to-peak amplitude are shown in Fig. 12. These are curves of the system frequency response characteristics with the *R-C* filter A and without the *R-C* filter B. For any other input greater than 10% peak to peak, the response can be approximated by drawing a horizontal line corresponding to the input magnitude and extending to the minus 2 slope line. With input signals less than 10%, the system is not velocity-limited and the curve is not valid.[5] (An input of 25% peak to peak is illustrated by the dashed line.) At approximately 20 cps the attenuation curve changes from a minus 2 slope to a minus 3 slope due to the attenuation characteristics of the filter.

Conclusions

The principles of operation of a high-speed industrial recorder have been discussed. By considering the characteristics of the *R-C* input filter and potentiometer circuit, amplifier, motor, and feedback networks a high-performance instrument was developed. Instruments of this type are being applied to many industrial applications where high torque, sensitivity, and speed are required.

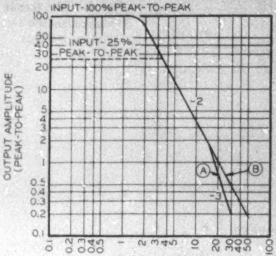

Fig. 12. Frequency response: velocity limited system

Appendix. Derivations

In the following derivations use is made of the Laplace transform operations and pairs for solving the equations.[4]

Lag and Lead Filter Sections

R_1 and C_1 have been described as constituting the lag section of the filter. Lag in this sense means a damping, or "hitch" in the response characteristic. This type of response occurs when the filter causes the error voltage to become zero before the true balance point is reached.

The lead section, consisting of R_2 and C_2, causes the opposite effect, making the instrument overshoot. This response occurs when the error voltage becomes zero after the true balance point is reached.

In the derivation of the equations in this Appendix, the following assumptions are made; see Fig. 13:

1. The measured quantity E_1 is a step with magnitude equal to the span of the instrument.

2. The system is critically damped without the input filter, i.e., the pen moves at a constant rate across the scale and stops abruptly at balance.

3. The amplifier saturates with a 2% static error signal.

4. The system is velocity limited, causing the slide-wire voltage E_2 to equal Kt where $K\alpha S_W/t$. S_W is the distance which the slide wire travels, and t is the time for this travel.

5. The slide-wire voltage E_2, is directly proportional to the recording pen travel S_P; therefore

$$S_W/t\alpha S_P/t \tag{10}$$

6. The transient response of the system is neglected. Since the time in question is for full-scale deflection, the exponential terms are small.

7. E_2 begins in zero time. Since the system saturates with a 2% error signal and the time for ramp E_2, to start is small, the above assumption can be made.

LAG FILTER HITCH POINT

With reference to Fig. 14(A), the following basic loop equations are established:

$$\frac{E_1}{S}=\left(R_1+\frac{1}{C_1S}\right)i_1(S)-\left(\frac{1}{C_1S}\right)i_2(S) \tag{11}$$

$$-\frac{K}{S^2}=-\left(\frac{1}{C_1S}\right)i_1(S)+\left(\frac{1}{C_1S}+R_2\right)i_2(S) \tag{12}$$

where E_1/S is the transform for a step signal of magnitude E_1, and K/S^2 is the transform for a ramp signal. Kt is generated by the repositioning of the slide wire. The sign is negative because Kt is opposing E_1.

Solving for $i_2(S)$ yields

$$i_2(S)=\frac{E_1}{(R_1+R_2)\left(\frac{R_1R_2C_1S}{R_1+R_2}+1\right)S}-\frac{K(R_1C_1S+1)}{(R_1+R_2)\left(\frac{R_1R_2C_1S}{R_1+R_2}+1\right)S^2} \tag{13}$$

Considering the exponential components insignificant for a full scale response signal, the inverse transform of equation 13 is

$$i_2(t)=\frac{E_1}{R_1+R_2}-\frac{K}{R_1+R_2}\left(R_1C_1-\frac{R_1R_2C_1}{R_1+R_2}+t\right) \tag{14}$$

Determining the time when $i_2=0$ gives

$$t=\frac{E_1}{K}+\frac{R_1R_2C_1}{R_1+R_2}-R_1C_1 \tag{15}$$

Since E_1 = a step signal equal to E_0 (full span voltage) and K = the slope of the recording pen or slide-wire voltage during maximum speed across the chart equal to

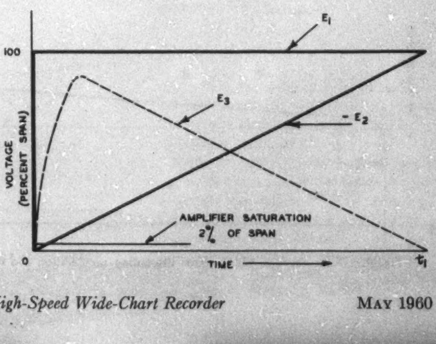

Fig. 13. Response characteristics to step input signal

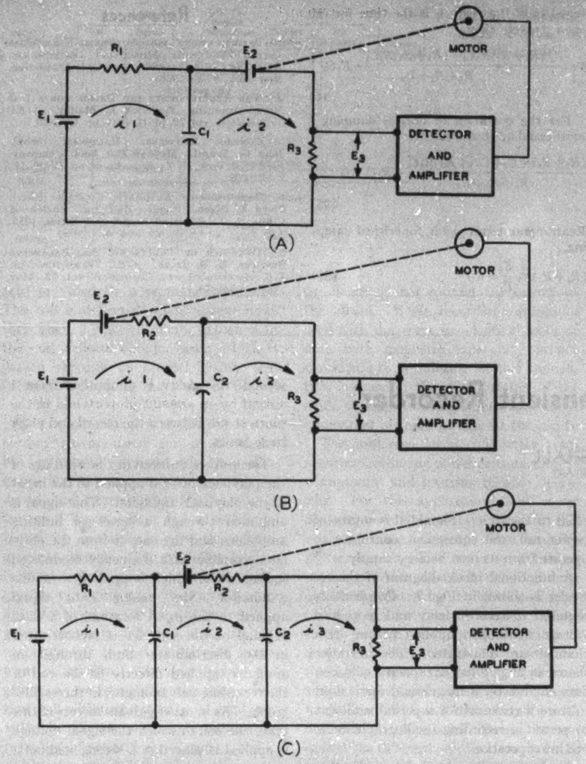

Fig. 14. A—Simplified schematic of R-C lag filter and bridge network. B—Simplified schematic of R-C lead filter and bridge network. C—Simplified schematic of combined R-C lag and lead filter and bridge network

E_0/t_1, where t_1 is the time for full scale travel. Then

$$t=t_1-\left(\frac{R_1^2C_1}{R_1+R_3}\right) \tag{16}$$

Expressed in terms of per cent of full scale, t/t_1 will be the point where the recording pen will hitch:

$$t/t_1=\left(1-\frac{R_1^2C_1}{t_1(R_1+R_3)}\right)100\% \tag{17}$$

LEAD FILTER OVERSHOOT POINT

With reference to Fig. 14(B) the following basis loop equations are established:

$$\frac{E_1}{S}-\frac{K}{S^2}=\left(R_2+\frac{1}{C_2S}\right)i_1(S)-\left(\frac{1}{C_2S}\right)i_2(S) \tag{18}$$

$$0=-\left(\frac{1}{C_2S}\right)i_1(S)+\left(R_3+\frac{1}{C_2S}\right)i_2(S) \tag{19}$$

where E_1 and K are the same as stated for the lag filter hitch point. Solving for $i_2(S)$ yields

$$i_2(S)=\frac{E_1}{(R_2+R_3)S\left(\frac{R_2R_3C_2S}{R_2+R_3}+1\right)}-\frac{K}{(R_2+R_3)S^2\left(\frac{R_2R_3C_2S}{R_2+R_3}+1\right)} \tag{20}$$

Considering the exponential components insignificant for a full scale response signal, the inverse transform of equation 20 is

$$i_2(t)=\frac{E_1}{R_2+R_3}-\frac{K}{R_2+R_3}\left(t-\frac{R_2R_3C_2}{R_2+R_3}\right) \tag{21}$$

Determining the time when $i_2=0$ yields

$$t=\frac{E_1}{K}+\frac{R_2R_3C_2}{R_2+R_3} \tag{22}$$

With the same conditions as stated in equation 15

$$t=t_1+\frac{R_2R_3C_2}{R_2+R_3} \tag{23}$$

Expressed in terms of per cent of full scale, t/t_1 will be the maximum point the recording pen will overshoot:

$$t/t_1=\left(1+\frac{R_2R_3C_2}{t_1(R_2+R_3)}\right)100\% \tag{24}$$

LAG AND LEAD CHARACTERISTICS COMBINED

By combining the lag and lead characteristics, a filter can be designed that will not affect the damping characteristics. With reference to Fig. 14(C) the following loop equations are established:

$$\mathcal{L}[E_1(t)]=\left(R_1+\frac{1}{C_1S}\right)i_1(S)-\left(\frac{1}{C_1S}\right)i_2(S) \tag{25}$$

$$-\mathcal{L}[E_2(t)]=-\left(\frac{1}{C_1S}\right)i_1(S)+\left(R_2+\frac{1}{C_1S}+\frac{1}{C_2S}\right)i_2(S)-\left(\frac{1}{C_2S}\right)i_3(S) \tag{26}$$

$$0=-\left(\frac{1}{C_2S}\right)i_2(S)+\left(R_3+\frac{1}{C_2S}\right)i_3(S) \tag{27}$$

where $E_1(t)$ and $E_2(t)$ are the exciting voltages.

Solving for i_3, clearing factors and combining terms, yields the general filter equation

$$i_3(S)=\frac{\mathcal{L}[E_1(t)]-\mathcal{L}[E_2(t)](R_1C_1S+1)}{(R_1R_2R_3C_1C_2)S^2+[(R_1+R_2)R_3C_2+(R_2+R_3)R_1C_1]S+R_1+R_2+R_3} \tag{28}$$

Let

$X=R_1R_2R_3C_1C_2$
$Y=(R_1+R_2)\ R_3C_2+(R_2+R_3)\ R_1C_1$
$Z=R_1+R_2+R_3$

$$i_3(S)=\frac{\mathcal{L}[E_1(t)]-\mathcal{L}[E_2(t)](R_1C_1S+1)}{XS^2+YS+Z} \tag{29}$$

In time-constant form

$$i_3(S)=\frac{\mathcal{L}[E_1(t)]-\mathcal{L}[E_2(t)](R_1C_1S+1)}{(T_1S+1)(T_2S+1)(R_1+R_2+R_3)} \tag{30}$$

where

$$T_1T_2=\frac{X}{Z}$$

$$T_1+T_2=\frac{Y}{Z}$$

For a step input $\mathcal{L}[E_1(t)]=E_1/S$ and $\mathcal{L}[E_2(t)]=K/S^2$

$$i_3(S)=\frac{E_1}{S(T_1S+1)(T_2S+1)(R_1+R_2+R_3)}-\frac{K(R_1C_1S+1)}{S^2(T_1S+1)(T_2S+1)(R_1+R_2+R_3)} \tag{31}$$

Again considering the exponential components insignificant for a full scale response signal, the inverse transform of equation 31 is

$$i_3(t)=\frac{E_1}{R_1+R_2+R_3}-\frac{K}{R_1+R_2+R_3}\times(t-(T_1+T_2)+R_1C_1) \qquad (32)$$

Determining the time when $i_3=0$ and solving for t yields

$$t=\frac{E_1}{K}+\frac{(R_1+R_2)R_3C_2+(R_2+R_3)R_1C_1}{R_1+R_2+R_3}-R_1C_1 \qquad (33)$$

Since E_1=a step signal equal to E_0(full span voltage), and K=the slope of recording pen travel or slide-wire voltage during maximum speed across the chart, and is equal to E_0/t_1, where t_1 is the time for full span travel, then

$$t=t_1+\frac{(R_1+R_2)R_3C_2+(R_2+R_3)R_1C_1}{R_1+R_2+R_3}-R_1C_1 \qquad (34)$$

For the condition of critical damping t must equal t_1; therefore

$$\frac{(R_1+R_2)R_3C_2+(R_2+R_3)R_1C_1}{R_1+R_2+R_3}-R_1C_1=0 \qquad (35)$$

Rearranging terms yields, for critical damping,

$$(R_1+R_2)R_3\frac{C_2}{C_1}=R_1^2 \qquad (36)$$

A Power-Line Transient Recorder

C. H. HOSHALL
NONMEMBER AIEE

THOSE WHO have been associated with the industry during recent years have witnessed a most progressive expansion and improvement of electric power generation and distribution facilities. This growth has been accompanied and perhaps preceded in many instances, by improvements in instrumentation techniques and equipment. The recorder described here has capabilities which exceed those of similar recorders in general use. It provides a means of recording waveforms which exist in a power system immediately prior to, during, and after the occurrence of a fault or other disturbance without continuous consumption of photographic recording medium. This instrument will record current and voltage waveforms, or other waveforms if desired, as long as required after the disturbance occurs.

General Description

The field-test model of this equipment, with front doors removed, is shown in Fig. 1. The unit has been made entirely self-contained so that it can be moved about and readily adapted to field-test conditions. Under normal operating conditions, 117-volt 60-cycle power is supplied to the unit. Should this source of power fail, the equipment continues to operate from its own battery supply.

A functional block diagram of the recorder is shown in Fig. 2. Components required to record, delay and reproduce voltage waveforms applied to one data channel are illustrated. The recorder shown in Fig. 1 has a capacity of seven data channels. A magnetic drum is used to store waveforms for a period sufficient to permit a recording oscillograph to be put into operation.

As shown in Fig. 2, the input signal is applied to a voltage-controlled oscillator. The output of this oscillator is frequency modulated by the input signal, and is applied to an amplifier which supplies sufficient power to drive a recording head. Magnetic particles which have been applied to the storage surface of the drum are influenced by the magnetic field produced by current through the winding of the head; and data is recorded on the drum in a manner analogous to that in which saturation recording is accomplished in conventional frequency modulation magnetic tape instrumentation systems.

Slightly less than 1 second after any point on the periphery of the drum passes under the record head, it passes under the gap of the playback head. The recorded pattern is then "erased" as it passes under a permanent-magnet erase head which is located between the playback and record heads. Thus, a delay of slightly less than 1 second is provided. Since the drum makes one revolution each second, this delay is diminished from 1 second by an amount proportional to the shortest arc between the record and playback heads.

The voltage induced in the windings of the playback head is applied to the input of the playback amplifier. This signal is amplified through a series of limiting amplifiers, and the output from the playback amplifier is a frequency modulated square wave, which is applied to a discriminator. The analog data signal applied to the input terminal of a data channel of the recorder is reconstituted in the discriminator and, through an amplifier, applied directly to the coil of the recording galvanometer in the oscillograph. As in other galvanometers of this type, the coil to which the signal voltage is applied is placed in a strong magnetic

Y., January 31-February 5, 1960. Manuscript submitted November 23, 1959; made available for printing January 18, 1960.

C. H. HOSHALL is with the Minneapolis-Honeywell Regulator Company, Beltsville, Md.

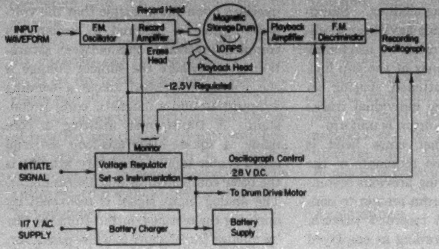

Fig. 2. Functional block diagram of fault recorder

field provided by a permanent magnet. The coil is deflected when current flows through it. A small mirror attached to the coil deflects a light beam which is passed through an optical system and brought to focus in the plane of the recording film.

The signal voltage is applied to the recording galvanometer coil at all times, but no record is made on the oscillograph film because lamp brilliance is reduced and because the film is not in motion. When a fault occurs and is detected by initiating relays, the oscillograph is started. The recording lamp is brought to full brilliance, and the photographic recording paper is drawn past an aperture in which the light beam from the galvanometer is deflected along an axis perpendicular to the direction of movement of the film. The recording oscillograph can be brought to operating condition well within the storage interval provided by the drum, thereby permitting recording of prefault waveforms.

Also shown in Fig. 2 is the instrumentation unit. This unit contains a voltage regulator which provides regulated -12.5 volts from which all the electronic circuits in the recorder operate. Also contained in the instrumentation unit are a reference oscillator, reference channel recording and playback module, and circuits with which operation of the recorder can be monitored once initial calibrations have been made.

A 120-cps (cycles per second) sinusoidal reference signal is recorded on the drum, played back, and recorded on the oscillograph in exactly the same manner as the data signals. This reference signal aids in the analysis of the oscillograph records.

Design Considerations

The very important requirement that the unit function reliably for extended periods of time without adjustment or service has been met by using a magnetic drum as the storage medium. There is no wear of the recording medium because the heads do not contact the surface of the drum. While recording techniques used with the drum are identical to those used with magnetic tape, tape is not considered to be suitable for this application because of the deterioration of the oxide coating resulting from wear caused by contact of the tape against the heads.

The fault recorder is completely transistorized, reducing power consumption to a minimum and insuring reliable operation. For this application, low power consumption is important because this equipment must operate from standby power sources which may be of limited capacity. Also, transistorized circuits are ideally suited for modular packaging utilizing printed circuit cards. These cards provide for maximum consistency from unit to unit. The modular packaging used in this equipment permits simple and rapid exchange of plug-in modules in the event that circuits with different characteristics should be required for different applications, or in the event of circuit failure.

Since the field-test equipment described here has a capacity of seven data channels and one reference channel, each head used has a total of eight tracks. All tracks of the record and playback heads are assembled and cast as integral units. This simplifies adjustment and alignment of the heads.

Wide-band FM (frequency modulation) recording is used because it is the only recording technique readily adaptable for this application that can provide the required amplitude linearity. This is necessary so that the amplitude of the recorded waveforms can be accurately scaled, and so that the recorder introduces only negligible distortion in waveforms which it preserves. Another important advantage of FM recording is that irregularities in the level of the signals played back from the drum have less influence on an FM recording system than on other types of systems. Irregularities in playback signal level may be caused by slight imperfections in the drum surface or by nonhomogeneity of the magnetic dispersion applied to the drum.

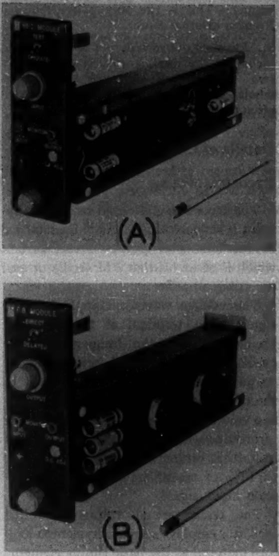

Fig. 3. Fault recorder electronic units

A—Record module
B—Playback module

General Specifications

Performance specifications of the field-test equipment, in addition to those which have already been mentioned, are as follows:

1. Data frequency response: The response of the entire unit from input terminal to oscillograph record is flat to within ±10% from 45 cps to 500 cps.
2. Amplitude accuracy (linearity) of data channels at all frequencies in the data pass band: The amplitude response from input terminal to oscillograph record is linear to within ±3% of full-scale deflection.
3. Signal input voltage: 2.0-volt rms causes full-scale deviation of the recording oscillator. An adjustable input attenuator is provided.
4. Oscillator input impedance: approximately 1,000 ohms.
5. Maximum oscillograph record amplitude: 4 inches, peak-to-peak.
6. Timing marker frequency accuracy: ±2%.
7. Power requirements: The unit operates from a 24-volt storage-battery supply. The battery charger requires 117-volt a-c

supply. This is the only power required from an external source.

8. Physical dimensions: The entire unit, including the oscillograph, is mounted in two standard 19-inch-wide Radio-Electronics-Television Manufacturers Association relay racks, 5 feet high.

Details of Circuit Operation

Record Module

The record module used in this equipment is shown in Fig. 3(A). Each record module houses one printed circuit card on which is assembled an FM oscillator and recording amplifier.

The voltage waveform applied to the signal input terminal of the recording oscillator causes the frequency of the oscillator to be deviated from its center frequency by an amount proportional to the deviation of the signal from its average value. The center frequency of the recording oscillator is 3 kc, and deviation from this center frequency is ±1.2 kc (±40% of center frequency) with full-scale input signal.

The transistorized voltage-controlled oscillator employs a square-hysteresis-loop core material as the basic timing element. The oscillator is well suited for this application because it has a very linear frequency-versus-voltage characteristic, is simple, and is stable despite temperature variations.

Front panel controls, shown in Fig. 3(A), include an input selector switch (for selection of either test or data signal), an input attenuator control, and a control for adjusting the center frequency of the oscillator. Monitor jacks facilitate monitoring of waveforms at selected points in the circuit.

Magnetic Storage Drum

The magnetic storage drum used in this recorder is 10 inches in diameter and $1^3/_4$ inches wide. It is an accurately machined metallic drum made of a nonmagnetic material. A dispersion coating, which has magnetic properties similar to the oxide used on magnetic tape, is applied to the prepared surface of the drum. Since it is difficult to apply a sufficiently smooth coating of this dispersion by direct application, an excess of oxide is applied and the surface is machined to remove irregularities. The thickness of the finished coat is approximately 0.001 inch.

The drum is driven by a governor-controlled, d-c motor which is operated from the fault recorder storage-battery supply. Belts and pulleys are used to provide a drum speed of 1 revolution per second.

Record and playback head gaps are spaced approximately 0.001 inch from the surface of the recording medium. Standard magnetic tape heads have been modified for use with the drum by machining the heads along the apex at the gap line. With the heads so flattened, spacing between the gaps of the individual tracks and the surface of the drum is uniform.

A permanent-magnet erase head is used to insure that no remnants of the patterns recorded during previous revolutions of the storage drum remain to contaminate the desired recorded pattern. In FM saturation recording as employed in magnetic-tape systems, the recording head is in direct contact with the recording medium. A separate erase head is not usually required because the magnetic pattern is completely re-established each time any portion of the tape passes over the record head gap. Because it is considerably more difficult to completely saturate the magnetic medium when it does not contact the record head, a separate erase head has been supplied.

Playback Module

The playback module used in this equipment is shown in Fig. 3(B). Two printed circuit cards are mounted in each playback module housing. One card is the playback amplifier; the other is a discriminator and amplifier.

The playback head output is approximately 3 millivolts rms with the head unloaded and with an unmodulated 3-kc carrier signal recorded on the drum. The playback amplifier output, when unloaded, is a square wave in which the transitions occur at the instant the input voltage passes through zero. In addition to amplifying and limiting the signal from the drum, the playback amplifier supplies sufficient power to operate the discriminator, which is connected to its output.

The discriminator circuit used in this instrument employs a magnetic core as the frequency-sensitive element, and operates upon the principle that the volt-second integral required to accomplish complete reversal of flux between saturation levels (where the subject voltage is the voltage impressed across a winding wrapped around a magnetic core) is constant. A transformer utilizing a core made of square-hysteresis-loop material and a center-tapped secondary winding is the basic component of this discriminator. The analog input signal is recovered by applying the rectified output from the discriminator transformer to a low-pass filter. The cutoff frequency of this filter is approximately 550 cps. Carrier and higher frequencies are attenuated, and data frequency signals are passed with a minimum of attenuation. The analog signal output from the filter is applied to a feedback-stabilized transistor amplifier which supplies sufficient power to operate the oscillograph galvanometers. The output signal can be attenuated, if desired, by use of an L-pad output control mounted on the front panel of the playback module.

Front panel controls are provided for circuit adjustment and monitoring. A small portion of the recording module output can be applied to the input of the playback amplifier by means of a toggle switch on the playback module. In this manner, the magnetic storage drum is bypassed and adjustments or tests can be made when the drum is not in operation.

Instrumentation Unit

Other circuits essential to operation of the system are contained in the instrumentation unit. The electronic units of the recorder must be supplied from a low-impedance power source, and the supply voltage must be constant despite changes in battery supply voltage caused by variations in battery condition and load.

The instrumentation unit contains all circuits required to set up the recording

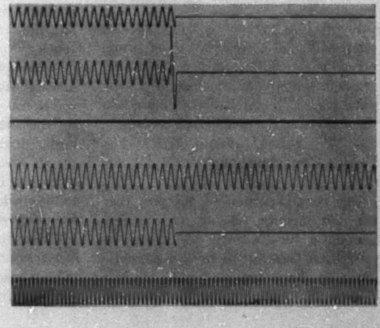

Fig. 4. Laboratory record

oscillators and discriminators, and to monitor battery and regulated supply voltages. Selected points in all recording channels can be conveniently monitored on the front panel meter, and at a single pair of monitor jacks on the front panel of the instrumentation unit by use of function and channel selector switches. Sufficient instrumentation is provided within the unit to permit operation of the entire recorder without the use of external test equipment.

The reference signal recording and playback module located in the instrumentation unit consists of three printed circuit cards which are, except for small differences in external wiring, identical to the FM data-channel cards.

OSCILLOGRAPH

The oscillograph is a standard unit that uses fluid-damped galvanometers flat to within ±5% from 0–600 cps. To insure long lamp life, the recording lamp is operated continuously at reduced brilliance, and is brought up to full brilliance upon the advent of a fault. The oscillograph has a capacity of 200 feet of photographic paper which can be run at any rate between 144 and 0.031 inches per second. The amount of film run out upon each initiation can be preset with a front panel control. Record numbers can be photographed directly upon the film. The quality of the record produced is illustrated in Fig. 4.

Applications

The field-test equipment discussed here is packaged in two racks. However, the delay unit is a distinct and separate unit and, as such, can be operated entirely independently of the equipment mounted in the companion rack. The storage drum and associated equipment can be used for applications other than for recording power-line transients and for fault recorder applications where operation of the equipment from existing station battery supplies is desirable. Any oscillograph can be used which uses galvanometers with sensitivities that will provide the deflection desired, so long as it can be brought to operating condition within 1 second so that prefault information can be recorded.

This recorder can be of considerable value in experimental and developmental work as well as in operational installations. When incorporated into operating systems, it can be used to record voltage or current waveforms at the most advantageous points. When used with suitable shunts and transformers, phase currents and voltages, and residual currents can be recorded. Under-voltage, over-voltage, or over-current relays can be placed in the system to initiate action of the recording oscillograph.

Through analysis of permanent records made with this recorder, location of faults is made easier and the sequence of operation of protective relays can be determined. This recorder can also be used during staged tests to determine if protective devices are properly adjusted and are in good operating condition.

Dial-Selected Industrial Television for Ticket Reservation Facilities

J. W. ALINSKY
NONMEMBER AIEE

ABOUT 6 years ago Pennsylvania Railroad found that an improvement in the method of handling ticket sales and reservations was necessary in order to decrease the time and effort required to process ticket sales. In the following years, they designed and built new ticket facilities at Philadelphia and Pittsburgh, Pa., experimenting with new ideas and new equipment until they had a system operating which would meet the transportation demands of these cities. In 1954, they began planning a new ticket facility for Pennsylvania Railroad Station in New York City, one of the largest railroad passenger terminals in the world, handling nearly a half-million passengers daily. This made necessary a system utilizing methods which were more efficient than those previously used in Pittsburgh or Philadelphia. After considerable study of the performance and cost of several systems, closed circuit TV (television) was decided on to handle the storage and distribution of the vast amount of information necessary for the sale and reservation of space on Pennsylvania Railroad trains.

System Description

Referring to Fig. 1, the ticket facility has three areas between which TV is used to transfer information: the ticket counter where direct sale of tickets for reserved space is handled, the telephone positions where reservations are taken by telephone, and the coupon file center where coupons representing all reserved space are held until requested by ticket agents or the telephone clerks.

The system performs three main functions. First, it supplies information on available reserved space to all operating positions in the facility. Since the information is readily available, this eliminates any possibility of wasted effort requesting space that has already been sold, and it is of basic importance in reducing the work load on a ticket reservation system. This portion of the system is capable of having all positions select the same camera at the same time. Second, a 2-way audio and 1-way video system between the ticket agents and the coupon file center is used for agents to request space. Third, a system to flash coupons between the coupon file center and the telephone reservation operator is used to confirm space requested by the operators. When the system is not used for these functions, it is used to provide other information such as train arrivals, orders of the day, and institutional advertising on the ticket counter monitors.

The telephone reservation operation is shown in Fig. 2. The customer *A* calls in to reservation clerk *B*, who dials the proper space availability camera *C* to check and determine if general space is available for the date and time requested by the customer. The clerk *B* then dials the coupon flash-back center *D* and requests the customer's space over the TelAutograph system. The clerk at *D* pulls the proper coupon, which represents a specific space and places it in front of the coupon flash-back camera. This camera flashes the coupon back to a monitor located at the reservation clerk's position *B*, who then checks to see if the specific space given falls within the limits of the general space requested. Clerk *B* then tells the customer what specific space has been given to him, i.e., roomette number and car number. This coupon representing the specific space is filed in the coupon file until the customer either purchases or cancels the space. For the customer to pick up his reserved space he must come to the ticket counter where the ticket agent will request the space. The procedure is the same for the direct sale of tickets described in the following paragraph, except that dialing space availability is not required.

For direct sale of tickets the operation follows Fig. 3. The customer *A* comes to the ticket agent *B* and requests space on a train for a certain date. The agent *B* dials space availability system *C* to check if the space is available. He then dials the coupon center via the audio-video system. The audio is used by the agent *B* to request the customer's space. The video permits the customer to see the space being obtained by the coupon center clerk *D*. This space is then sent to the agent via Western Union Intrafax.

While this method of processing the ticket may seem complicated, it must be realized that the earlier method required more steps without the availability of rapid communications. A major contribution of the audio-video system is the psychology applied to the customer who sees action taking place on the processing of his ticket. The dynamics of this operation has reduced the impatient complaints to practically zero.

System Requirements

Information gathered from the previous system in the Pennsylvania Station and the new systems at Pittsburgh and Philadelphia was used to determine the number of operating positions to handle sale and reservation of space efficiently. Seventy-two operating positions were decided necessary to handle telephone requests for reservations. Each position is equipped with a video monitor, TelAutograph transmitter and dial selection of the video and TelAutograph circuits.

Paper 60-260, recommended by the AIEE Broadcasting Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted November 25, 1957; made available for printing December 14, 1959.

J. W. ALINSKY is with the Dage Television Division of Thompson-Ramo-Wooldridge Inc., Michigan City, Ind.

The author wishes to express his appreciation for a large portion of the details of this paper to William J. Toeller, who was resident field engineer on the Pennsylvania Station project for the first year of operation.

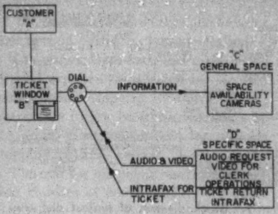

Fig. 3. Ticket pickup operation

For direct sale of reserved space, 16 positions are required, each equipped with a microphone and speaker, a monitor and selector equipment located at the ticket counter. Four additional miscellaneous positions selecting only space availability were used in various locations. Also, two positions, designated "Special Handling," are necessary for persons requiring special service where transactions could be handled either by direct sale or space reservation.

The number of cameras necessary for each system, i.e., space availability, coupon flash-back, and audio-video, were determined previously by the number and sizes of trains involved and the statistical data available for past experience on the popularity of each schedule.

The space availability system is most critical, requiring the reproduction of symbols and representing reserved space for periods to 8 weeks on one schedule of trains and to 16 weeks on another schedule. Results of experimental work showed that this information could be handled on 36 specially designed charts, each covering a period of 2 weeks. To provide for future expansion, 40 camera positions were designed into this system.

Forty-two cameras were used for the coupon flash-back system and 20 cameras for the audio-video system. These cameras are selected within each group through a hunting system, whereby if the first unit in a group is busy, the second is selected, etc. If all are busy, redialing is necessary.

System Engineering

To work out engineering details, the system was divided into the following parts: camera, video distribution, sync generators and sync distribution, power for distribution system, monitors, audio system, and switching.

CAMERA

Specifications for the camera were: not less than 400-line horizontal resolution, 0.5-volt peak-to-peak noncomposite video output, driven horizontal and vertical sweep for maximum stability, self-contained power supply, and all controls located on the camera. Video test points should be included which are available from the exterior of the camera. Roof prisms are used on the cameras to provide their better positioning and also to allow a horizontal placement of the camera to minimize vidicon spot damage.

VIDEO DISTRIBUTION

A video distribution amplifier had to be designed to meet the requirements of video distribution for three separate groups of cameras. In the space availability system, a camera would have to feed 99 monitors (which would provide a system expansion of five additional monitors). This assumes that all positions might require information from the same camera at the same time. In the coupon flash-back system, one camera is capable of feeding only one monitor at a time out of the 74 monitors using this system. Here the distribution amplifier must supply isolation between switching units. The audio-video system is similar to that of the coupon flash back except that video distribution is provided to only 18 monitors. In addition to these electrical specifications, the distribution amplifier had to be designed so that it was easy to maintain.

To solve these problems, it was necessary to have an amplifier supplying 99 outputs at an impedance of 75 ohms with sufficient isolation between outputs to prevent loss of high-frequency components in connection with line capacity, and to minimize any effect caused by line reflection.

Fig. 4 illustrates the output circuit of the distribution amplifier capable of feeding 25 75-ohm lines at 0.5 volt peak to peak. The load on the amplifier is 6 ohms and consists of the 25 lines, each separately connected to the amplifier through a 75-ohm isolation resistor. This method provides about 22 decibels of isolation between lines, which was sufficient to provide a clean picture.

A distribution amplifier constructed by combining four of these channels on a module or plug-in chassis was capable of meeting all specifications. By bridging the inputs of the channels together, 100 outputs were made available from one input to meet space availability camera requirements. By dividing the 74 positions which used the coupon flash-back system into groups of three, one channel could supply video to the resulting 25 groups. For the audio-video system, one channel could directly feed the 18 positions.

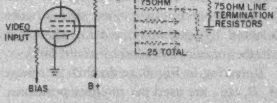

Fig. 4. Output circuit of video distribution amplifier

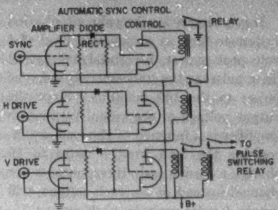

Fig. 5. Automatic sync control

Fifty-six distribution amplifiers were necessary for the video distribution system. Constructing the distribution amplifier as a module helped solve the maintenance problem, since a defective unit can be replaced by plugging in a spare unit.

SYNC GENERATORS AND SYNC DISTRIBUTION

For the synchronizing system, two Dage *410-A* sync generators are used supplying Radio-Electronics-Television Manufacturers Association pulses to the equipment. These two units are controlled by an automatic changeover which provides protection to the equipment against pulse failure.

Referring to Fig. 5, the automatic changeover operates by sampling three pulses from the generator in service, the vertical drive, the horizontal drive, and the sync, each feeding separate channels. The pulse is amplified in half of a twin triode and rectified by a diode. The resultant voltage is used as bias on the second half of the triode which operates as a control tube with a relay in its plate circuit. With pulses supplied, three relays are energized, closing single-pole single-throw contacts. The contacts of the relays in the three channels are in series with the coil of a control relay which energizes a solenoid-operated rotary switch selecting the proper sync generator. The automatic control unit is designed to switch generators when any component in the unit or the pulse which is feeding it fails.

It is necessary for the pulse distribution system to feed, at a minimum level of 4 volts peak to peak, horizontal and vertical drive pulses to the 100 cameras, and sync pulses to the 100 monitors. Since the output voltage of the video distribution amplifier is a function of the load, by increasing the load from 6 ohms to 50 ohms, i.e., using only three outputs per channel instead of 25, each output will supply 4 volts peak to peak into a 75-ohm line. With cameras divided into 12 groups and the monitors into 12 groups, and all units in each group bridging off the line, two distribution amplifiers are necessary for pulse distribution to the cameras, and one for sync distribution to the monitors. Using this method of synchronizing instead of composite video for locking in the monitors to cameras provides optimum performance during switching and eliminates any vertical bouncing or horizontal tearing.

Power for Distribution System

Since self-contained power supplies on each distribution amplifier would have made a unit too large or bulky for plug-in operation and also would have doubled the amount of rack space necessary for the system, the filament transformer was the only power equipment mounted on each chassis. Plate power for the 59 video and pulse distribution amplifiers totaled 30 amperes at 150-volts d-c and was supplied by two 40-ampere 150-volt d-c copper oxide rectifiers. These two rectifiers are controlled by a timer changeover unit which switches rectifiers once daily. Also included is a relay, controlled by the output voltage of the rectifier, which switches rectifiers in case of failure. Filtering for the rectifiers consists of a capacitor input filter with 1,000-μf (microfarad) 200-volt input condenser and a 5,900-μf 200-volt output capacity which is made up by 100 μf in each of the 59 distribution amplifiers. The 100-μf capacitors serve a dual purpose in this application. In addition to serving as filters for the d-c supply, they also provide necessary isolation and decoupling of the d-c line between distribution amplifiers.

Monitors: A 14-inch monitor is used at the operating positions, utilizing a video amplifier of an 8-megacycle bandwidth and a gain of at least 45 decibels. This provides a high-resolution high-contrast picture with a noncomposite video input of between 0.3 and 0.5 volt peak to peak. The monitor must be capable of a high-luminance raster while maintaining good over-all focus. For maximum stability during switching, the monitor sync circuits have to be driven. A Dage *602* monitor is used, which provides sufficient video gain and bandwidth to meet these specifications, plus a 12-kv regulated high-voltage power supply to prevent blooming at high brightness levels.

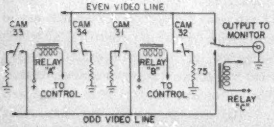

Fig. 6. Space availability video relay panel

Audio System

The audio system which supplies the 2-way communication link between the ticket counter and the coupon file center should provide sufficient gain to permit operation within 3 feet of microphone or speaker. The amplifier used is designed for low-impedance input, and an output of 500 ohms, since long lines between microphone, amplifier, and speaker are used. The input stage is built around a *GE 2N78* n-p-n junction transistor in a grounded emitter circuit which provides an input impedance around 500 ohms, thus eliminating the need for microphone input transformer. The remaining stages in the amplifier are resistance-capacitance coupled triodes.

Switching

The switching system is divided into two parts: 1. video switching for the space availability cameras, and 2. selector units for each monitor position, which control the availability video relays and switching circuits for either the coupon flash-back or audio-video systems.

Space Availability Switches

The space availability system requires switching video from 40 distribution amplifiers to 99 monitor positions. This system had to be designed so that any number of these positions could select the same camera simultaneously while maintaining a 75-ohm termination impedance.

Instead of one relay used for each video signal to be switched, a system was devised whereby two video signals were selected by one relay, cutting the total number of relays needed by about 50%.

Referring to Fig. 6, to do this, 21 relays *A*, *B*, etc., are used per monitor positions, each switching two different video signals from the distribution system to two separate lines (odd line and even line), which are common to the 21 relays. On one of these lines the odd-numbered cameras are switched, i.e., 37, 39, 41, etc., and the other line receives the even-numbered cameras, i.e., 38, 40, 42, etc. The video from each of these lines is then selected by an odd-even relay *C*, and fed to the monitor. The selection of a camera requires two operations: the energizing of the proper video relay, and either energizing or nonenergizing the line selector relay. The method of selection will be explained in the next section.

Fig. 7. Block diagram of typical dial controlled selector unit

Selector Unit

A method of selecting circuits for the coupon flash-back and audio-video systems and some means of controlling the availability video relays were necessary. This method had to be simple, since unskilled workers were to operate the equipment.

Push-button selection, which has been predominantly used in the industry, was discarded because of the size and wiring complexity where a large number of circuits were to be controlled. A dial pulse controlled system similar to a telephone system is employed instead, providing a method which is familiar to everyone.

At each operating position, a dial, an indicator light, and a dial release key are mounted, performing the same function as the dial, tone, and cradle of a telephone system.

Referring to Fig. 7, by turning the dial key to dial position, the pulsing and control relays are energized, lighting the indicator light. Dialing a 2-digit code operates the control relays in the proper sequence actuating 10-, 25-, and 50-point rotary stepping switches.

Space availability video relays are controlled by two of the 10-point stepping switches. One operates as a function of the ten's digit, the other a function of the unit's digit. When dialing an odd number, i.e., 37, 39, 41, etc., both stepping switches operate to select the proper video relay. The odd-even relay is energized by the unit's stepping switch. When dialing an even number, i.e., 38, 40, 42, etc., a similar action takes place except that the odd-even relay is not energized.

The coupon flash back and audio-video circuits are directly selected by 25-point and 50-point stepping switches. These operate as rotary hunting switches with the group positions marked by 10-point stepping switches.

The unit for telephone reservation position consists of control relays for space availability switching and stepping switches for coupon flash-back switching.

The ticket counter switching unit combines control relays for space availability and stepping switches for the audio-video system.

Some Pertinent Statistics

Over 60 miles of wire and coaxial cable were used in the wiring of the racks. The system employs 3,000 tubes and more than 3,500 relays and switches; more than 100,000 connections were used in the installation of the system. Reliability of the system has been more than gratifying; it has been in operation for approximately one year, representing over 100 camera years and 100 monitor years of operation. The total repair time on the cameras was less than 33 hours; the total repair time on the monitors was approximately 110 hours. The maintenance time on the cameras, which includes checking of tubes, cleaning of lenses, dusting and adjustment of controls, was less than 500 hours for the year.

One of the greatest areas of service problems was in the switch modules where over 500 hours were used in cleaning switch contacts and repair. Most of this is attributed to the fact that the equipment was installed concurrently with a rebuilding construction program within the station allowing much loose plaster dust, sawdust, etc., to accumulate within the racks. It is interesting to note that all the other equipment, which includes power supplies, sync generators, distribution amplifiers, etc., had a total repair time of less than 20 hours for the year.

A few major problems were encountered during the first few weeks of operation, the most noticeable of which was crosstalk in the video of the space availability switching system. Examination revealed that the video current flowing through the ground busses on the video switching panels was developing an excessive amount of voltage across the busses. Installing 1/8- by 1-inch ground straps across the existing busses bypassed this current to the main ground and eliminated the crosstalk.

A Military 4-Wire Field Telephone Incorporating an Electronic Signalling System

J. L. FAHERTY
NONMEMBER AIEE

A. S. HOWELL
MEMBER AIEE

A NEW field telephone has been designed for use with the 4-wire electronic switchboards now being developed for the U.S. Army Signal Corps. This local battery instrument incorporates new features in systems applications. All telephone signalling to and from the switchboard is accomplished on a voice frequency basis, thereby providing compatibility with radio and wire carrier. The digit tone signalling plan is readily adaptable to the use of a key-type selector set. The latter affords more rapid digit setup speeds than are possible with the use of the conventional rotary dial. The introduction of a 4-page wire system eliminates critical hybriding in the telephone as well as throughout the switching centers.

Compatible functioning of this telephone with the above-mentioned electronic switchboards requires locally powered compound tone generators for outgoing signalling and replacement of the conventional bell ringer by electronic means to produce a station-audible signal on incoming calls. These functions are accomplished through the application of solid-state devices.

Several other features have been incorporated including a provision for extension telephones and built-in facilities to convert for point-to-point operation. In addition, improved voice transmission is obtained from the replacement of the conventional carbon microphone with a high-quality magnetic transducer.

The pattern of this instrument reflects the new point of view of the military laboratories in field set packaging. A carrying case of low, flat silhouette containing and supporting all apparatus is designed to eliminate the need for a separate carrying bag. A new lightweight molded handset is secured to the supporting cradle by magnetic means. Consistent with modern circuit-packaging techniques, all circuit assemblies are of the plug-in type, making maximum usage of printed wiring.

Service test production units of this new 4-wire electronic telephone are now being completed by the Stromberg-Carlson Company. These instruments, together with the newly developed electronic local, long-distance, and tandem switchboards will be field tested at Fort Huachuca, Ariz., by the U. S. Army, during 1960. This paper will describe the engineering considerations and some of the problems involved in developing an instrument to meet the broad objectives outlined above.

Application

The primary function of the 4-wire field telephone is to provide reliable voice frequency signalling and voice transmission between the user and the local electronic switchboard, when interconnection is by means of nonloaded 4-wire field cable. The operating range is up to a 25-db (decibel) maximum loop loss at the highest signalling frequency assuming cable attenuation characteristics similar to those of *WDI-TT* field wire. Digital signalling to the switchboard is

Paper 59-259, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1-6, 1959. Manuscript submitted November 28, 1958; made available for printing September 18, 1959.

J. L. FAHERTY is with the U.S. Army Signal Research and Development Laboratories, Fort Monmouth, N. J., and A. S. HOWELL is with the Stromberg-Carlson Division of General Dynamics Corporation, Rochester, N. Y.

The solutions for problems occasioned by the nature of this project represent the combined thinking and advice of many engineers too numerous to mention. The writers gratefully acknowledge this assistance from members of the Telecommunications Division of the Stromberg-Carlson Company, and the U.S. Army Signal Research and Development Laboratories.

accomplished by compound tones using a two-out-of-five frequency code. Preference was given to a system whereby the compound tones are applied simultaneously rather than sequentially. Such choice was favored because of the attendant reduction of mechanical complexity in the keysender and minimization of the effects of fading when a radio link is interposed between the local and long-distance switchboards.

To accommodate all switchboard signalling functions, including the digits, seven frequencies extending from 1,700 to 2,900 cps (cycles per second) are utilized. These frequencies are spaced 200 cps apart as a result of practical filter design considerations. The requirements for teletype transmission in the frequency range of from 850 to 1,650 cps dictated that this allocation be chosen for the signal tones. Otherwise, placement at the lower end of the speech frequency band would prove desirable because of the increase in nonloaded cable attenuation with frequency. The signalling plan may be illustrated by describing the operation of the telephone from the user's station.

Outgoing Calls

When the handset is removed from the cradle, a timed-out burst of seize tone is transmitted from the telephone. The receipt of this signal at the switchboard is acknowledged by the return of a 600-cps dial tone which occurs at the telephone receiver.

Upon hearing dial tone, the calling party may transmit the desired number by manual operation of the keysender. Each digit key selects a specific compound 2-tone signal. Direct operator access before digiting is obtained by depressing the *O* button after receipt of dial tone. Operator access during a conservation is obtained by means of a recall key and another compound frequency assignment.

At the conclusion of the conversation, the handset is replaced upon the cradle, thereby returning the hookswitch contacts to normal. At the same time, a compound release tone is applied to the transmitting line pair through action of a release signal control. This release signal will persist for several seconds, after which the telephone automatically returns to stand-by condition. When the telephone is in stand-by or on-hook condition only the tone ringer detection and the release control circuitry are active, drawing a low idling current in the microampere range.

Incoming Calls

An interrupted 600-cps ringing signal generated in the switchboard is amplified and detected in the telephone. The detector activates a 2,700-cps generator and an amplifier through which the tone signal is applied to the handset receiver and coupled to an acoustical radiator to produce the station-audible signal.

When the handset is lifted from the cradle, seize tone again is sent out. The reception of seize tone at the switchboard removes the ringing signal. The latch-up circuit in the telephone operates under control of the seize signal to place the circuit in talking conditions.

During voice transmission, incoming signals on the receiving line enter a receiving amplifier provided with a manual gain control, then they are applied to the telephone receiver. Voice frequency currents from the microphone are amplified, then applied to the transmitting line pair. A unidirectional sidetone path is included between the send amplifier output and the telephone receiver.

Signal Frequency Assignments

In the signal frequency assignments, shown in Fig. 1, the make-up of the first two digits is chosen to include a common frequency. This simplifies the register used in routing calls to local lines or trunks for prefix numbering of digit 1 or digit 2. Otherwise, the specific digit frequency assignments are arranged to simplify the keysender design, as will be described. An additional system requirement is that the release compound not contain the seize frequency. The latter provision prevents reseizing of the switchboard when disconnect occurs before the decay of the release signal.

Keysender Switching Plan

The keysender provides the means to set up the digit and recall signals by suitable switching of frequency-controlling tank circuit elements in the two telephone signal generators, designated *A* and *B*. To reduce the number of switches and thereby effect economies of space and cost, mechanical compounding is employed. The switching plan, illustrated in Fig. 2, is designated to permit the operation of a particular tuner switch by adjacent keys using a common mechanical linkage. Thus only 10 tuner switches are associated with the digit keys, where otherwise 20 switches would be necessary.

Several further considerations are involved in the keysender plan. It is preferable that the tuner switching described be accomplished on a "dry" basis, whereby the connections are established before the oscillators are powered. This is done through control

Vol.
Pt. 1
196

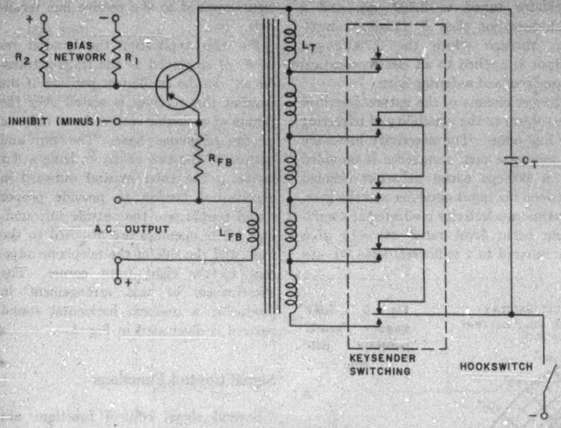

Fig. 3. Signal oscillator circuit

of the battery switch by a sequentially operated mechanical link common to all signalling keys. To obviate the need for a separate seize tone generator it is necessary that one of the signal oscillators be tuned to the seize frequency when the keys are in the nonoperated position. Hence, the *Y* switch in Fig. 2 is used as a transfer switch operative from a common key link to shift the *A* tuning from the seize frequency to the basic tank frequency upon the operation of any key.

Human engineering studies were made to determine an optimum arrangement of the digit keys based upon operator performance. Subjective tests were conducted on three plans comprising placement of the buttons in two horizontal rows of 5, two vertical rows of 5, and four horizontal rows of 3, 3, 3, and 1. Although the findings from these tests indicated no difference among the key sets in the time required to send a telephone number, a significant reduction in the total number of errors was made with the use of the two horizontal rows-of-5 pattern. It was noted further that the digit selection speed for numbers between three and ten digits in length averaged two digits per second.

Signal Oscillator Design

Effective and reliable functioning of the signal oscillators, as well as all telephone circuitry, must be maintained over an operating ambient temperature range of −40 to +149 degrees Fahrenheit. System requirements dictated a signal frequency stability of ±20 cps and an essentially distortion-free output which can be controlled by mechanical as well as electronic switching means. In a portable, local-powered instrument it is essential that these functions be accomplished at maximum economy of current drain, components, space, and weight.

The basic oscillator configuration, shown in Fig. 3, is designed to utilize a general-purpose-type p-n-p germanium transistor having a beta value greater than 60 at 25 degrees centigrade. In this arrangement a frequency controlling resonant circuit is formed by capacitor *CT*, and an inductance *LT*, which is wound as a number of separate sections on a toroidal core. A feedback winding, *LFB*, part of the same magnetic structure, is placed in the emitter circuit where it serves the dual function of supplying the feedback to the amplifier and the output voltage to the load. Degeneration to limit distortion products is provided by resistor *RFB*. Mechanical switching control is obtained through the keysender and hook switch functions, whereas electronic control is obtained from a negative inhibit voltage which reverse biases the emitter circuit. The operating bias network is formed by resistors R_1 and R_2 in conjunction with the nominal 9-volt battery supply.

Much consideration was given to the process for frequency-tuning the oscillator tank circuit during manufacture. The desired frequencies could be set up either by padding out the capacitive element with the use of shunt trimmer units or by the adjustment of individual taps on the inductive element. The latter method was chosen because it yields important space savings through the use of fewer components, with over-all assembly costs no greater.

Tone Ringer

The design function of the tone ringer is to provide an adequate station-audible signal on incoming calls at minimum operational and stand-by current drains. For maximum audibility under battle conditions it is desirable that the output signal be of high harmonic content with maximum emphasis on frequencies between 2,000 and 3,000 cps. The radiated signal at 3 feet from the source must meet a minimum level requirement of 60 db above reference sound pressure exclusive of all components below 2 kc in frequency. In addition, the full-volume signal output must be audible 100 feet from the telephone in all directions in an ambient noise level of +60 db. A manually adjustable volume control must be provided which is capable of reducing the acoustic output to a barely audible level close to the telephone under quiet conditions.

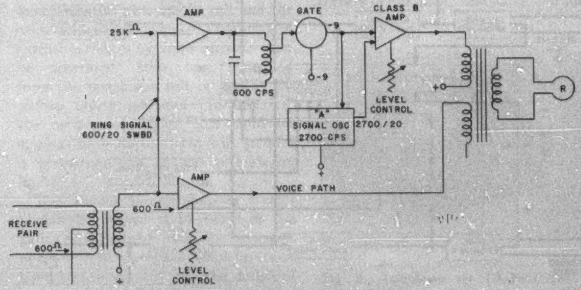

Fig. 4. Block diagram of tone ringer circuitry

The developed tone ringer circuit is designed for a high input impedance level to permit direct bridging across the receiving voice circuit. This eliminates the need for the switched removal of the ringer input when the telephone is off-hook. In the arrangement illustrated in Fig. 4, a 600-cps–20-cps interrupted ring control signal generated and cycled at the switchboard is applied at the ringer circuit input. The output of the amplifier is applied to a transistor gate. The latter is operative in the presence of ringing signal to turn on the *A* signal oscillator tuned to 2,700 cps, and a high-distortion class *B* transistor amplifier, through which the 2,700/20-cps output is applied to an electroacoustical transducer and radiating horn.

Ringer circuits of the nature described are subject to the possibility of triggering by line noise. The selectivity necessary to minimize such occurrence is provided by a 600-cps tuned network included between the input amplifier and the gate. Maximum selectivity is effected at a minimum input level rated at −15 dbm (db referred to 1 milliwatt) for a 600-cps signal applied to the receive line terminals.

For this application the handset receiver is employed as the ringing transducer. In the cradle rest position of the handset this receiver is seated over the throat of a double-section horn built in to the telephone base. The top and bottom of the two radiators have a flat section. The sides expand outward in exponential fashion to provide proper sound coupling to the outside surroundings. The openings are disposed to the front and the side of the telephone adjacent to the right front corner. The effectiveness of this arrangement in producing a uniform horizontal sound pattern is illustrated in Fig. 5.

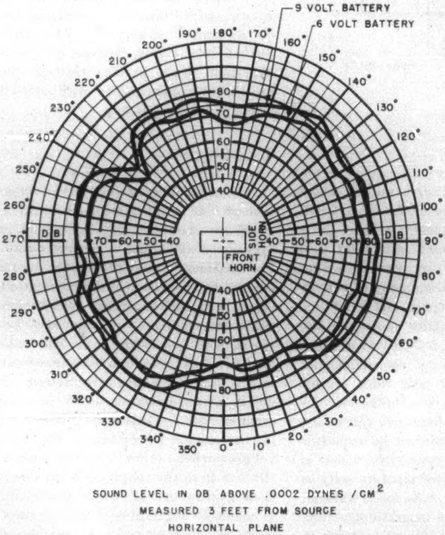

Fig. 5. Tone ringer sound radiation pattern

Signal Control Functions

Several signal control functions are necessary for the proper operation of this telephone with the switchboard. Of these, seize tone timing, latch-up, squelch, and release are automatic operations incorporated into the circuitry shown in the block diagram of Fig. 6. Such electronic means are employed in addition to the circuit controls provided by the hook switch and the keysender. These needs will now be described.

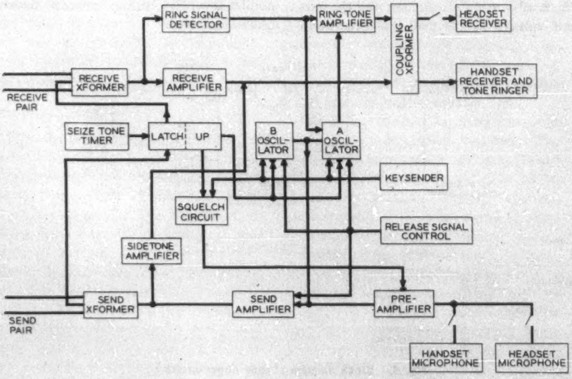

Fig. 6 (below). Block diagram of telephone circuitry

The application of timed-out seize signal from the telephone permits dial tone and busy signal to be returned for user recognition at a low level, nominally −18 dbm. The higher level of such supervisory signals, otherwise necessary to effect the electronic removal of seize signal at the telephone, would prove disturbing to the listener. The timing-out function is accomplished by means of a Zener diode regulated storage that controls a transistor gate. The latter gate drives a latch-up circuit of the 2-transistor type that operates to inhibit the signal generators.

The nominal voice output of the telephone is −9 dbm on a 1-kc tone basis for 28 dynes per centimeter² pressure applied to the microphone. The signalling output is −3 dbm maximum for compound tones. To prevent the simultaneous transmission of ambient noise picked up by the microphone, it is desirable to inhibit the transmitting preamplifier during outgoing signalling. On an incoming call similar inhibition is necessary when the handset is picked up during the receipt of 600/20-cps ringing tone from the switchboard. This is because the 1,700-cps seize tone, returned to the switchboard to trip the ringing, can be masked by ring signal entering the send path through the acoustical

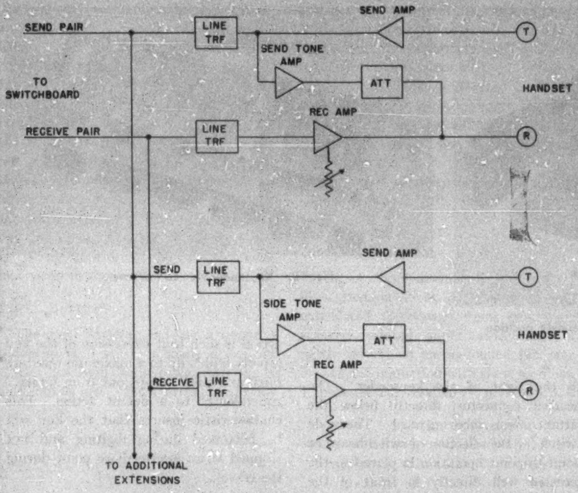

Fig. 7. Transmission path in extension service

coupling between receiver and microphone. These squelch functions are accomplished by a resistor-diode switch that is controlled by the latch-up circuit during seize signal transmission, and by the keysender when the digits are selected.

Following the completion of a call, the local switchboard link is disconnected by a compound tone sent from the telephone upon hang-up. It is desirable that this signal persist for several seconds to insure release in the presence of a radio fade. This release signal control is accomplished by means of a resistance-capacitance transistor gate. The capacitor in the timing circuit is alternately charged and discharged in the off-hook and on-hook conditions, utilizing hook switch contacts.

Hook switch control is utilized to apply battery to the operating circuits, to transfer the *A* oscillator for release or seize tone signalling and to charge and discharge the release control capacitor as described. Two additional disconnects, one between the ring tone amplifier and the battery, the other between the ring tone amplifier and the receiver-coupling transformer, were found necessary in the off-hook condition. These inhibit the otherwise undesirable effects quiescent transistor current on the latch-up control and on distortion during voice reception. The noted facilities are provided by four mechanically operated individual switches.

Extension Service

Several telephones may be bridged on the local line to provide extension service. The voice transmission pattern in such application is indicated in Fig. 7. It is noted that the unidirectional side-tone circuit included in the telephone is placed between the output of the send amplifier and the telephone receiver. Hence, the side-tone level is independent of the receive amplifier gain setting. Transmission between telephones on the extension line takes place at side-tone level in this 4-wire system. This level is nominally 9 db below the voice output appearing at the send line terminals.

Extension operation involves several necessary control functions between the first station to pick up the call and the other bridged telephones. Triggering of extension ringers by voice currents must be prevented. Seize tone generated from the telephones will be audible on pickup unless inhibited. In addition, the sending of release tone until all stations have disconnected will produce a premature trip of the switchboard link.

The control of extensions is accomplished by means of a simplexed d-c gating signal which inhibits the oscillators at the off-hook stations. These functions have been integrated into the design of the latch-up circuit discussed in conjunction with switchboard signalling. In this system the off-hook telephone sends out only trigger control power resulting in a nominal current of but one milliampere per extension.

Point-to-Point Operation

Point-to-point operation, as understood here, is communication between telephones without intermediate switchboards. Facilities provided in this instrument accomplish this service employing either voice frequency or d-c signalling. Voice frequency signalling is necessary when a radio link is interposed between stations; however, the signalling range over cable facilities alone is limited to approximately 4 miles. For operation over long cable loops, up to 20 miles, d-c control of the ringing detector gate is applied to the line on a simplexed basis. Such means are similar to those described for extension control.

A mode switch includes three positions to select switchboard or either method of point-to-point operation. For point-to-point communication the recall key is used for signalling, while both seize and release control functions are made inoperative. During voice frequency signalling, the signal oscillator frequency is shifted to 600 cps, the tuned frequency of the ringing detector. Otherwise, the telephone circuits function as described for switchboard operation.

Instrument Packaging

The form of the new instrument in the packed condition is illustrated in Fig. 8. For ease of stacking, a rectangular shape was chosen and proportioned for maximum stability in the horizontal rest position shown. To the same end all projections beyond the exterior walls of the box have been eliminated. Thus, the posts for carrying strap attachments are located in cutouts in the two rear corners of the base. Similarly, the line-

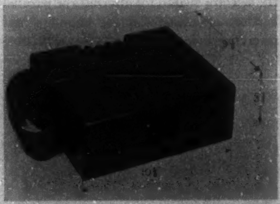

Fig. 8. Telephone set TA-341( )/PT in packed condition. Dimensions in inches: height $3^3/_4$, width $10^5/_8$, depth $9^1/_8$

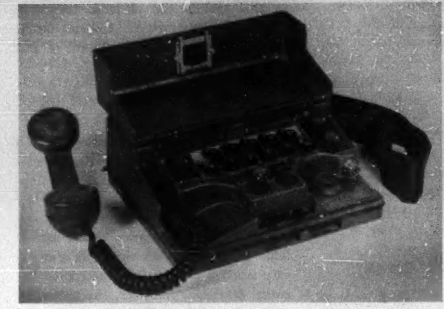

Fig. 9. Telephone set TA-341( )/PT in operating position

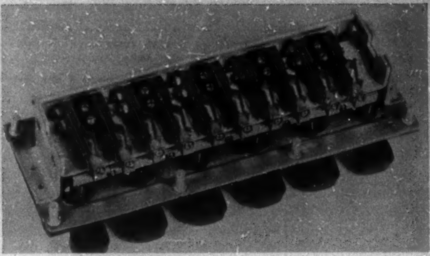

Fig. 10. Keysender viewed from rear

binding posts are placed in an *L* recess in the rear wall of the case. The booted latch provided in the front cover is flush with the wall surface.

The carrying case is of 3-piece construction comprising a cover, body, and base. These parts are molded of high-strength glass-filled polyester material. The base, including the battery well, is secured to the body in assembly upon addition of a waterproof gasket.

Opening of the hinged cover, by actuation of the one hand-operated latch, quickly changes the telephone from the packed to the unpacked condition; it is then ready for use. This operating position is shown in Fig. 9: here the handset has been removed from the cradle to expose the cushion seat and horn coupling for the handset receiver in the right foreground. The rectangular openings visible in the base expose the front section of the double horn radiator disposed to the front and the right-hand side of the box.

All panel controls and accessories are placed for maximum operating convenience in so far as feasible. Thus, the keysender, containing ten digit keys and a recall button, is centrally positioned. To the left of the keysender is located the selector switch for alternate or parallel headset operation. Ringer loudness and receiving voice level controls are visible to the right of the keysender. The headset connector, directly below the latter controls, faces outward. The mode switch for the selection of switchboard or point-to-point operation is placed in the recessed well directly in front of the keyset.

Major Functional Assemblies

KEYSENDER DESIGN

A rear view of the keysender is illustrated in Fig. 10 In this design all electrical switches are of the leaf spring type employing twin contacts. Spring pile-ups are cam-driven by sliders associated with each switch, and actuated from pivoted key toggles. The latter are individually waterproofed by rubber bonding at the pivot points. Crossbars on the toggle arms engage and move adjacent sliders to provide the mechanical compounding previously described.

Two important human engineering factors were considered in the areas of key spacing and key action. Thus the staggering of the keys on the upper and lower rows develops maximum inter-button spacing without increase in keyset height. Wide button spacing minimizes the danger of false digit selection when arctic glove liners are worn. Similar operating facility is designed into the key movement. The action is such that depression of the key rapidly builds up to a maximum resisting force and then "drops out from under," equivalently to a detent action. This characteristic insures that the key will be bottomed during digiting and not stopped at an intermediate point during the travel.

HANDSET DESIGN

The new lightweight handset is molded of a high-impact thermoplastic material. In addition to the transducers it includes a plate of magnetic material secured to the flat section of the handle. The latter provides magnetic handset hold-down by attraction to permanent magnets in the telephone case. The military *TA-235/PT* ring armature type of telephone receivers are utilized as transmitter and receiver elements. For microphone use a substantially linear frequency response characteristic is obtained by external low-frequency acoustical equalization.

MAGNETIC HOOK-SWITCH

The magnetic hook-switch illustrated in Fig. 11 represents an effective solution to a complicated design problem. Service conditions necessitate the location

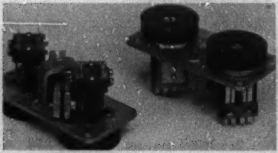

Fig. 11. Magnetic hook switch

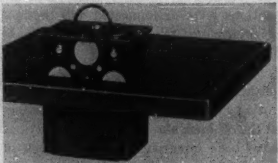

Fig. 12. Battery holder

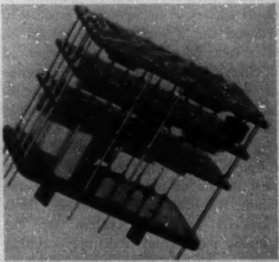

Fig. 13. Typical circuit module before encapsulation

of the switch on the inside of the case, and operation through a waterproof barrier. At the same time, magnetic hold-down of the handset is desired. In the latter case the flux change from handset removal may be utilized to rotate an armature. Applying this principle, the permanent magnets for handset retention are included in the switch, thereby eliminating any need for complex booting and mechanical linkages. The armature operates to actuate four switches of the leaf spring pile-up type. It is dynamically balanced to resist motion from shock.

Local Battery

The local battery, yielding a nominal potential of 9 volts, is made up of six *C*-size flashlight cells replaceable in a gasketed holder. Such arrangement facilitates the provision of battery taps. The use of three such taps has proved advantageous in accomplishing the circuit functions at minimum total current drain. The holder is inserted from the base of the telephone. Fig. 12 shows a bottom view of the molded base with the battery holder partly inserted into the waterproof well. As here applied, the expected capacity of this battery is 2,500 3-minute calls before replacement.

Circuit Packaging

Plug-in circuit modules are of the form illustrated in Fig. 13. These are encapsulated throwaway items employing stacked printed wafer assemblies. A newly developed spring-loaded pin jack is used in conjunction with these modules. Except for the oscillators, mounted in a separate package, the circuitry is divided into four units of similar size on a functional basis.

Conclusions

The new equipment described incorporates many new concepts in telephony. It is expected that the improved operating speed, reliability, and better transmission characteristics will prove of advantage to the military user.

A Delay Distortion Simulation Set

FRANCES C. DUNBAR
NONMEMBER AIEE

Synopsis: The delay simulator is a test instrument which produces delay as a function of frequency in the voice frequency range: 300–3,300 cps (cycles per second). Its primary function is to simulate the delay distortion of Bell System transmission facilities, including open wire, loaded cable, and carrier systems. This is accomplished by combining four variable delay characteristics. The wide variety of delay characteristics thus obtainable may be useful for testing actual data transmission systems or any other waveforms.

THE DEVELOPMENT of data transmission systems for use over Bell System facilities requires techniques for the determination of effects of the transmission medium on system performance. It is hard to predict analytically the results of amplitude and delay distortion on complicated waveforms. For this reason, it has been customary to conduct tests with actual lines rented from operating companies. This method has some obvious drawbacks. Reproducibility of the transmission line depends upon switching through the same cable circuits and carrier channels. Even if this were readily accomplished, there would be variations in noise and temperature effects.

These disadvantages could be avoided by using electric networks to simulate the transmission characteristics of Bell System facilities. A scheme with sufficient flexibility would also be valuable as a standard for determining limits on distortion for an operable data system. The initial step in the implementation of such a plan was the design of a delay simulator This instrument produces delay as a function of frequency at voice frequencies—300–3,300 cps. Included within the scope of the simulator are open wire, loaded cable, and carrier systems. These facilities exhibit delay versus frequency characteristics which are roughly U-shaped, but not symmetrical. Minima of delay occur over a wide range of frequencies, from approximately 600–2,200 cps. The simulator reproduces these delay curves for any practical length or combination of transmission media. Fig. 1 illustrates several delay characteristics. *H-44* and *B-88* cable are widely used in local cable circuits. The two carrier channels represent extremes of delay distortion produced by upper and lower channels of long-haul carrier systems. In each case, the delay distortion was obtained by subtracting the minimum delay from the absolute delay.

Realization of such a variety of delay characteristics demands a scheme which is both flexible and easy to use. This is accomplished by combining the four variable delay characteristics shown in Fig. 2. These characteristics introduce delay distortion in four overlapping frequency bands. Each one adds no distortion outside its own range (within the 300–3,300-cps voice frequency limits). The first characteristic provides delay which decreases from a maximum at 300 cps to zero distortion at 800 cps

$$\text{Delay}=A\left[\frac{(800-f)}{(800-300)}\right]^3$$

where $f=300\text{–}800$ cps

The second decreases from 300–1,600 cps

$$\text{Delay}=B\left[\frac{(1600-f)}{(1600-300)}\right]^{3/2}$$

where $f=300\text{–}1{,}600$ cps

The third increases from no distortion at 1,200 cps to a maximum at 3,300 cps

$$\text{Delay}=C\left[\frac{f(-1200)}{(3300-1200)}\right]^{3/2}$$

where $f=1{,}200\text{–}3{,}300$ cps

The fourth increases from 2,200 to maximum distortion at 3,300 cps

$$\text{Delay}=D\left[\frac{(f-2200)}{(3300-2200)}\right]^2$$

where $f=2{,}200\text{–}3{,}300$ cps

Paper 60-45, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted November 5, 1959; made available for printing November 27, 1959.

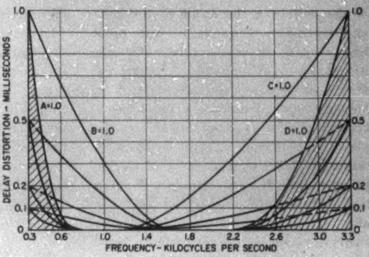

Fig. 2. Variable delay characteristics

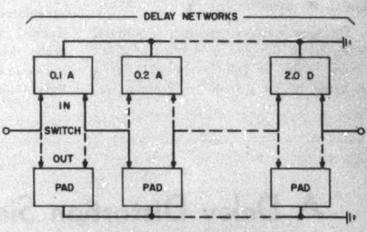

Fig. 3. Block diagram of delay simulator

The coefficients *A*, *B*, *C*, and *D* represent the maximum amounts of delay distortion added by each characteristic at 300, 300, 3,300, and 3,300 cps, respectively. Each coefficient has been furnished in units of 0.1, 0.2, 0.2, 0.5, 1.0, and 1.0 millisecond maximum delay. Therefore by combining these units, each coefficient may be varied in steps of 0.1 millisecond up to 3.0 milliseconds. Two additional units of 2.0 milliseconds (not shown on Fig. 2) have been added to the *B* and *D* series. The total maximum delay distortion which has been provided is 3.0 milliseconds each for *A* and *C* characteristics, and 7.0 milliseconds each for *B* and *D* characteristics.

Each coefficient (0.1 *A*, 0.2 *A*, etc.) is realized as a separate network which may be switched into the circuit independently of any other. When a network is connected into the circuit, it introduces delay which varies with frequency. In addition, it has an amount of delay which remains constant with frequency. This flat delay plus the delay distortion comprise the absolute delay of one coefficient. Each delay network also added some loss distortion as a result of dissipation in the component inductors and capacitors. It is apparent that any appreciable loss distortion could not be permitted in a device for studying delay effects. As a result, networks producing greater than ±0.2 decibel (db) distortion were equalized to some constant amount of loss. The deviation from flat loss for one coefficient ranges from ±0.02 to ±0.3 db. Equalization increased the loss of some of the networks to as much as 3.5 db. To avoid readjusting gain levels whenever a network is switched into the circuit, a pad with the appropriate loss has been inserted in the OUT position of each switch. The total flat loss of the simulator is 34.6 db, with a deviation which is determined by the coefficients in use. Therefore, for any combination of coefficients, the loss remains approximately constant and the absolute delay is the sum of the delay distortion and the flat delay of the coefficients. A block diagram of the simulation set is given in Fig. 3.

Some examples of simulated transmission lines are represented in Fig. 1 by dashed lines. The proper coefficients were determined as follows. An approximation was obtained in the 800–2,200-cps region by matching the required delay at 800–2,200 cps with the *B* and *C* coefficients, respectively. Where additional delay distortion was required at lower and higher frequencies, coefficients *A* and *D* were added. Sufficient amounts were selected to add the necessary delay at 500 and 3,000 cps. A wide variety of delay curves may be simulated in this way. For a narrower frequency range it may be expedient to readjust the coefficients slightly or to choose different matching

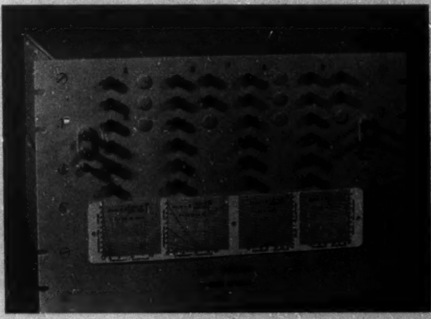

Fig. 4. Exterior view of delay simulator

Vol
Pt.
196

frequencies for one or more coefficients. If the coefficients for individual transmission lines are known, the delay distortion for any combination may be simulated merely by summing the coefficients. In the case of loaded cable, the delay is proportional to cable length (assuming typical circuit make-up), and therefore coefficients may be scaled from those obtained for one particular length. The delay of carrier systems depends mainly upon the number of carrier terminals and the channel allocations at these terminals. Consequently each system should be considered individually, or an average make-up may be assumed.

As previously mentioned, each coefficient is realized by a separate network. The network may contain from two to four all-pass sections and, in some cases, one loss equalizer section. These sections are all constant-resistance types which are unbalanced to ground. The impedance level is 1,000 ohms. All of the delay networks have been housed in special cans which are mounted on a front panel by means of supporting brackets. The pads are assembled on resistor mounting strips which are suspended beneath the top cover. Push buttons on the front panel actuate the switches that connect the delay networks or their associated pads into the circuit. Input and output terminals of the simulator are located on either side of the bank of push button switches. Ground terminals are insulated from the chassis but may be grounded to the front panel if so desired. Fig. 4 shows the simulator.

The value of this delay simulator lies in its flexibility and ease of operation. It provides delay characteristics which may be employed individually or in any combination. Furnishing delay distortion in four distinct but overlapping ranges has enabled the accurate simulation of a wide variety of Bell System transmission media. After the coefficients have been determined, any length or combination of facilities may be reproduced simply by scaling or addition of coefficients.

Redstone Arsenal Closed-Circuit Educational Television System

J. P. ARGO
NONMEMBER AIEE

I. N. HOWELL
ASSOCIATE MEMBER AIEE

THE REDSTONE ARSENAL at Huntsville, Alabama, is now pioneering in fields other than missile development. To illustrate this fact, the U. S. Army has had in operation for slightly over a year a unique and extensive educational TV (television) network. This network, with its associated administration, resembles very closely a nationwide broadcasting studio.

The Army desired a system for multipoint transmission from mobile TV studios with capabilities for programing on a video base-band basis and retransmitting on both a video and r-f (radiofrequency) basis. Furthermore, all outside plant had to be of aerial construction for security reasons. The r-f retransmission was to be confined to the U. S. Army base or post while the video retransmission was to be fed into the American Telephone and Telegraph Company's video facilities for delivery to Fort Knox, Kentucky, and other locations. In addition, the Army was providing another studio near the master-control room where the video was fed directly to the console. In an adjacent room, four Ampex Corporation video-tape recorders were also to be provided by the Army. The system uses components which have generally been found suitable for our company's purposes in providing educational TV service. While these system components have been adequate for normal educational TV requirements, where home-type receivers are used for viewing, no evaluation had been made where more rigid quality standards were desired. Fortunately, our company has had excellent co-operation from the Army and all others concerned with this system to assist in achieving the quality which is necessary in order that this type of educational TV system succeed.

System Description

This system as engineered consists of two separate networks on the Army base with the ability to program material received simultaneously over five separate video channels for purposes of retransmission over any one channel into the nationwide TV network on a closed-circuit basis. Of the two on-base closed-circuit systems, the one transmitting to the master control room is normally referred to as the transmitting network. This network, Fig. 1, consists of an aerial cable r-f amplifier layout which permits each mobile van equipped with high-quality image orthicon and studio vidicon camera chains to transmit on one of five channels from any of 21 transmitting locations over the network and into the master-control center. The channels in use are standard vhf (very-high frequency) 2, 4, and 6, plus channels 7 and 9 modulated downward in frequency to transmit over the cable system as subchannels between 36 and 52 mc (megacycles). There are several reasons for the use of subchannels. Five standard vhf channels in the channel frequency range of 2 through 13 require almost twice as much amplifying equipment. In addition, cable equalization problems are more complex. Also, the Army wanted the subchannels for a minor security technique in that those receivers not authorized for secret material were not to be converted from subchannels to standard vhf 7 and 9. This permitted programing the material on a selective basis for on-base consumption.

At the master-control center a group of extremely well qualified technicians, most of whom were formerly with major networks, strip the synchronizing pulses from the base-band video signals, reinsert new synchronizing pulses, and program the show for retransmittal to the second on-base system. Since the receiving system closely resembles the transmitting system, no drawing of it is included. The receiving r-f system receives information transmitted from the master-control room to some 29 receiving locations equipped with high-quality receivers. Simultane-

ously, one channel, selected by the director, is transmitted by radio relay to distant cities in the United States as required by the Army. On at least one occasion, the show was simultaneously transmitted to Fort Knox, the Pentagon, the Washington Press Club, and to New York, while also being received over the closed-circuit r-f receiving system on the base. At the distant cities a projection-type receiver is used and the video information is displayed on an 8-foot by 10-foot screen to permit large audience viewing for mass training purposes. Expansion of the video material for large-screen viewing requires that the transmitted signal be of excellent quality since the need for viewing very small electrical and mechanical parts is a necessity if training is to be as successful as if performed on the base.

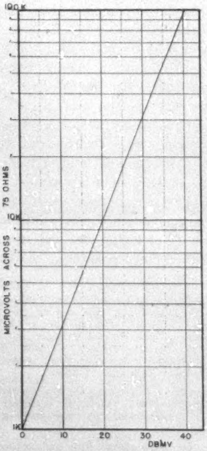

Fig. 2. Microvolts across 75 ohms versus dbmv

For the modulating source a Chromatron *2123-A* modulator was used to convert the video and audio signals received from the camera chain to r-f carriers. This modulator accepts a standard 1-volt peak-to-peak video signal from the camera chain and transmits it at nominally +40 dbmv (decibels referred to 1 millivolt); see Fig. 2 for dbmv. The output is filtered to reduce spurious frequencies and achieve better channel separation. One modulator is located in each mobile unit and terminated so that connection to the cable transmitting system can be made at any transmitting point without extensive adjustments. This connection is made through the use of a short length of triaxial *RG-11U*-type cable associated with the van. Triaxial cable is used to provide flexibility, to prevent radiation, and to improve reliability in the presence of radar. A short length of flexible cable is also secured to the utility pole and extends to a level of about 20 feet above the ground for connection to a Western Electric Company air dielectric 3/8-inch-diameter *CA-1878* coaxial cable. The *CA-1878* cable is supported by 6,000-pound tensile strength stranded wire to permit placing a ladder against it at midspan without danger of breaking. To minimize reflections no severe bends are permitted in the *CA-1878* cable.

Patch cords of the *RG-11U*-type triaxial cable are used to extend the *CA-1878* cable up and down the pole at each amplifier location or other locations where severe bending and flexing are necessary.

The amplifiers used for this system are

of the *SKL-211* type and are mounted in metal cabinets at such a level as to permit maintenance from the ground. Associated equalizers, pads, etc., are also installed in these metal cabinets. Every third amplifier is equipped with an *SKL-830* automatic level control device to permit regulation of levels with temperature changes. No automatic slope equalizer has been incorporated in the system; therefore, seasonal adjustments are necessary for slope. The maximum level into the cable from any of the amplifiers is held to +42 dbmv. Levels higher than this tend to cause intermodulation. To keep noise within acceptable limits, the minimum input level to any amplifier was originally designed at +11 dbmv or better. Subsequent changes in the system, however, permitted reduction of this to +8 dbmv.

In the master-control room the various channels are demodulated through Conrac, Inc., *AV-12B* television tuners. From these the video is amplified by Western Electric Company *1-B* clamper amplifiers which also reduce low-frequency noise and distortion.

The Army is then given, at their master-control console, a standard 1-volt peak-to-peak video signal. The associated audio signals are separately cabled to the audio console. Throughout the portion of the system where the audio and video are utilizing the same facilities, audio levels are maintained approximately 10 db below the video levels. To facilitate level control a *77MC* pilot frequency is transmitted from one of the longer legs. The level of this pilot is maintained 5 db below the r-f carrier.

Other details of the design are in accordance with industry standards and have been covered in other papers.$^{1-3}$ It should be pointed out here that where band-pass filters are utilized they must be isolated from the cable network, preferably with an amplifier in each mobile unit, to avoid reflections which tend to degrade the echo rating of the system.

The requirements furnished by the Army were met with little difficulty with the exception of equalization at the sub-channel frequencies. The system was engineered assuming a flat 10-db loss for the tap side of the chromatap. Subsequently it was found that this item of plant, rather than having a flat loss, has the characteristics shown in Fig. 3. We are continuing to use the chromatap, however, because of its extremely good isolation characteristics. In the transmitting legs requiring several chromataps, with transmission required through the tap side, reverse equalizers were designed and constructed locally to achieve an over-all response characteristic flat within ±1 db from 30 to 90 mc. The channel characteristics for each video channel may, of course, be maintained considerably flatter than this. Another of the requirements of this system is that the signal from any transmitting point for any channel must arrive at the master-control room at essentially the same level. This requires extensive loss "building-out" and very close attention to maintenance to prevent unequal levels with associated cross modulation.

System Installation

Although the installation of a comparatively new type of r-f distribution system offered many unanticipated problems, previous experience by the Southern Bell Telephone and Telegraph Company in the placing and splicing of cables and the installation and interconnection of various types of equipment facilitated completion of this project on schedule.

Prior to placing the outside cables, discussions were held with supervisory and craft personnel responsible for the completion of the cable project. At this time the effect of such items as minimum bends, sheath breaks, moisture in cables, etc., was discussed. It was necessary to go even further with the cable splicers and give instruction on the splicing and on the terminating of solid and air dielectric coaxial cables.

Personnel designated to complete the installation and interconnection of the various items of equipment were selected on the basis of their ability in related work and the probability of using them in the line-up and maintenance of the system. Extremely close co-ordination was maintained between supervisory and craft employees during this phase of installation.

Redstone Arsenal, like many military installations, has continued to grow on an expedited basis. Consequently, its power distribution system and communications cables have been supplemented on a "when needed, where needed" scale. As a result, pole space available for the Southern Bell Telephone plant did not allow for maintenance of Bell System standards as to road and power clearances in a number of cases. An unusual amount of time was required by U. S. Army post signal and engineering groups, in co-op-

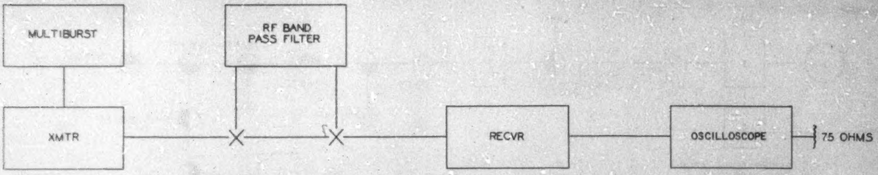

Fig. 6. Test setup for checking band-pass filters and video receivers in maintenance shop

eration with our own construction forces, to relocate and rearrange power fixtures and telephone cables to provide for standard clearances.

Since time was a most critical item throughout the entire project, the system was engineered on a crash basis and orders for equipment and outside cable placed immediately. In spite of these efforts, much overtime work was required to complete the installation prior to the required service data. As a result, line-up time was limited to the barest minimum.

In all cases, air dielectric coaxial cables were terminated in coaxial connectors on the messenger with triaxial cable used as patch cords to interconnect with tapping devices and amplifier equipment. Even though extreme caution was used in terminating all cables, a great amount of difficulty was experienced in securing water tightness at these points. This problem became quite serious during the cold rainy season but was finally solved by placing a short section of plastic tubing over these joints as shown in Fig. 4. The sleeve was installed in such a manner as to permit removal and reinstallation as required.

The placing of outside equipment cabinets at ground working level saved many man-hours of labor during the preservice line-up.

Because of the time element, it was necessary to form a co-ordinating committee consisting of a representative of the customer, the television equipment contractor, the television operating contractor, and the Bell Telephone Company. This group assumed the responsibility for authorizing deviations from original plans and on-the-spot solutions to problems as they arose. Without such co-operation from the interested parties, it is doubtful that the requested service date could have been met.

System Operation

The operation of this system can best be discussed under three separate categories: 1. preservice line-up, 2. daily operation, and 3. routine maintenance.

As expected, certain general problems were encountered common to the three areas of discussion, in addition to numerous problems which were unique to each particular category.

In the provision of a new service, technical in nature, an adequate supply of trained personnel is always a problem. In this particular case, time did not permit the establishment of formal training classes. Consequently, practically all training was done on the job.

Electronic circuit components and test instruments are mainly designed for use on TV community antenna systems. In some cases these provided neither the performance expected by personnel accustomed to broadcast-studio quality nor quality desired by the Army for this particular operation.

Ideally, this system should be essentially flat, between 36 mc and 88 mc, in order to pass the channels utilized. Little difficulty was experienced in obtaining flat response with ±1 db on channels 2, 4, and 6. This was not true, however, of the subchannel region. The design of the line amplifiers and tapping devices was such as to provide unwanted frequency distortion over the pass band. Because of the number of taps required in a limited geographical area, over-equalization resulted at a number of points. The cable layout shown in Fig. 5(A) was swept from 30–90 mc, the portion of the band now in use, in order to determine frequency attenuation characteristics, Fig. 5(B).

An attempt was made to utilize pure resistance tapping devices to improve frequency response at some of these points. It was possible to effect a definite improvement in this manner; however, it was necessary to add 75-ohm pads in the branches of these devices in order to provide isolation from impedance irregularities. The addition of pads necessitated the addition of line amplifiers to overcome increased losses.

This problem was resolved by a rearrangement of tapping devices which eliminated equalization effects on certain legs of the system. In a number of cases, as mentioned previously, it was necessary to design inverse equalizers with high-frequency losses in order to counteract over-equalization.

Two items of particular value throughout the preservice line-up and daily operation of this system, were a van-body truck equipped as a mobile shop and a Polaroid oscilloscope-adapted camera. The truck was equipped with work benches, storage lockers, power cords, a-c outlets, and r-f patch cords. Use of this truck enabled equalization, line-up, and maintenance work to continue regardless of weather conditions.

The Polaroid camera was used extensively to record sweep patterns during equalization and channel line-up efforts. Comparison of initial pictures with succeeding results provided an accurate indication of progress.

Admittedly, while this system has not provided broadcast quality video transmission on all channels simultaneously and consistently, it compares favorably with transmission over a fairly long intercity system. On the other hand, impairments in quality to an extent acceptable in community antenna distribution systems could not have been tolerated, owing to the more rigid requirements set by the extensive use of large-screen television projectors.

Even though the over-all video signal-to-noise ratio has been satisfactory, low-frequency noise has been troublesome, particularly where it has keyed the vertical oscillator in the video-tape machines and caused vertical rolls. In most cases, this resulted from low r-f levels caused by moisture in cables. Also, power distribution system electric faults have introduced impulse noise.

Radio-frequency interference has been fortuitous and therefore difficult to locate and eliminate. The r-f field in this area varies in intensity and frequency in accordance with the number and types of radar and r-f test sets in operation. The most serious source of r-f interference is caused by intermodulation products generated within the various pieces of

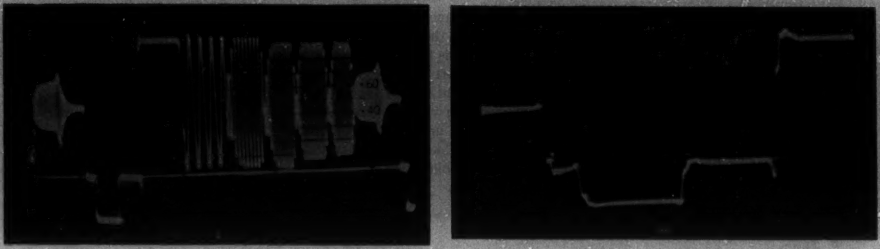

Fig. 7. Typical multiburst pattern with band-pass filter inserted, calibrated 1 volt peak to peak (A). Blanking interval of (A) expanded to show ringing (B)

equipment and falling within the pass band of a particular channel. This has proved to be a particular problem with a combination of channels 4 and sub-7, causing r-f patterns to occur in channel 6. Although it has been impossible to eliminate completely this interference, close co-ordination of levels at common amplifier points has been helpful to keep it within acceptable limits.

Ringing has been particularly troublesome throughout the entire operation, especially on projected pictures. It has been found that r-f band-pass filters and video receivers are the major contributors to ringing problems. The test layout shown in Fig. 6 was set up in the maintenance shop for the purpose of studying the causes of ringing. The response pattern shown in Fig. 7(A) is the result of passing a multiburst signal through the transmitter and receiver, with an r-f band-pass filter inserted. In this case, both the receiver and filter had been tuned for optimum results. An expanded view of the blanking interval is shown in Fig. 7(B). Here, the presence of ringing is obvious. It was also noted that the loss of setup in the multiburst pattern was because of the presence of the filter. Later it was discovered that still better results could be obtained by tuning the filters in the working circuits for which they were designed.

Cross-talk, although not as serious as noise and ringing, has been a problem. Most cases of cross-talk resulted in sync cross-over into various channels. Readable picture cross-talk, however, exists between channel sub-7 and channel 2 as a result of insufficient front-end selectivity of the channel 2 receiver, allowing the sub-7 to be fed through and accepted in the i-f (intermediate-frequency) pass band of the channel 2 receiver. While co-ordination of transmitting levels has been helpful in reducing sync cross-over it was necessary to insert a channel 2 r-f band-pass filter in front of the channel 2 receiver. Addition of this filter has not eliminated the cross-talk completely, but has reduced it to the extent that no longer is a readable picture evident. Cross-talk is now responsible for only slight loss of definition in channel 2 pictures.

The usable frequency response of any channel is limited by high frequency roll-off such that ringing will be at a minimum. In most cases, better detail can be obtained with gradual roll-off in the interest of reducing ringing. The multiburst pattern shown in Fig. 7 (A) indicates optimum roll-off for an acceptable channel.

Stability of operation has been of major concern throughout this project. Any of the operating deviations discussed have been subject to change from hour to hour and day to day. R-f interference evident in channel 2 one day might clear and then be present on some other channel the next day. Channels aligned for optimum transmission one afternoon might be unacceptable the following morning. This is caused in part by temperature differences at the various equipment locations and temperature changes from hour to hour.

Transmitters and channel-to-subchannel converters are installed in aluminum body vans in addition to the remote TV equipment. Even though these vans are equipped with exhaust fans, the temperature level becomes quite high on warm days. Line amplifiers are installed in pole-mounted boxes painted white for heat dissipation. The temperature in these boxes never reaches the temperature in the vans, in spite of the absence of forced ventilation. Subchannel-to-channel converters and video receivers are located in the master-control room which is air-conditioned to accommodate all heat generated in the area.

Master oscillators in the transmitter, although crystal controlled, are not equipped with ovens and are subject to some frequency drift with temperature changes. Master oscillators in the subchannel converters are not crystal controlled and are subject to intolerable frequency shift with temperature changes. It is obvious that frequency drift in components in the various temperature zones will not be linear and receivers will not necessarily track their respective transmitters.

Equipment maintenance, initially a serious problem because of lack of experienced technicians and comprehensive instruction bulletins, has become a routine matter. Personnel selected to operate the system have become quite proficient in maintaining and aligning all components involved.

Cost of maintenance for a system of this type is still a matter of conjecture. However, a routine has been established by which all time spent maintaining and operating this system is coded and logged to the various phases, such as, system line-up, channel line-up, transmitter line-up, transmitter repair, etc. In addition, individual maintenance records are maintained on each unit of equipment. This record shows trouble indication, trouble location, specific vacuum-tube usage, and time required on each maintenance effort. It is felt that these records will be of great value in estimating cost of maintenance of future systems and of particular types of equipment.

Conclusions

It is becoming increasingly evident that aerial-cable closed-circuit TV utilizing r-f distribution techniques has a definite place in both industrial and educational fields. In a number of applications TV service can be provided in this manner which could not be provided economically or practicably in any other way. For example, to have provided the Army with a base-band system in this case, would have required a separate underground cable from each of the transmitting points with separate amplifiers for each of these cables at a cost which would have been almost double the cost of the existing system. Reasonably good service can, however, be provided quite economically if strict maintenance procedures are utilized throughout the system. To permit expansion in this field, it is our belief that continued effort should be applied toward improvement in the design and manufacture of the various components which go to make up a system of this type, in order to achieve uniformity, stability, and dependability.

An Omnidirectional Circular Antenna Array Excited Parasitically by a Central Driven Element

H. P. NEFF
NONMEMBER AIEE

J. D. TILLMAN
ASSOCIATE MEMBER AIEE

THERE IS a continuing practical need for antennas which radiate a pattern which is omnidirectional in azimuth, but with a specified shape in the vertical direction. One example is that of a broadcast station, where the radiated power should be concentrated along the ground. Conventional solutions of this problem make use of an array of colinear elements, or of sectionalized elements, or of top-loaded antennas. The height of the antenna is often of the order of a half-wavelength. Page[1] proposed that a circular array be used for this purpose, and showed that an array of several radiators distributed about the circumference of a circle, and with an element at the center, could be made to radiate an omnidirectional pattern in azimuth, with a null at any prescribed vertical angle. In the antenna described by Page all of the elements are driven, which entails complicated matching and phasing networks. It is the purpose of this paper to describe an antenna, similar in geometry to that of Page, in which only the center element is driven. The remaining elements are excited by mutual coupling from the center element, and the desired null in the vertical pattern can be controlled either by varying the length of the parasites, or by inserting a tuning reactance at the center of the parasites.

Derivation of the Expression for the Radiation Pattern

The antenna described in this paper is shown in Fig. 1, and consists of m identical, parallel parasitic elements, which are spaced symmetrically about the circumference of a circle of radius ρ. A similar element is at the center, and is driven by a voltage V_c. From the symmetry, it is evident that equal currents will be induced in each of the parasites. Let the current in the center element be designated by I_c, and the current in each parasite by I_p. Let the antenna no. C be located at the origin of a conventional spherical co-ordinate system, oriented so that the circle lies in the plane $\theta=\pi/2$ and element no. m in the plane $\phi=0$.

The radiation from the center element depends on its half-length h_c, and will be designated by F_{ec}.

The pattern of the ring array of parasites is 2

$$F_p=mI_p\left[J_0\left(\frac{2\pi\rho}{\lambda}\sin\theta\right)+\right.$$
$$\left.2\sum_{k=1}^{\infty}j^{km}\cos km\phi\, J_{km}\left(\frac{2\pi\rho}{\lambda}\sin\theta\right)\right]F_{ep} \qquad (1)$$

In equation 1 F_{ep} is the element factor of the parasites, which depends upon their half-length h_p, $J_n(x)$ is the Bessel function of the first kind of order n, and λ is the wavelength. All of the terms in the summation can be made negligible by choosing m so that

$$J_0\left(\frac{2\pi\rho}{\lambda}\right)>>J_m\left(\frac{2\pi\rho}{\lambda}\right) \qquad (2)$$

For a circumference of the order of 2.4 which will be shown to be desirable, $m=6$ makes the pattern

$$F_p=mI_pF_{ep}J_0\left(\frac{2\pi\rho}{\lambda}\sin\theta\right) \qquad (3)$$

to within less than 0.5 decibel for all directions θ or ϕ. This choice is discussed in reference 2. For the remainder of the discussion m will be assumed to be large enough to satisfy equation 2.

The pattern of the entire array is the sum of the patterns of the center element and of the ring. Then

$$F=I_cF_{ec}+mI_pF_{ep}J_0\left(\frac{2\pi\rho}{\lambda}\sin\theta\right)$$
$$=I_cF_{ec}\left[1+\frac{mI_p}{I_c}\frac{F_{ep}}{F_{ec}}J_0\left(\frac{2\pi\rho}{\lambda}\sin\theta\right)\right] \qquad (4)$$

Equation 4 gives the radiation pattern of the array. The pattern is omnidirectional in azimuth, since there is no dependence on ϕ. The pattern is dependent on θ in two ways: the element factors are functions of θ, and the Bessel function has a function of θ as its argument. The element factor of a thin dipole is

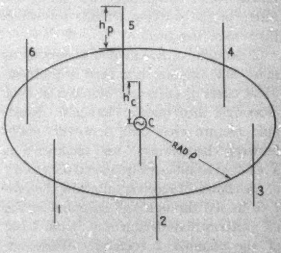

Fig. 1. Antenna array consisting of six parasites equally spaced on the circumference of a circle and a central driven element

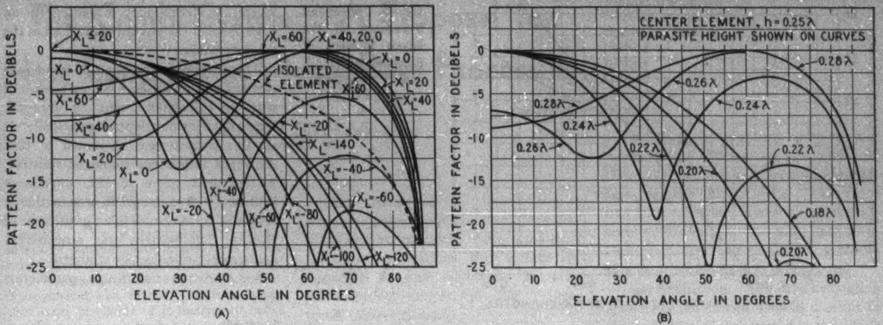

Fig. 2. Vertical patterns obtainable from the array of Fig. 1 by varying

A—Parasite termination
B—Parasite height

$$F_e=\frac{\cos\left(\frac{2\pi h}{\lambda}\cos\theta\right)-\cos\frac{2\pi h}{\lambda}}{\sin\frac{2\pi h}{\lambda}\sin\theta} \tag{5}$$

Inspection of equation 5 indicates that the ratio F_{ep}/F_{ec} is always real, and provided h_p is not greatly different from h_c, it is very nearly equal to one. It follows from equation 4 that a null exists at an angle θ_n such that

$$J_0\left(\frac{2\pi\rho}{\lambda}\sin\theta_n\right)=-\frac{I_c}{mI_p}\frac{F_{ec}}{F_{ep}} \tag{6}$$

and that for such a null angle to be real requires I_c/I_p to be real. If I_c/I_p is complex, a quasinull exists at the real angle θ_n given by

$$J_0\left(\frac{2\pi\rho}{\lambda}\sin\theta_n\right)=-\Re\left(\frac{I_c}{mI_p}\right)\frac{F_{ec}}{F_{ep}} \tag{7}$$

and the residual field in the direction of this quasinull is proportional to

$$\Im\left(\frac{I_c}{mI_p}\right)$$

Derivation of Expression for Currents and Impedance

It is evident that the performance of the array depends on the ratio I_c/I_p. This ratio depends on self- and mutual impedances of all of the elements. Let each parasite be terminated in a load impedance Z_L so that the voltage at the center of each parasite is $-I_pZ_L$. As in any linear system one can write

$$\left.\begin{aligned} V_c&=I_cZ_{cc}+I_1Z_{1c}+\ldots+I_mZ_{mc}\\ -I_1Z_L&=I_cZ_{1c}+I_1Z_{11}+\ldots+I_mZ_{1m}\\ &\vdots\\ -I_mZ_L&=I_cZ_{mc}+I_1Z_{1m}+\ldots+I_mZ_{mm}\end{aligned}\right\} \tag{8}$$

The symbols in equations 8 have the conventional meanings: that is, if $i\neq j$, Z_{ij} is the mutual impedance between elements i and j, and if $i=j$, Z_{ii} is the self-impedance of element i. Now from symmetry, $I_1=I_2=\ldots I_m=I_p$, $Z_{1c}=Z_{2c}=\ldots Z_{mc}$, and $Z_{12}=Z_{1m}$, $Z_{13}=Z_{1(m-1)}$, ... Then equations 8 reduce to two equations. These are

$$\left.\begin{aligned} V_c&=I_cZ_{cc}+mI_pZ_{1c}\\ 0&=I_cZ_{1c}+I_p(Z_{11}+Z_{12}+\ldots Z_{1m}+Z_L)\end{aligned}\right\} \tag{9}$$

The impedance of ${}_0Z=Z_{11}+Z_{12}+\ldots+Z_{1m}$ is the terminal impedance of each element in the circular array with all of the elements driven in phase.[3] It is called the zero-sequence impedance, and may be calculated from mutual impedance data.[4,5] If $h_p=h_c$, these data also give Z_{1c}. If $h_p\neq h_c$, the expression developed by Cox applies.[6] Equations 9 now become

$$\left.\begin{aligned} V_c&=I_cZ_{cc}+mI_pZ_{1c}\\ 0&=I_{c1}Z_c+I_p({}_0Z+Z_L)\end{aligned}\right\} \tag{10}$$

From the first equation, the impedance of the driven element is

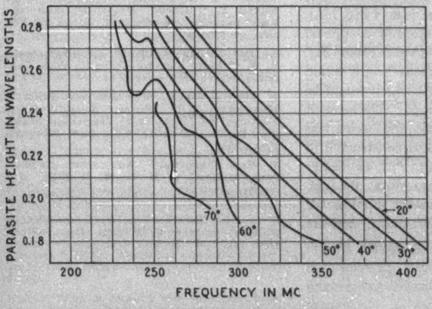

Fig. 3. Measured null angles for the array of Fig. 1

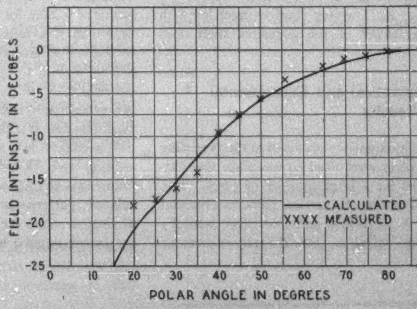

Fig. 4. Measured and calculated patterns for the array of Fig. 1 with $h_p=0.20\lambda$, and $\rho=0.383\lambda$

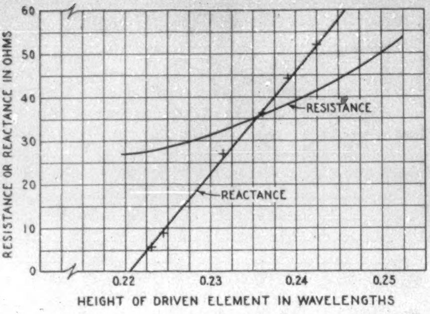

Fig. 5. Measured impedance of the driven element of the array of Fig. 1 with $h_p=0.20\lambda$, and $\rho=0.383\lambda$

$$Z_c=\frac{V_c}{I_c}=Z_{cc}+\frac{mI_p}{I_c}Z_{1c} \tag{11}$$

and from the second

$$\frac{I_c}{I_p}=-\frac{{}_0Z+Z_L}{Z_{1c}} \tag{12}$$

It is this ratio upon which the location of the null was shown to depend. This ratio depends on the radius of the ring, the element heights, and on Z_L. If there is to be no loss in Z_L, this impedance must be a pure reactance jX_L. A fortunate coincidence occurs in the numerical values of ${}_0Z$ and Z_{1c} which makes the ratio I_c/I_p nearly real if ρ is about 0.4λ. At this radius $|{}_0Z|$ goes through a minimum, and has only a small real part. Also, Z_{1c} is nearly a pure reactance at this spacing. Then, with ${}_0Z={}_0R+j{}_0X$

$$\frac{I_c}{I_p}=-\frac{{}_0R+j({}_0X+X_L)}{Z_{1c}} \tag{13}$$

Since both numerator and denominator are nearly pure imaginaries, their ratio is nearly real, and according to equation 7 a deep quasinull will exist. The angle θ_n of this quasinull can be controlled either by varying X_L, or by varying the height of the parasites, which varies both ${}_0X$ and Z_{1c}. Z_{1c}, however, changes much less with the height of the parasites than does ${}_0X$.

Theoretical and Experimental Results

The equations obtained in the preceding sections were used to calculate the patterns for a large number of cases. Fig. 2(A) shows the vertical patterns obtained for $h_c=h_p=\lambda/4$, and $\rho=0.388\lambda$, with X_L as the variable. Fig. 2(B) shows a similar set of patterns where $h_c=0.25\lambda$, $\rho=0.383\lambda$, $X_L=0$, and h_p is the variable. In both cases it is seen that quasinulls can be obtained at any desired elevation angle.

To obtain experimental confirmation, a model was constructed with the dimensions given above at 300 megacycles. Fig. 3 shows experimental null angles as a function of frequency. The irregularities in the curves for null angles of 60 and 70 degrees are caused by the difficulty in precisely locating a null in a region where the field intensity is low on either side of the null. The thickness of the elements in the model which affects the self reactance accounts for slight differences in the measured and calculated position of the null.

Typical Design

As an example, an array of the type which could be used by a broadcast station to reduce fading will be designed. For this purpose, the elements should be monopoles, driven against ground, instead of dipoles. A quasinull at a polar angle of about 30 degrees (elevation angle 60 degrees) meets this need. Using a radius of 0.383λ, for the case of Fig. 2(A), ($h_p=0.25\lambda$), a termination of $X={}_L-60$ to $X_L=-80$ would serve. From Fig. 2(B) if $X_L=0$, the parasite height would between 0.2λ and 0.21λ, which would be less expensive to construct. The element thickness also is a factor, and taking this into account for a model constructed of welding rod ($h/a=75$) with a center frequency at 300 megacycles, the calculated pattern is shown in Fig. 4. Measured points are also shown, and the agreement is good except at low angles, where the discrepancy is caused by an edge effect of the ground plane used in the measurements.

The measured impedance of the driven element was about $50+j85$, as compared with a calculated value of $50+j50$. Since Z_{1c} does not depend principally on h_c, this element was shortened so that the input impedance would be resistive. A measured curve of this impedance is shown in Fig. 5 and it is seen that a height of 0.22λ results in an impedance of $28+j0$. The pattern was remeasured, and was not significantly changed.

Summarizing, the design parameters are:

$h_p=0.20\lambda$

$h_c=0.22\lambda$

$\rho=0.383\lambda$

$m=6$

and this results in the pattern of Fig. 4, and a terminal impedance of the driven element of $28+j0$.

Conclusions

The method described in this paper can be used to design an array having a pattern which is omnidirectional in azimuth, and which has a null at any desired elevation angle. Given adequate data on the mutual impedances, the design is simple, and the resulting array is easy to excite and to match to a feed system. The use of parasites in the ring results in a much simpler excitation system than previously suggested designs for accomplishing the same result.

The Combi-System—A Proposal for New Concepts in Digital Data Processing

HELMUT SCHWAB
NONMEMBER AIEE

Synopsis: A new systematic organization of the field of digital data processing is proposed. This is motivated by recent extensive developments in this area. The subgroups—data acquisition, data handling, data evaluation, and data display—are distinguished, and defined; and it is shown that most problems of industrial or commercial data processing belong to the group of data handling. Data-handling problems in the past have been mostly solved by general purpose computers or systems based on computer technology. A new approach, based on basic functions of data handling is proposed. In the field of computing, basic functions are: add, subtract, multiply, and divide. In the field of circuit logic, basic functions are: and, or, not, memory, and time. The proposed basic functions for data handling are: position-selection, value-comparison, switching, memory, control, and translation. Similar to proceedings in computer technology or circuit logic, symbols are proposed for the basic data handling functions. These symbols allow a block diagram approach as well as eventually a new type of algebra in solving data handling problems. The use of these symbols is demonstrated in some practical examples. The practical building blocks for a data handling system based on the forementioned functions are discussed. To each of the functions corresponds one or a group of building blocks as selector, comparator, buffer, switch, and control unit. The advantages of this system are briefly discussed. It seems possible to combine the advantages of flexibility and ease of modification in general purpose machines with the advantages of simplicity and efficiency in special purpose equipment through a building block design of the proposed system.

THE FIELD of electronic digital data processing was first entered by scientific computers. The goal was to handle rather complex mathematical operations automatically. Their speed and volume of operation was low in comparison to today's machines. The general purpose machine was apparently the right approach, where the size was determined by the volume of operation. Soon it became apparent that commercial applications were economically more promising. In these applications the volume of operation is more important than the mathematical complexity. Fig. 1 illustrates this relationship.

This development has led to data-handling systems. Searching and filing, for example, are the main operations in the handling of patents in a patent office. These operations require the handling of a very large volume of data yet do not involve any mathematics.

An attempt has been made to handle the total area from scientific computation to large-volume data handling with increasingly large general purpose computers. It seems, however, more economical to look now for new approaches to these new areas. An approach from the data source of the data flow, as in contrast to the approach from the computer side, seems promising. The following presents an analysis of the data flow in digital processing systems.

Digital Data Processing

ORGANIZATION OF DIGITAL DATA PROCESSING

The field of digital data processing shall be subdivided into four areas:

Data Acquisition
Data Handling
Data Evaluation
Data Display (see Fig. 2)

Data Acquisition. Original information might be available in form of physical parameters, written records, or any other form. The problem of data acquisition is to transform this information into electric digital signals in the code or format required by a following data-processing system such as:

Analog-to-digital converter systems
Telemetering ground stations
Manual input devices

Data Handling. The following list of data-handling problems might best delineate the intended coverage of this area:

Data selection (reduction)
Format translation
Medium translation
Searching–reading
Sorting
Mixing
Correcting
Monitoring
Memory

None of these problems involve any mathematical operations. In addition, the output data contain the same information as the input data. The data-handling operations concern the arrangement of the data in the total data flow, their sequence, their selection or translation on other media or in other codes.

Data Evaluation. The data-evaluation area furnishes output data as a result of the evaluation of the input data and which therefore, are different from the latter. Computers and arithmetic units are typical data-evaluation systems or units.

Data Display. This area covers the equipment for conversation of the electronic data into a form which can be understood by human beings: plotters, printers, and other displays. It could also cover outputs from the data processing for any kind of action such as actuation of valves in chemical plants or control of machine tools.

Data Handling

DATA-HANDLING PROBLEMS

The organization of the field of digital data processing shall help to initiate a measure of order in this vast field and to choose the appropriate approach for each area. The approach which is good for data handling might not be ideal for data acquisition. Similarly, the computer is probably not the best approach for data handling either. A more systematic analysis of the area of data handling might be useful in arriving at a new approach.

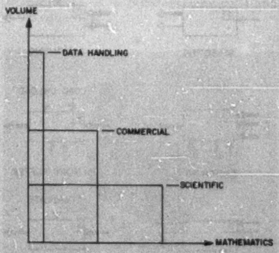

Fig. 1. Digital computers

Data-handling problems can be found in banking systems, air-traffic control, large-scale production control, instrumentation data editing, format transla-

tion, curve smoothening, scale correcting, process control, patent office filing, warehouse inventory, and many others.

It was already mentioned that all these applications can be reduced to a rather small number of fundamental problems. Such are:

Data selection (reduction): Systematic selection or editing of data for time selection, channel selection, and digit selection.

Format translation: Rearrangement of the electric or magnetic pulse pattern of one computer language into the "format" of another computer language. The information content is not changed in this process.

Medium translation: The transcribing of information from one storage medium to another, for instance from magnetic tape to punched cards.

Searching reading: Searching of a specific data block in a large file of information, where the block is characterized by some search digits, but not by its location. Also searching of single digits in a data block.

Sorting: For instance, alphabetic or numerical sorting of random input information. Quite important in all warehouse-type operations.

Mixing: Collating of two or more data flows each of which are sorted in the same manner.

Correcting: Mainly correcting of single digits in a data block. This operation consists of two parts, "cancel information" and "add information." The correction of a whole data block can rather be considered as a sorting and mixing operation.

Monitoring: In-limit or out-of-limit indication, very common in process and quality control, but also used in editing and other applications.

Memory: A passive operation, in contrast to the active operations already mentioned, but nevertheless very essential. It is independent from the previous operations and belongs to the area of data handling.

DATA-HANDLING FUNCTIONS

The previous paragraphs have already explained two steps in the systematic organization of data processing and data handling: the organization of the data-processing field in subareas, and the organization of data handling in basic problems. There is still one more step possible which has essential consequences for the "hardware," the definition of fundamental data-handling functions.

The basic data-handling problems can be reduced to six fundamental functions:

Selecting
Comparing
Switching
Memory
Control
Translation

These functions are basically known. It is with their systematic investigation in the area of data handling that this paper is concerned.

Position Selection. Selection or indication of a specific area in a data flow (for instance, selection of the N th block in a flow of data blocks, or of the N th digit within any data block).

Value Comparison. Comparing of two or more selected characters mainly for their numerical relation (A greater than B, A smaller than B, or A equal to B).

Data Flow Switching. Mixing of a data flow from one or more inputs or distribution to one or more outputs, or a combination of both through flow switching (gating).

Data Memory. This includes buffering as well as long time memory. A shift register might be a specific memory.

Systems Control. Control functions are needed for the co-ordination of the previous functions to complete systems. Command gating and memory are essential parts of the control, as are also clock and reset functions.

Character Translation. In certain systems it is useful to introduce the translation function. This is not required in cases of table translation (memory function) or simple rearrangement (control function). Code changes, however, are typical translations. Some scale-correction systems belong also to this group.

APPLICATIONS

The foregoing theory introduces the idea of fundamental functions for data-handling problems. It shall be mentioned that such a theory for a logical field is not new. In mathematics, it has been known to solve problems with the use of the four functions:

Add
Subtract
Multiply
Divide

In circuit logic, a similar approach yielded the five functions: And, Or, Not, Memory, and Time.

The definition of fundamental functions

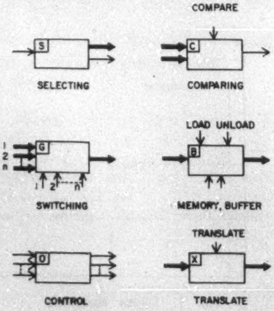

Fig. 3 (left). Data-handling symbols

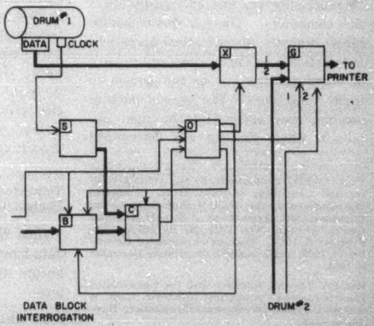

Fig. 4 (right). Data-handling application

Fig. 5 (left). Submodules

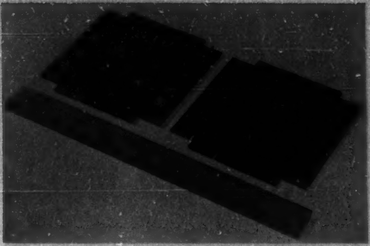

Fig. 6 (right). Printed cards

allows the introduction of symbols for their representation. Actually, there are two types of symbols, those used for block diagrams (or flow diagrams) and those used for algebraic equations. This is especially apparent in circuit logic. There, one finds the gate symbols as well as the symbols for the Boolean Algebra. One could even say that it is only the creation of symbols which allows the solution of complex problems by the method of block diagrams or algebra. The creation of data-handling symbols would, then, be an essential advantage in using the foregoing approach to data-handling problems. Fig. 3 shows block-diagram symbols for the proposed system.

Fig. 4 shows an example of a data-handling problem solved with the "Combi-System" block diagram approach. It presents in a schematic fashion a detail of a larger system. This detail is the read-out of data blocks from a magnetic drum system to an electromechanical printer as interrogated (addressed) by an external, nonsynchronous, data source.

The interrogating block address is held by the memory-function *B*. The selector-function *S* is controlled by the drum clock and, thereby is used as drum address selector. Its output is compared with the interrogating address by the comparator-function *C*. In case of a coincidence the translator-function *X* is actuated. This allows read-out of, for example, a *BCD* code if the drum had a straight binary code. The switch-function *G* permits connection of several drum systems to the same printer. The control-function *O* co-ordinates the previous functions.

It can be seen that there are two different flows of information, the data flow (heavy lines), and the command flow (light lines). This is also apparent in the symbols in Fig. 3.

The data flow is formed by four tracks plus parity check (and sign) in the *BCD* code and by six or more tracks plus parity check in the straight binary code. The transmission of true signals as well as false signals might be possible.

The command flow consists normally of one channel only. Possibly, however, a philosophy corresponding to the "standard level exchange" in Consolidated Electrodynamics Corporation's Micro-SADIC may be followed. There, each command consists of three parts:

1. The preparation signal, one clock period long prior to the command.
2. The action level for the length of the action.
3. The end level, one clock period long prior to the end.

Examples of the function of the command are:

Load, unload, recycling, or reset command for the memory function.
Comparing and decision-making command for the comparator function.
Step command for the selector function.
Gate opening for the switch function.

With these rules, Fig. 4 can be understood in the following way.

The interrogating data source delivers an address through its data flow and simultaneously a load command to the memory function. This command also instructs the control function that a new address has been delivered.

The selector unit, controlled by the clock of the drum, delivers that address on the drum which is just passing the read heads. Zero address is selected as a command to the control unit for reset purposes. The comparator unit receives the interrogation address as well as the drum address. It also receives a command telling when to effect the comparison. This command is identical with the recycle command for the memory-function. The result of the comparison is delivered to the control unit. Through the latter (or directly) it activates the translator-function and the switch function. Thereby a read-out to the printer is effected. Certain commands from the selector might be used in the control function to determine the block length.

It has already been mentioned that another set of symbols might be created for an algebraic approach to data-handling problems (similar to the Boolean algebra). This shall be explained for the problem of Fig. 4. The symbols shall be

⁚ select. $D ⁚ A$ means select data flow D in correspondence to information A.
∞ compare. $A \infty B$ means compare A and B for equality.

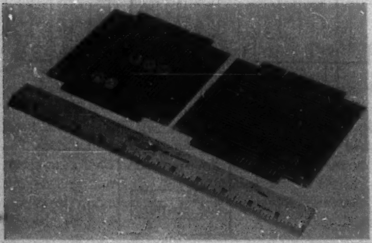

Fig. 7 (left). Logic cards

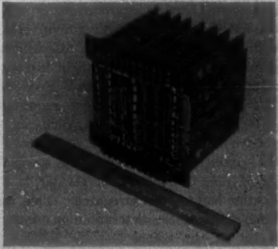

Fig. 8 (right). Submodule (complete)

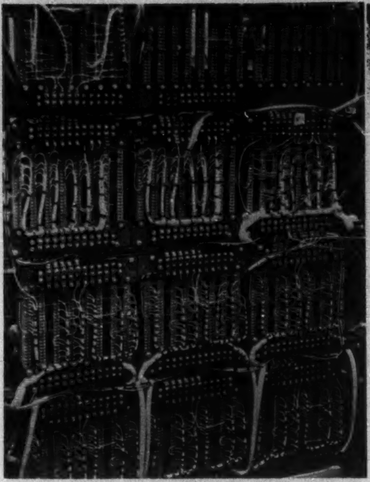

Fig. 9 (left). Combi-system model

Fig. 10 (above). Model of an integrated digital data-processing system

$*$ memory. A^* means keep A in memory.
— translate. $A-D$ means translate D in accordance with information A. This corresponds remotely to the minus sign in algebra.

If we define A as the incoming address, D as the data flow from the drum, and G as the output data flow, then the example in Fig. 4 is represented by the equation:

$$G=A^*\infty(D : A)-D$$

Another possible solution of the same problem is apparently

$$G=A : (A^*\infty D)-D$$

At this moment this equation is only a shorthand notation of the problem. It shows, however, in what direction studies have to be directed in order to establish a data-handling algebra. Its use would correspond to that of the Boolean Algebra in circuit logic.

The Combi-System has been used, for example, for the design of an air traffic control system. The problem was to give conflict monitoring, fix area monitoring, and flight history for 200 airplanes in a 400-mile-square 100,000-foot-high area with 200 fixes and 50 sectors. Updating period is 1/16 of a second, flight history evaluation period is less than 6 seconds. The conflict evaluation alone required 40,000 comparisons per scan, each comparison for three dimensions. Previously, the conflict tolerance for the specific sector (one out of 50) for the airplane location had to be interrogated. This, in turn, required the determination of the sector of the actual airplane location. Each conflict resulted in a time determination, count, and successive printout of all pertinent data.

Hardware

Building Blocks

A system has been designed which applies the foregoing theory to a series of building blocks. This system has acquired the name "Combi-System." The basic philosophy of this system is to provide a family of standard building blocks for each fundamental data-handling function. The blocks are also called "submodules." The idea is, then, to combine the standard building blocks into tailor-made systems.

The creation of the submodules is a new step in the modularization of systems. Building blocks in form of standard circuits on printed cards are widely in use. Another level of modularization is the use of standard operational units, for instance the major parts of a computer (memory unit, arithmetic unit, input-output devices, control). This type of standardization finds its limitation in the great variety of applications. The new step, as a result of the theoretical investigation of the fundamental data-handling functions, modularizes on a level which corresponds to the largest common building

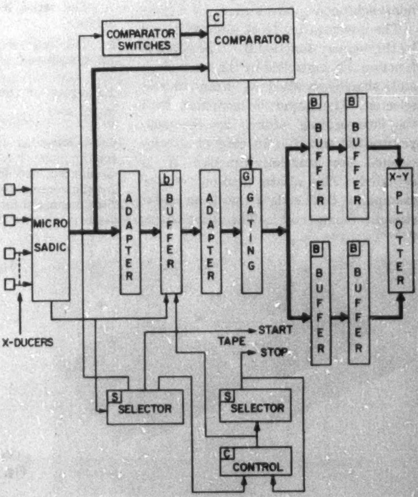

Fig. 11. Data-processing experimental system

block for all applications. These new "submodules" are formed by a certain number of standard circuits or "cards." Several submodules together can form an operational unit. Since the submodules correspond to the fundamental functions, they bring advantages for designing of systems, trouble-shooting in systems, and modification of systems. Beside that, they have the normal advantages of standard building blocks for production and maintenance.

Each submodule has provision for combining eight printed cards. The module itself consists only of the eight connectors, their wiring, and an iron frame, as shown in Fig. 5. Fig. 6 shows printed cards (one flip-flop card and one logic card), and Fig. 7 shows a general purpose logic card (crossed wire-grid type). Fig. 8 shows a submodule with printed cards inserted.

Fig. 9 shows a laboratory arrangement of submodules in a larger frame system. The interconnecting cabling in this laboratory model is achieved by card-plugs for the data flow and barrier-strip connections for the power supply and command flow. A more advanced design is being tested.

All circuits and standard cards used in the Combi-System are the same as those considered standard for Consolidated Electrodynamics MicroSADIC. Therefore, power supply and signal specifications are the same for the Combi-System as for MicroSADIC.

SYSTEM MODEL

Fig. 10 shows a feasibility model for an integrated system including data acquisition, data handling, and data display. Fig. 11 shows its block diagram.

The system model has a model rocket as test object. Transducers (potentiometers) indicate its pitch, yaw, and roll. A first oscilloscope is used as a quick-look device, displaying the pitch and yaw as an *X-Y* plot. These values are, then, sent to a MicroSADIC in unblocked data flow operation at low sampling rate, similar to a PDM link. From this data acquisition section, the data flow to a data-handling system using laboratory Combi building blocks. This section first does time editing on preset start and stop time based on time digits in the data flow. This section also translates the data flow into an International Business Machines Corporation's *704* format which might be recorded by a tape unit. The tape unit is directly controlled by the translator. The data-handling unit, finally provides a double-channel selection, again for the pitch and the yaw samples in the data blocks. The last part of the system provides data display. The electronic section also uses Combi blocks (shift register and digital-to-analog converter). The display is again in the form of an *X-Y* plot. At present, a cathode-ray tube is used for the final display. Later, a photographic process or the like might be more appropriate.

This feasibility model shall prove how data handling fits into the total data-processing system and how essentially the same hardware can be used in all parts of an integrated system, from data acquisition to data display.

Conclusions

The Combi-System has different aspects. One is the more philosophical aspect, treating the data-handling theory. The result is the systematic definition of the fundamental functions, select, compare, switch, control, memory, and translate. It also includes the introduction of symbols for these functions, allowing the solution of data-handling problems in simple block diagrams, and possibly with specific algebraic methods.

Another aspect is the hardware, created as a consequence of the theory. This includes the fundamental Combi-System building-block families: comparator, selector, memory, control, and translator. New ideas for framing, cabling, and front panels are connected to these new building blocks. There are no essentially new technologies used in this approach. The hardware utilizes standard circuitry and cards from MicroSADIC.

The previously defined data-handling functions and circuits are basically known. The contribution of this paper shall be their systematic investigation and definition under the aspect of general use in data handling. This simplifies considerably the design and manufacturing of data-handling systems. The Combi-System is a new systematic approach to the field of data handling.

In this new approach, the foregoing theory allows a practical way of solving even complex data-handling problems (for instance, the air traffic control problem) and the new hardware arrangement allows an economical design of such systems with already available material.

This report has presented new concepts in organizing the field of digital data processing. Especially for data handling, the attempt has been to show new ways for problem solution using Combi-System theory and standard hardware in fundamental functions for using standard building blocks.

A Precision, Continuous Voltage Reference for Industrial Recorders

PAUL B. ROBINSON
MEMBER AIEE

A NEW PRECISION voltage reference for use in industrial null-balancing recorders is described. The reference employs a Zener diode as the voltage element and replaces the conventional dry cell, standard cell, and standardizing mechanism used in most recorders. The reference is currently being supplied as standard equipment in the new General Electric strip chart recorder.

The Need for a Voltage Reference

In the past several years, a number of attempts have been made to eliminate the standard cell and dry battery that have been standard equipment in most industrial null-balancing potentiometric recorders. While these voltaic cells have rendered long and dependable service, they have also represented a service expense and inconvenience to the user, who has had to replace the dry cell periodically, hopefully, but not necessarily, before the useful life of the dry cell has been exceeded. The standard cells have also limited the temperature to which a recorder could be exposed, since the cells freeze only a few degrees below the freezing point of water. In cases where excessively low temperatures were unavoidable, heaters had to be added to the recorder or the standard cell located re-

Paper 60-114, recommended by the AIEE Recording and Controlling Instrumentation Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted November 23, 1959; made available for printing November 27, 1959.

PAUL B. ROBINSON is with the General Electric Company, Lynn, Mass.

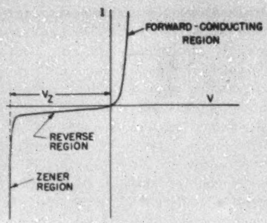

Fig. 1. Volt-ampere characteristics of Zener diodes

mote from the recorder to prevent freezing.

The necessity of periodically standardizing the dry cell against the standard cell has meant momentary interruption of the measurement of the process variable and the loss of control or alarm functions. This loss is, of course, for brief intervals only. But regardless of how brief, the standardizing mechanism with its clutches, cams, and switches, has been an unavoidable part of every recorder using the cells.

The standardizing rheostat also represents a problem with instruments having highly suppressed scales, since each convolution of the rheostat winding begins to represent a noticeable shift in the instrument's calibration. Thus, the standardizing adjustment no longer appears continuous but is a series of discrete steps. The result is apt to be shifts in instrument calibration following each standardizing period.

For these reasons, a replacement for the standard cell-dry cell combination has long been recognized as desirable. Needed is a voltage reference that is at once simple, virtually maintenance-free and above all, sufficiently precise to be used as a reference in the 1/4% class of industrial null-balancing recorders where voltaic cells are now used.

This paper describes a reference which, it is believed, meets these requirements. The reference is currently being applied in the new General Electric types *HF* and *HG* recorders, and has been used in special applications with the type *HE* round chart recorder.

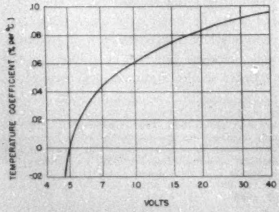

Fig. 2. Zener breakdown voltage

Zener Diodes

Volt-Ampere Characteristics

The principal element in the reference to be described is a Zener diode. These diodes have been described in detail in published literature and are simply silicon junction diodes. They exhibit the volt-ampere characteristic shown in Fig. 1, which is very similar to the volt-ampere characteristic for other semiconducting diodes except for the breakdown or Zener region. In this region, the voltage across the diode is nearly independent of the current flowing through the diode, a trait that immediately suggests the possibility of using the diode as a reference.

Comparison of Zener Diodes with Gas Regulator Tubes

The similarity between the volt-ampere curve of the silicon diode in the Zener region and the volt-ampere curve of a gas regulator tube is obvious. The diode has two immediate advantages over the regulator tube, however. One is that the diode does not need a voltage in excess of its Zener voltage to conduct in the breakdown region as does a gas tube. Thus, "starting" the diode is no problem and need not be a part of the calculation of circuit parameters as it must with the gas regulators. The second advantage is that there are no discontinuities in the volt-ampere curve in the diode's Zener region as there are in gas regulators. These discontinuities are caused by sudden changes in the ionization pattern within the gas tube as current varies. The diodes seem to have no comparable phenomenon, for the slight effect of diode current on Zener voltage is a continuous and dependable one.

Temperature Characteristics of Zener Diodes

Silicon diodes are available with a wide range of Zener voltages, but the selection is limited when the need is for a precision reference. This is because the breakdown voltage is a definite function of temperature, with the magnitude of the temperature effect being a function of the breakdown voltage. This relationship is shown in Fig. 2, which indicates that for reference work, where a low temperature coefficient of voltage is necessary, relatively low voltage units are called for.

Experience has shown that while the lowest temperature coefficient appears to be around 5 volts, the predictability of this coefficient from diode to diode is not so good at 5 volts as it is at 7 volts. Thus, it has proved better to work with the 7-volt diodes and compensate them for their positive but reasonably dependable temperature coefficient.

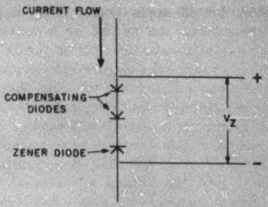

Fig. 3. Circuit of temperature-compensated Zener diodes

Temperature Compensation

Compensation in commercially available reference diodes is accomplished by connecting two additional silicon diodes in series with the Zener diode, but in the forward direction, as shown in Fig. 3. The forward-connected diodes have negative temperature coefficients of voltage, their voltage drop decreasing with increasing temperature. The magnitude of this coefficient is about half that of the Zener diode's positive temperature coefficient, and, by proper selection and matching, the two forward diodes can be made to compensate the Zener diode exactly. The result is that units with temperature coefficients very close to zero are obtainable, and this over a wide temperature range.

The voltage drop in the compensating diodes accounts for the unit's voltage rating being above 7 volts. The *1N430* is rated at 8.0 to 8.8 volts.

Dynamic Resistance

While the diode voltage in the breakdown region is very nearly independent of current, it is not completely so, there being a slight slope to the volt-ampere characteristic. If the diode's Zener voltage is considered equivalent to a battery,

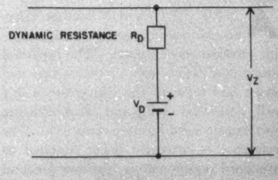

Fig. 4. Equivalent circuit of Zener diode

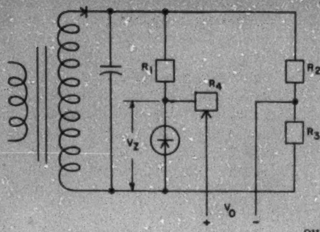

Fig. 5 (left). Circuit of precision reference

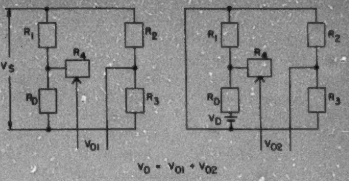
Fig. 6 (right). Equivalent circuits of reference resulting from superposition



the slope of the characteristic curve can be represented by an equivalent resistance in series with the battery, as shown in Fig. 4. Another inherent advantage of the Zener diode over the gas regulator tubes is that this equivalent, or dynamic resistance, is an order of magnitude lower in the diode, being about 15 ohms in a temperature-compensated reference diode.

The Precision Reference Unit

DESIGN CRITERIA

The design of the General Electric precision voltage reference started with a commercially available temperature-compensated Zener diode, the *1N430*. This diode is rated at 8 to 8.8 volts and has a dynamic resistance of 15 ohms at 10 ma (milliamperes). Its temperature coefficient is no greater than ±0.002%/C (degrees centigrade).

Given a temperature-compensated diode then, the principal problem is to eliminate the effect of the diode's dynamic resistance. Two ways of doing this are available. One is to provide a buffer for the diode so that it sees virtually no line voltage variations. This can be done by using a constant-voltage transformer or a higher voltage and uncompensated Zener diode in the reference diode's power supply. In this way, line voltage variations of ±10% can be reduced to ±1% or less, a wholly reasonable value. If diode current is 10 ma, a 1% variation would be 0.1 ma. This change across the 15-ohm dynamic resistance is 1.5 millivolts out of 8 volts, or 0.02%.

Another way of eliminating the effect of dynamic resistance, however, and the one used in the reference described, is to compensate for the resistance with a bridge network. The circuit is shown in Fig. 5.

Resistor R_1 and the Zener diode form one leg of the compensating bridge, and R_2 and R_3 the other leg. Replacing the Zener diode with its equivalent circuit (Fig. 4) and then analyzing the circuit by superposition gives the two equivalent circuits shown in Fig. 6. Here the net output voltage, V_o, is the sum of the two voltages, V_{o1} and V_{o2}. Obviously, V_{o1} is the line voltage-sensitive component, while V_{o2} is independent of line voltage. V_{o1} can be brought to zero by balancing the Wheatstone bridge, thus eliminating line voltage effect. The bridge is balanced by letting $R_1/R_D=R_2/R_3$.

Resistor R_1 serves the additional purpose of limiting the current through the diode to the desired 10 ma. The supply voltage, V_s, and thus R_1, want to have as high a value as practical so that $V_s-V_z/V_s \rightarrow 1$, where V_z is the Zener diode voltage. In this way, a given percentage change in V_s, caused by a line voltage change, will produce only a slightly greater percentage change in diode current. If, however, as an example, $V_s-V_z/V_s=0.5$, the percentage change in the diode would be doubled, making the compensation for dynamic resistance more difficult.

The success of the bridge-balancing compensation described above is only as good as the assumption that R_D and V_D are independent of diode current. Neither is entirely constant, of course, but the assumption is good enough so that ±10% line voltage changes produce within ±0.03% output voltage changes.

One of the problems involved in designing the bridge resistors is measuring the dynamic resistance, R_D. The fastest method is to impose the 10-ma direct current on the diode, then to modulate this direct current with a 60-cycle current of known magnitude. Measuring the alternating voltage across the diode and dividing by the alternating current gives a value for R_D. However, resistors R_2 and R_3, computed from this value, do not give the best compensation and it was discovered that the 60-cycle method does not include a slow (less than a second, however) thermal effect. Therefore, a more dependable way of measuring R_D is to impress two values of current in the region of interest and measure the two corresponding voltages. The resulting ΔE divided by the ΔI gives a good measure of R_D.

The reference unit is designed to supply a fixed current of 2 ma to a known load at 7.5 volts. It will not regulate with the same precision with variable output currents. To adjust for the variation in diode voltage from unit to unit, resistor R_4 is added. This is adjusted until the output voltage is the desired 7.5 volts at the rated 2 ma.

Life Test Data

The *1N430* diode has been extensively tested to determine its suitability as a reference on the basis of age and various environmental influences. The following tests were made:

1. Diode voltage as a function of time
2. Dynamic resistance as a function of time
3. Temperature coefficient as a function of time
4. Extreme temperature exposure
5. Thermal shock
6. Repeatability
7. Humidity
8. Vibration
9. High potential

1. The life tests were conducted on a large sample of diodes, which were operated at approximately 10 ma continuously. The diode voltages were checked at precisely 10 ma periodically. Most diodes exhibited a tendency to increase their output voltage slowly with time. When deviation was plotted against the logarithm of time, the resulting curve was roughly a straight line. With failure arbitrarily defined as 0.05% change of breakdown voltage, the best least-square line through the data predicted an average life of 71 years. The scatter of the data indicated 95% confidence that no more than 5% of the diodes would fail before 2.7 years.

One of the most difficult parts of the life tests, and all other tests, for that matter, was in setting up test equipment with stability good enough to give the needed accuracy. Since the tests were run beyond 2 years, the requirements were rather severe.

2. It was important to test the stability of the diodes' dynamic resistance because of the bridge circuit used to bal-

ance its effect on the output of the reference unit. The variation of the dynamic resistance with time was found to be small enough to be completely neglected.

3. Likewise, the temperature coefficient showed no tendency to vary with time.

4. The most severe test on the diodes was the extreme temperature exposure. The diodes were exposed to −55 C and 100 C, with checks at 25 C between exposures. This indicated a slight hysteresis effect on diode output, with the low temperature exposure increasing voltage at 25 C and the high temperature decreasing voltage. The cause of this effect is unknown, though it may be due to adsorption and desorption of impurities on the silicon junctions from the surrounding material.

This severe test produced one of the few failures, as one diode shifted 0.18% from its original breakdown voltage.

5. Five of the *1N430* diodes were subjected to 14,800 thermal shocks over a 6-day period. The thermal shock consisted of pulsing the diodes at their rated power dissipation, which is well above their normal operating level. The effect here was negligible, indicating that the diodes are conservatively rated.

6. In order to test repeatability, diodes were switched on and off over 600 cycles, the voltage during each "on" period being recorded automatically. Results indicated that the diode's ability to produce the same voltage repeatedly is comparable to that of a standard cell.

7. Five diodes were tested in high humidity as outlined in military specification *MIL E-5272A*. The results showed a maximum voltage variation 0.012% and average of 0.010%. Humidity evidently has negligible effect.

8. Diodes were subjected to vibration in three planes with the following frequencies and magnitudes:

Frequency cps	Total Travel or Acceleration
5 to 10	40 mils
10 to 75	16 mils
75 to 500	5 g*

* Gravitational acceleration.

These tests indicated no effect on diode voltage.

However, it was discovered during the vibration tests that the diode voltages are slightly sensitive to diode position. A change of 0.018% resulted from a 90-degree change in orientation. The presumed reason for this was the change in heating effect caused by the flow of the silicone oil in which these diode junctions were immersed. As the diodes are applied in a recorder, the position influence is of no consequence, as the diode's orientation is fixed.

9. A 500-volt potential was applied to five diodes from case to one terminal. No failures were found, and diode voltage was virtually unaffected.

Conclusions

The results of these tests indicated that the diodes meet the manufacturer's specifications and that they further appear to be stable over long periods. They also withstand many severe environmental conditions. On the basis of these data, the diode has been used in the precision reference described in this paper, which in turn is being supplied as a part of the General Electric Company's strip chart recorder.

Thermal Voltage Converters for Accurate Voltage Measurements to 30 Megacycles Per Second

F. L. HERMACH
MEMBER AIEE

E. S. WILLIAMS
NONMEMBER AIEE

Synopsis: Thermal voltage converters, each consisting of a resistor in series with a thermoelement in a coaxial line, have been developed for measurements of rms voltages of 1 to 200 volts at frequencies from 3 cps (cycles per second) to 30 mc (megacycles). An accuracy of 0.1% or better may be obtained by a-c–d-c transfer techniques up to at least 10 mc and 0.2% at 30 mc.

A THERMAL VOLTAGE converter, according to ASA Standards,[1] is a thermoelement of low current input rating with an associated series impedance or transformer, such that the emf (electromotive force) developed at the output terminals gives a measure of the voltage applied to the input terminals. Thermal voltage converters containing thermoelements in series with wire-wound resistors can be used to make highly accurate voltage measurements at audio and ultrasonic frequencies.[2,3] The frequency range of such voltage converters is limited primarily by the residual reactances of their wire-wound resistors, but tests have indicated that for some of them good performance might be expected to frequencies approaching 1 mc.

This paper describes thermal voltage converters of low and computable reactance that have been developed at the National Bureau of Standards to meet the need for determining the frequency limit of such instruments. Single-range converters with deposited-carbon resistors have been constructed with ranges of 1 to 200 volts. Each has a frequency influence less than 0.1% to 10 mc and less than 0.4% at 30 mc. These rms voltage converters may also be used to calibrate 1/2% r-f (radio-frequency) thermocouple voltmeters which are now commercially available, and, with sine wave generators, could be used to calibrate electronic voltmeters as well.

Description and Construction of Converters

The r-f thermal voltage converters make use of the transfer principle,[2] in which a direct voltage is substituted for the alternating voltage to be measured. The direct voltage is adjusted to give the same output emf of the thermoelement that was obtained with the alternating

Paper 60-135, recommended by the AIEE Indicating and Integrating Instruments Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted October 30, 1959; made available for printing December 9, 1959.

F. L. Hermach and E. S. Williams are with the National Bureau of Standards, Washington, D. C.

The authors wish to acknowledge the help of R. Richardson and J. Scofield, who checked the equations and carried out the computations which made possible Fig. 4 and the last column of Table II, and of J. E. Hill, who assisted with some of the measurements. Thanks are also extended to M. C. Selby and L. Behrent for their careful calibration of the 1-volt converter.

voltage applied, and is measured with a potentiometer or other suitable means. Thus only good short-time stability, high precision of reading, and small known frequency influence are required of the transfer standard.

Each converter consists of a cylindrical deposited-carbon resistor in series with a uhf (ultrahigh frequency) thermoelement having a short straight heater in line with its supports, coaxially mounted in a brass cylinder, as shown schematically in Fig. 1. The residual reactances are much smaller than those of wire-wound resistors, and can be computed at least approximately, so that the frequency errors can be estimated. The frequency errors of the uhf thermoelements as current converters are believed to be small to over 100 mc.

The dimensions of the converters and additional data are given in the caption of Fig. 1. Each converter is assembled by first soldering the resistor, *R*, to the thermoelement, *TE*, and to the coaxial input connector, *A*, which is mounted in disk, D_1. This disc is then fastened to the cylinder, *F*, and the two thermocouple leads are soldered to the 2-pin output connector, *B*. Disk D_2, which has a small hole with a cross wire at *G*, is then fastened to *F* and the free end of the heater of the thermoelement is soldered to the cross wire. For clarity both thermocouple leads are shown in the figure. However the plane of the thermocouple leads and the pins of the output connector are actually at right angles to the axis of the cylinder so that minimum emf is induced in the output circuit. In use *F* must be grounded through the input connector.

Other symbols same as Fig.1 except that F is 2.5 in. diameter and 7.5 in. long
Note: Plane of thermocouple leads at right angles to axis of F

The 100- and 200-volt converters contain two resistors and two cylindrical inner shields, S_1 and S_2, as shown in Fig. 2, to reduce the effect of the distributed capacitance from the resistors to the outer cylinder. This considerably extends their frequency range. Shield S_2 is centered in *F* by a narrow ring, and is fastened to *F* by three equally spaced screws. Slots in *F* make axial adjustment of S_2 possible. The end-plate of S_1 is soldered to the input lead and to the resistor in assembly and this shield is fastened to D_1 by small insulators. The assembly is otherwise similar to that described for the other converters. The 50-volt converter has a single resistor and a fixed inner shield like S_1 in a cylinder of the dimensions given in the caption of Fig. 1.

Additional information on the voltage converters is given in the first three columns of Table I. The commercially available deposited carbon resistors are 1/8 inch in diameter and 2 inches long, and are vacuum sealed within a 3/16-inch-diameter glass cylinder. Some resistors of a different construction showed unaccountable a-c–d-c errors above 10 mc when used in earlier converters. The 5- and 10-ma uhf thermoelements, each with colinear supports and heater wire, are also commercially available, with an output voltage of about 7 mv (millivolts) at rated current. Each is in an acorn shaped evacuated glass bulb, and has a small bead between the heater and hot junction of the thermocouple to insulate them electrically but not thermally.

A Lindeck potentiometer rather than a millivoltmeter is connected to the output emf of the converter to provide high resolution. A circuit diagram is shown in Fig. 3. The potentiometer has ranges of 0.15, 0.75, 7.5, and 15 mv. The two lowest ranges are used for sensitivity checks. With a galvanometer having a sensitivity of 200 mm (millimeter)/μa (microampere) it provides a selected resolution of either 2 or 10 μv (microvolts) per mm deflection. The potentiometer is completely shielded, and a 2-conductor shielded cable connects the output of the converter to the terminals marked *E* in the figure. The advantages of this potentiometer are its low thermal emf (less than 1 μv) and its freedom from drift (much less than 0.01%/minute under ordinary laboratory conditions).

Theory

Because of the geometry, the resistor, *R*, in the cylinder of each low-voltage converter (without inner shields) may be represented as a transmission line of length, *l*, with a uniformly distributed series impedance of *z* ohms per unit length and a uniformly distributed shunt ad-

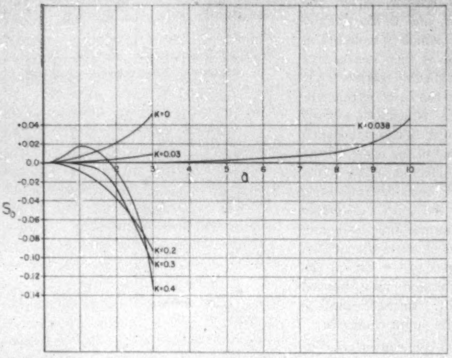

Fig. 4. Computed a-c–d-c difference as a function of the parameters a and k

mittance of y mhos per unit length. The line is terminated by the heater of the thermoelement. We are interested in the magnitude of the transimpedance $Z_c=V_t/I_o$ where V_t is the input voltage being measured and I_o is the current through the heater. If the heater resistance, R_h, is much less than that of the resistor, R, we may to a first approximation consider this a short-circuited line. It will be apparent later that this is not a drastic approximation at low frequencies since we are concerned only with the effect of the line reactance on Z_c. Then by ordinary steady-state transmission-line theory,

$$Z_c=\frac{Z}{\sqrt{ZY}}\sinh\sqrt{ZY} \qquad (1)$$

where $Z=z\ell=R+j\omega L$, and $Y=y\ell=j\omega C$ and R, L, and C are the total resistance, series inductance, and shunt capacitance of the line. We are interested in the low-frequency range in which the effects of the reactances are small.

We may define the parameters $a=\omega CR$ and $b=\omega L/R$. If each of these is less than unity the hyperbolic function may be approximated by the first three terms of its series expansion, so that

$$Z_c=Z\left(1+\frac{ZY}{6}+\frac{(ZY)^2}{120}+\ldots\right)$$

Then if all terms in a^nb^m for which $m+n>3$ are discarded we find that

$$Z_c\approx R(1+jb)\left(1-\frac{ab}{6}-\frac{a^2}{120}+\frac{ja}{6}\right)$$

and, to the same order,

$$|Z_c|\approx R\left(1+\frac{a^2}{90}+b^2-\frac{ab}{3}\right)^{1/2}\approx R\left(1+\frac{a^2}{180}+\frac{b^2}{2}-\frac{ab}{6}\right) \qquad (2)$$

The a-c–d-c difference of a voltage converter is defined as

$$S=\frac{V_{ac}-V_{dc}}{V_{dc}} \qquad (3)$$

where V_{ac} and V_{dc} are the rms alternating and direct voltages required to obtain the same response (output emf) of the converter. If the thermoelement has no a-c–d-c difference and if we define $k=b/a$, this becomes

$$S_o=\frac{|Z_c|-R}{R}\approx\frac{a^2}{2}\left(k^2-\frac{k}{3}+\frac{1}{90}\right) \qquad (4)$$

where S_o signifies that other possible causes of a-c–d-c differences are neglected.

The relation makes it possible to estimate S_o to this approximation very simply. For the cylindrical construction of Fig. 1 with a cylindrical unspiraled resistor, $L = 0.012\ell M$ microhenry and $C=0.61\ell/M$ picofarad, where $M=\log_{10}(g/h)$ and g and h are the diameters of the cylinder and resistor, respectively, and ℓ is in inches. Thus numerically, $k=1.9\times10^4(M/R)^2$ and $a=3.8\times10^{-12}f\ell R/M$, where f is the frequency.

For example if $R=2{,}000$ ohms, g and h are 2 in. (inches) and 1/8 in., and $\ell=2.0$ in., $S_o=+0.001$ (+0.1%) at 40 mc.

It is apparent from equation 4 that to this approximation certain values of k should make $S_o=0$. These are $k_1=0.038$ and $k_2=0.30$. The numerical values of resistance required are $R_1=710M$ and $R_2=250M$. Unfortunately the logarithmic relationship for M permits little range in R for reasonable values of g and h, for if g is greater than the length of the resistor, end effects may become pronounced.

It is of interest to extend the analysis to higher values of the parameter, a. This has been done by solving equation 1 for Z_c with the aid of Kennelley's tables and graphs of hyperbolic functions having complex arguments,[4] and then computing $S_o=(|Z_c|-R)/R$. The results are shown in Fig. 4. It is rather striking that the first solution of equation 4, $k_1=0.038$, results in reasonably small a-c–d-c differences (<5%) to $a=10$, a range much greater than that permitted by the initial assumptions.

For low-voltage converters the effect of the heater resistance R_h cannot be neglected. To the next approximation the heater can be considered as a lumped resistance termination for the transmission line. Then from steady-state transmission-line equations,

$$Z_c=R_h\cosh\sqrt{ZY}+\frac{Z}{\sqrt{ZY}}\sinh\sqrt{ZY} \qquad (5)$$

By expanding the hyperbolic functions and discarding higher order terms as before (for $a<1$ and $b<1$) we find that if $R_h<R$

$$S_o=\frac{|Z_c|-R_t}{R_t}\approx\frac{1}{2}\left(\frac{a}{1+m}\right)^2\left(k^2-Ak+\frac{B}{6}\right) \qquad (6)$$

where $R_t=R+R_h$, $R_h/R=m$, $A=m^2+2m/3+1/3$ and $B=m^2+2m/5+1/15$.

Table II. Comparative A-C–D-C Differences of Voltage Converters

100	200	90		0.00				−0.14	

Note: $D=100(S_B-S_A)$, where S is defined by equation 3, and the subscripts refer to converters A and B.

* Additional comparisons made at 25 and 35 mc.

The values of S_0 for the 1- to 20-volt converters have been calculated by equation 6 at a frequency of 40 mc, at which a and b are still less than unity. The results are given in the last column of Table II.

When $k<0.038$, distributed capacitance from the resistor to the cylinder predominates. At a given frequency and geometry, the resultant error is proportional to the square of the resistance. It can be minimized by the construction shown in Fig. 2 in which two inner cylindrical shields are used, with one connected to the input lead. Thus there are now two transmission lines in series. If $R_h<<R$, application of transmission line equations, with careful attention to signs, gives for the desired transimpedance,

$$Z_c=\sqrt{\frac{Z_1}{Y_1}}\tanh\sqrt{Z_1Y_1}\cosh\sqrt{Z_2Y_2}+\sqrt{\frac{Z_2}{Y_2}}\sinh\sqrt{Z_2Y_2} \quad (7)$$

where the subscripts 1 and 2 refer to the left and right hand lines (resistors and shields) of Fig. 2, and the resistance of the thermoelement is neglected.

If $Z_1=Z_2=Z$ and $Y_1=Y_2=Y$ we have

$$Z_c=\frac{2Z}{\sqrt{ZY}}\sinh\sqrt{ZY}$$

Thus the transimpedance is twice that of either line, and the a-c–d-c difference, S_0, will be that of half the total line. The parameter, a, of equation 4 will then be one-fourth that for a line of the same dimensions without inner shields. Thus at a given frequency for which $a<1$ the use of the double shield rather than a single cylinder of the same diameter should reduce the frequency error, for resistors of the same value and dimensions, by a factor of 16.

However, more detailed analysis indicates that even further improvement may be possible. For these converters $k<<0.038$, so that the series inductance of each line may be neglected. By expanding the hyperbolic functions of equation 7 and discarding higher order terms it can be shown by lengthy and rather tedious algebraic manipulation that $S_0\approx0$ when $\ell_1/\ell_2\approx1.032$, where ℓ_1 and ℓ_2 are the lengths of the left and right hand lines of Fig. 2, and $a<1$.

For the convenient dimensions shown in Fig. 1, the parameter, a, of each low-voltage (up through 20 volts) converter now being used is low enough that it has not been necessary to proportion the converters for minimum error in accordance with equation 6. The higher voltage elements are constructed with dual shields, with the grounded shield axially adjustable. This shield is set to give minimum frequency error as explained in the next section.

A useful theoretical study of coaxial lines, terminated by resistors, was published by Crosby and Pennypacker.[5] They show conditions for minimizing the input reactance.

Tests

Although long-time stability is not required of these converters, fluctuations or drifts in emf for the short time between the a-c use and the d-c calibration must be less than the desired accuracy. Such changes can arise from self-heating effects and ambient temperature changes, and from thermal emfs and other changes in the Lindeck potentiometer. Tests have shown that the self-heating of the carbon resistors, which have a load coefficient of about 1% per watt, is the largest source of drift. The change in resistance is very nearly exponential, with a time-constant of about 2 minutes. Since d-c calibrations can easily be made within 30 seconds of the a-c readings, this self-heating error is not significant in a-c tests if a short warm-up period is allowed. It is almost completely eliminated by the procedure used for a-c–d-c transfer tests. The effect of ambient temperature changes—the thermoelements have temperature coefficients up to 0.1%/C (degrees centigrade)—should also be insignificant in a laboratory with reasonable temperature control.

A great advantage of thermoelements for a-c–d-c transfer measurements is the almost complete electrical isolation of the input and output circuits. The uhf thermoelements have a small electrically insulating bead between the heater and hot junction of the thermocouple to eliminate conductive coupling. To minimize mutual inductance the plane of the thermocouple leads is at right angles to the heater and its colinear supports. Tests showed that at 4 mc the induced a-c voltage in the output circuit of each thermoelement was less than 20 μv, the resolution of the detector used. Induced currents in the thermocouple circuit can cause errors by joule heating of the thermocouple, but calculations indicate this should not be significant if the induced voltage is less than a few millivolts.

The shield of the Lindeck potentiometer provides reasonable immunity from induced fields. In some tests at 10 mc a current of 2 ma from the shield to ground through the lead from the potentiometer to the converter caused no significant error.

For transfer measurements the most important requirement is that the a-c–d-c difference of each of these converters be known to the full accuracy desired. The general principles on which such determinations are based have been given.[2] In the frequency range studied, the major error of each of these converters is caused by the reactance. For a given converter this error should be independent of voltage level. Thus, it was feasible to evaluate the relative errors by intercomparing converters of adjacent voltage ranges to determine their differences in frequency response. A complete series of such comparisons was made at two voltage levels for each pair of converters, at frequencies up to 40 mc. In each comparison the two converters were connected in parallel to a coaxial lead through a tee fitting (*GR 874*), and a shielded potentiometer was connected to each output. Each potentiometer was adjusted for zero deflection at the test voltage. The converters were then supplied in succession with alternating, direct, reversed-direct, and alternating voltage. Each voltage was adjusted to produce the same emf of the higher range converter and the deflection of the galvanometer connected to the other converter was observed. From the differences in emf, directly determined from these differences in deflection, the difference in the frequency response of the two converters was determined.[2] In these tests the movable inner shields of the 100- and 200-volt converters were adjusted for best performance over the desired frequency range, by comparison with the 20- and 50-volt converters. The errors of these adjustable converters were found to be complicated functions of the frequency and shield position.

The results of these intercomparisons from 0.1 to 40 mc are given in Table II. They show that for each pair of converters the relative a-c–d-c differences were independent of the applied voltage to 0.02% or less, and were less than 0.4% up to 30 mc. For the low-voltage converters they were less than 0.05% to 20 mc without exception and without evidence of systematic errors.

The relative a-c–d-c differences of most of the thermoelements used in the voltage converters were also determined before the thermoelements were installed, by making similar a-c–d-c intercomparisons as current-measuring elements at 40 mc. For these tests the two thermoelements were connected in series along the axis of a brass cylinder having the same dimen-

*For same reading of millivoltmeter at each frequency

sions as in Fig. 1 but with a coaxial input connector at each end and with two 2-pin output connectors. A split cylinder with one part readily removable facilitated changing thermoelements. The input was applied to one connector with the other short-circuited. Rough calculations indicated that at 40 mc the current should change by about 0.5% along the transmission line formed by the heaters of the thermoelements in this cylinder, but that the distribution should not be greatly dependent on the resistance of the heaters, less than 100 ohms each. Therefore, two determinations of relative a-c–d-c differences were made with each pair of thermoelements, with first one end then the other of the cylinder short-circuited. For each pair the two determinations differed by about 0.4% at 40 mc, but in each case their algebraic average was less than 0.02%.

These calculations and tests also provide assurance that even at 40 mc the current along the heater of a single thermoelement terminating a voltage converter is well within 0.1% of the value at the mid-point of the heater.

The 1-volt converter was compared at rated voltage with a wire-wound thermal voltage converter of known a-c–d-c difference at 3 cps and 20 kc, with observed differences of +0.02% and 0.00% respectively.

The response of the 1-volt converter, with a shielded d-c millivoltmeter connected to its output, was determined to better than 1% at frequencies from 1 to 400 mc by the bolometer bridge of Selby and Behrent,[6] with the results shown in Table III. It is evident that the frequency influence is very small to 100 mc. It increases rapidly at higher frequencies, becoming −5.2% at 300 mc. The calculated a-c–d-c difference at 300 mc by equation 6 is only −0.9%; this converter has a 1/4-in.-diameter unsealed resistor. Some of the discrepancy may be accounted for by the voltage rise in the connector. A type *N-UG58/U* input connector was substituted for the type *874* for these tests.

As a check on equation 6 at larger a-c–d-c differences, the 50-volt converter was tested before its inner shield was installed. The measured a-c–d-c difference at 40 mc was +1.3% and was accurately proportional to the square of the frequency. The computed values were 40% smaller, indicating that the effective length of the resistor, the end effect, was 1.2 times the actual length. At 40 mc the measured a-c–d-c difference was changed by less than 0.02% when the resistor was mounted 3/32 inch off the axis of the cylinder, indicating that exact centering is not critical even when the errors are large.

The intercomparisons of Table II show that the a-c–d-c differences of the five low-voltage converters without inner shields, and with 1- to 20-volt ranges, are all equal to better than 0.05% to more than 20 mc. At 40 mc they agree to 0.1% with the values calculated by equation 6. Values cannot readily be computed for the higher voltage elements with the inner shields. This unanimity between converters having such a wide range of resistors and different thermoelements gives good assurance against unknown sources of error. It is quite unlikely, but not impossible, that each converter would have the same a-c–d-c error. However the test of the 1-volt converter with the bolometer bridge provides most valuable additional assurance. The large errors of this converter above 100 mc decrease rapidly with decreasing frequency, well within the stated accuracy of the bridge measurements. For converters without inner shields almost all known causes of such errors, such as the effect of reactance, equation 6, skin effects in the resistor or thermoelement, etc., should cause a-c–d-c differences approximately proportional to the square of the frequency, over the range for which the errors are small. Thus the authors believe that the large measured errors above 100 mc can be extrapolated downward to lower frequencies to indicate with considerable confidence that the a-c–d-c difference of this converter is less than 0.2% at 40 mc and less than 0.1% below 30 mc.

Based on the foregoing consideration the authors assigned a value of zero to the a-c–d-c difference of the 1-volt converter to 40 mc, and then determined the a-c–d-c differences of all the other converters from the intercomparison data in Table II. The results, rounded to the nearest 0.05% to 10 mc and 0.1% to 40 mc, are given as observed values in Table IV.

Use

These converters are most conveniently used to measure the a-c–d-c difference or frequency influence of other rms instruments such as thermocouple voltmeters, which are now available with accuracies of 1/2% to 10 mc. A typical setup for this is shown in Fig. 5. The scale calibration of the voltmeter can then easily be checked on reversed direct current. The a-c–d-c difference tests are similar to the intercomparisons already described, and d-c calibration of the converter is not necessary once the scale factor of the Lindeck potentiometer is determined for each converter. This is the per-cent change in input voltage per centimeter change of galvanometer deflection.[3] Either direct or low-frequency alternating current may be used as the reference frequency and the test may be made rapidly and accurately. The results are only slightly affected by drifts in either instrument. At frequencies above about 20 mc a small lead correction may be necessary if the connectors between the junction plane and the two instruments are not electrically equal, but this is readily determined to the required accuracy.

For a-c measurements a d-c potentiometer of 0.1% accuracy or better is required to measure the d-c reference voltage. A deflection potentiometer and volt box, or an automatic self-balancing potentiometer ("digital voltmeter") should be convenient for this. For testing electronic voltmeters frequency-response measurements (differences in reading for

the same voltage at the test and reference frequencies) should be particularly convenient. The form factor and crest factor of the a-c sources must be within 0.1% of the values for a sine wave, 1.111 and 1.414 respectively, since most electronic voltmeters respond essentially to the average or crest (peak) values. Since these factors depend upon the phase angle as well as the magnitude of each harmonic it would ordinarily be necessary to make sure that the ratio of the magnitude of the nth harmonic to the fundamental does not exceed $0.1xn\%$ when an average-reading instrument is tested and 0.1% when a crest-reading instrument is tested. The results should then differ from those obtained with a sine wave by less than 0.1%.

An r-f generator of at least 5 watts output and good voltage stability is required but only moderate frequency accuracy and stability are needed. It is very difficult to construct broad-band generators of good wave form at this power level. However, a simple adjustable L/C (inductance capacitance) tuned circuit, with the instruments connected across the capacitor, can be used simultaneously to improve the wave form, match the impedance of the instruments to that of usual 50-ohm source, eliminate the capacitance loading of the instruments on the source, and provide the higher voltages often required. For these combined purposes the values of inductance and capacitance should be chosen so that $\omega L = 1/\omega C \approx \sqrt{R_1 R_2}$, where R_1 and R_2 are respectively the resistances of the source, including the inductor, and the load (instruments). For low voltages a 50-ohm resistor can be connected in series with the L/C circuit and the instruments and attenuators as needed can be connected in parallel with this resistor for improved wave form.

Conclusions

Cylindrical film resistors in series with a thermoelement in a coaxial line makes possible single-range thermal voltage converters that are useful as a-c–d-c transfer instruments over a very wide frequency range, 3 cps to at least 30 mc, with unusually high accuracy. They are inexpensive and easy to construct. Their frequency influence may be estimated by reasonably simple equations, with results which agree well with the measured values up to 40 mc. The voltage converters may be useful to considerably higher frequencies. The higher range converters require considerable power, up to 2 watts, and have a marked but short warm-up drift. These disadvantages could be reduced by using metal-film resistors of higher resistance with a 5-ma thermoelement, but this would very probably reduce the frequency range for the same attainable accuracy. The good performance of these converters was obtained with deposited-carbon resistors of a new type. Earlier converters with resistors of different construction showed discrepancies up to 0.5% at 40 mc. Further work is planned to determine the cause of these differences.

These voltage converters can be used quickly and easily to make a-c–d-c difference tests to determine the frequency influence of other rms instruments to 0.1% or better to at least 10 mc and to 0.2% at 30 mc. Direct a-c measurements are made by the transfer technique, which in most cases can be arranged for reasonable simplicity. With sources of suitable waveform, average-reading and crest reading instruments could also be calibrated if desired. In all of these applications the applied frequency need not be closely determined or held because of the flat frequency response of these voltage converters.

Discussion

Morley J. Lush (Rawson Electrical Instrument Co., Cambridge, Mass.): I feel that the instruments described in this paper are a real contribution to the art of accurate voltage measurements at high frequencies. Although it is difficult to make resistors with low reactances, Mr. Hermach has shown that these can be obtained, and that voltmeters can be constructed which have a flat frequency response all the way from direct current out to the megacycle region. The frequency response will remain stable for long periods of time, so only d-c calibrations are needed, once the frequency response has been determined. I have found from my own work that accuracies of 1% can be obtained at frequencies up to 100 mc and now these instruments are available on the market. A precision of 0.1% can be obtained, but the absolute accuracy is limited by the lack of a primary standard. I have been told that the National Bureau of Standards expects to be able to offer 0.25% certifications by the end of 1960.

Other workers in this field have used a fixed or variable capacitor as the attenuator element in series with the thermocouple. It is possible to make an excellent low-loss capacitor using a micrometer screw for adjustment. A wide frequency range and wide voltage range can be obtained on one instrument. However, the voltmeter cannot then be used for d-c to a-c transfer measurements, since it has zero response at zero frequency. Indeed, the response is directly proportional to the frequency, and it is necessary to calibrate the voltmeter at each voltage and frequency for which it will be used.

It should be pointed out that connections to these voltmeters are a problem, as they are in all high-frequency apparatus. The use of coaxial connectors can be misleading, as any appreciable length of 50-ohm coaxial line will cause errors due to standing waves, unless the voltmeter input impedance is made exactly equal to the impedance of the line. Careful matching of the line impedance will certainly be necessary if voltmeters of this type are to be used at frequencies above 100 mc.

F. L. Hermach and **E. S. Williams:** Mr. Lush's remarks are appreciated. We believe these thermal voltage converters, by taking advantage of the powerful a-c–d-c transfer technique, should make possible a new order of accuracy in a-c voltage measurements up to at least 30 mc. Their usefulness will probably fall off rapidly at higher frequencies, except for the lower voltage ranges, up to perhaps 10 volts.

A major advantage of an a-c–d-c transfer standard is that its a-c–d-c difference is relatively permanent so that once evaluated, it should not ordinarily need to be redetermined. Thus, elaborate repeated a-c calibrations are not required. This and the ease and simplicity of constructing these converters should offset the extra labor of making the a-c to d-c transfer for each measurement.

We mentioned connection errors only briefly. Each converter is a high-impedance load at the end of a short coaxial line from the junction plane to the converter. If this line is a small fraction of a wavelength the voltage rise from the junction to the end of the line is approximately $50h^2\%$, where $h=\omega CZ_0$ and C and Z_0 are the total shunt capacitance and the characteristic impedance of the line. At 30 mc for a 2-inch length of typical 50-ohm line the correction is only 0.1%. It is offset by a similar correction if an equal line is used between the junction plane and the test instrument or load to be measured. At higher frequencies or for longer lines the correction can be large and this approximate formula may no longer be valid. In such cases, however, voltage measurements probably have meaning only with lines terminated in their characteristic impedance, so that the standing-wave ratio is close to unity.

D-C Magnetic Crane Hoist Control for A-C Powered Cranes

A. H. MYLES
FELLOW AIEE

M. C. DAVIES
ASSOCIATE MEMBER AIEE

L. J. SRNKA
NONMEMBER AIEE

Synopsis: The use of a d-c series-wound motor, series-wound motor brake, and power-type overhoist limit switch for the hoist drive of an otherwise all a-c powered crane is highly desirable. Time proven safety and simplicity of d-c dynamic lowering hoist systems can now be further improved in performance, and better motor stability is possible when d-c power is made available through metallic plate rectifiers.

Methods of calculating motor performance under dynamic lowering connections are discussed.

FIFTY YEARS of development of crane hoist control systems have transpired since the first dynamic lowering control method was introduced to eliminate the need for mechanical load brakes. Moreover, during this time probably no other industrial control application has received more attention than has crane hoist control for both d-c and a-c motors and their respective power supply. It should be mentioned in this connection that users, crane builders, and control manufacturers have all generally favored the crane that is operated by d-c series motors because it offers advantages such as simplicity, low maintenance, and maximum safety from the use of series-wound brakes and power-type limit switches. On the other hand, crane control for a-c wound rotor motors has also been greatly improved and, in some designs, gives performance characteristics matching those obtained with direct current.

Modern power distribution systems in industry are generally 3-phase and, through properly connected transformers, provide a-c service at 230, 460, or 550 volts. Also, with the exception of the steel industry, large capacity d-c conversion equipment is usually not available for d-c hoist motors on cranes. This means, therefore, that, lacking a d-c source of supply for a crane hoist, it is desirable to make use of the recently improved metallic type of rectifiers, individually mounted for each application; such installations occupy a comparatively small space, are reasonably low in cost, and can be recommended to deliver dependable d-c power.

When a nominal 230-volt 3-phase source is used with a set of six bridge-connected rectifiers, the d-c output under loaded conditions is approximately 300 volts or 1.3 times the a-c input. This implies that a 230-volt d-c series motor will develop 1.3 times its 230-volt horsepower rating when used in such a rectifier-conversion system since for a given load current and developed torque, the motor speed is directly proportional to the voltage impressed across the armature terminals. Moreover, the use of the higher 300-volt source will have no damaging effect upon the motor since mill-type motors are designed to tolerate the higher voltage and are, in fact, regularly used in adjustable voltage systems at the higher potentials.

When the a-c system is supplied at 460 volts, it is recommended that a transformer be used to step down the input voltage to the rectifier to 230 volts. Three-phase rectification of 460 volts a-c will provide approximately 600 volts d-c. If a 550 volt d-c motor were considered, the increased speed and horsepower would be only 9% and the disadvantages associated with using the higher power and control circuit voltage as well as the higher motor cost could not be justified.

When a comparison is made between a d-c series motor and an a-c wound rotor motor, consideration must be given to each portion of the hoisting and lowering functions. An a-c crane hoist controller using a wound rotor motor will hoist or lower all normal loads at a maximum speed of near synchronous speed. In this connection, it should, however, be understood that a normal crane-hoist operates in the following cycle: (1) lowering an empty hook; (2) hoisting full load or less; (3) lowering full load or less; and (4) hoisting an empty hook. Motor horsepower calculations indicate that when used at 300 volts d-c the motor should have a normal 230-volt rating that is approximately 50% to 55% of its a-c counterpart, assuming that each one will complete its operating cycle in the same time. This advantage, possessed by the d-c motor, results from increased speed at the higher than normal voltage, the inherent higher light load speeds hoisting of the series motor, and the higher light load and heavy load lowering speeds of the d-c dynamic lowering control.

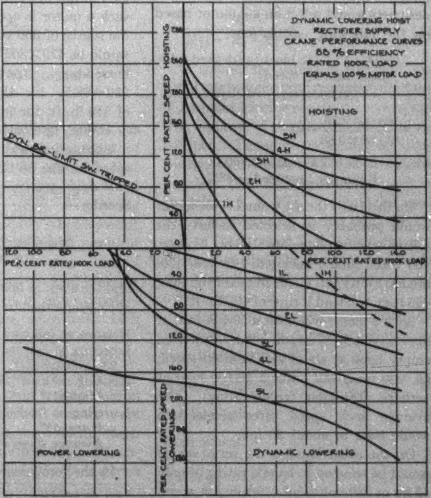

Fig. 1. Crane performance curves for d-c dynamic lowering control with rectified power supply

---

Paper 60-30, recommended by the AIEE Industrial Control Committee of the Industry Division and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted March 19, 1959; made available for printing November 18, 1959.

A. H. MYLES, M. C. DAVIES, and L. J. SRNKA are with the Square D Company, Cleveland, Ohio.

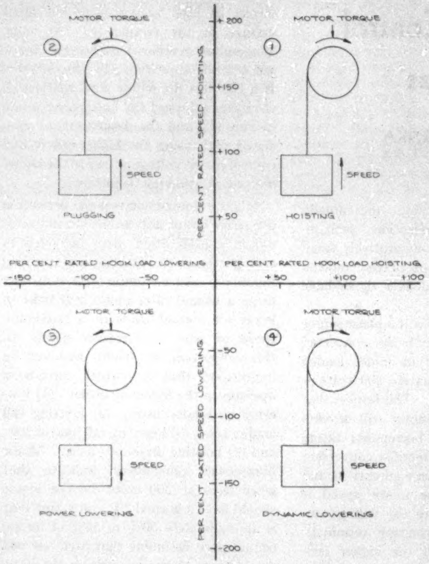

Fig. 2. Four-quadrant representation of crane hoist performance

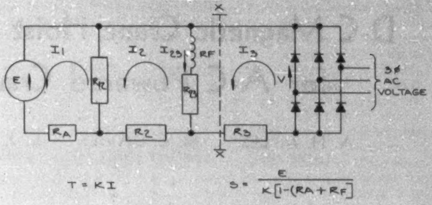

Fig. 3. Equivalent mesh network circuit for dynamic lowering hoist control with rectifier power supply

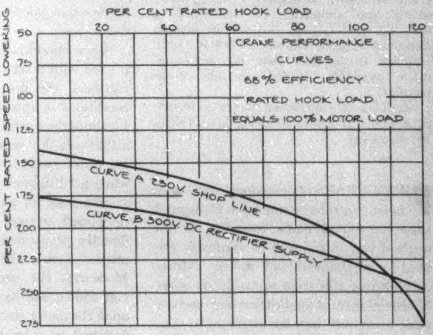

Fig. 4. Stability performance curves at maximum lowering speeds with 230-volt normal supply and with 300-volt rectifier power supply

To illustrate the foregoing discussion, consider a 50-ton crane hoist to give a full-load hoisting speed of 25 feet per minute (fpm), assuming a 460-volt 3-phase wound rotor motor. The crane designers would select an a-c motor based on the following calculation:

$$\text{hp} = \frac{(\text{payload} + \text{hook block}) \times (\text{desired full-load hoisting speed})}{33{,}000 \times \text{crane efficiency}}$$

$$= \frac{103{,}000 \times 25}{33{,}000 \times 0.88} = 89$$

where: hook block weighs 3,000 lb.
Efficiency (assumed) = 88%

On this basis the a-c wound rotor motor would probably be selected to have the following nameplate data: 100 hp, 3 phase, 460 volts, totally enclosed, 1/2 hour (30-minute) duty, 75 C (degrees centigrade), 865 rpm, full load torque of 600 lb.-ft.

Such a motor will hoist a 50-ton load at approximately 870 rpm, hoist or lower an empty hook at about synchronous speed, i.e. 900 rpm, and lower a 50-ton load at perhaps 920 rpm (regenerating). The average hook speed after acceleration would then be about 26 fpm.

On the other hand, a d-c series motor would be selected to have a rating of only 45 hp at 230 volts and 470 rpm; it would be totally enclosed with a 1/2 hour (30-minute) duty at 75 C and develop a full-load torque of 510 lb.-ft. However, when such a motor is operated from a rectified d-c source of 300 volts, its full load speed would be 470×300/230 = 610 rpm and its horsepower output would be 45×300/230 = 58.5; for the same load torque of 510 lb.-ft. the full load current would, of course, be equal to that at 230 volts.

Calculating next the full load hoisting speed for the 50-ton crane,

$$\text{Speed} = \frac{\text{hp} \times 33{,}000 \times \text{efficiency}}{103{,}000}$$

$$= \frac{58.5 \times 33{,}000 \times 0.88}{103{,}000} = 16.5 \text{ fpm}$$

and the average hook speed for a complete cycle would then be determined as follows:

Hoisting at full load	16.5 fpm
Lowering at full load (235% of 230 volt speed)*	29.8 fpm
Hoisting no load (250% of 230 volt speed)*	31.7 fpm
Lowering no load (175% of 230 volt speed)*	22.2 fpm

Average speed = 100.2/4 = 25 fpm

In the foregoing calculations it should be noted that the speeds are based on the values at no load and full load. In practice, however, the average load would probably be less than the full-load rating and this would therefore give an average speed that is somewhat higher than that obtained above. It should also be observed that the cycle of operations will be completed in the required average time although the hoisting speed of 16.5 fpm is somewhat less than the 25-fpm value.

In discussing dynamic lowering hoist control as applied to the d-c series motor, industry has established the conventional method of representing motor operation in four quadrants; this is shown in Fig. 2. Quadrant 1 is for power hoisting; quadrant 2 is for plugging from a hoisting to a lowering direction; quadrant 3 is for power lowering; and quadrant 4 is for dynamic lowering of overhauling loads. When analyzing crane hoist performance curves for a given motor in the four quadrants indicated, it should be pointed out that due to loading and hoist efficiency the actual speed regulation with load is always better than indicated by motor characteristic curves. This means that

D.C. DYNAMIC LOWERING HOIST CONTROL
WITH RECTIFIED A.C. SUPPLY

Fig. 5. Elementary wiring diagram of d-c dynamic lowering crane hoist control

motor loading and hoist efficiency should be carefully defined if the performance curves are to be properly interpreted.

With the high efficiency of modern crane hoists, the tendency of overspeeding an empty hook as it moves upward must be given consideration. This is because the stopping distance when entering the power limit switch may be excessive and commutator burning may be severe under conditions of strong dynamic braking. It is now common practice to apply a high resistance permanent armature shunt to such applications to limit the no load hoisting speed to 250% of rated value. With the application of 300-volt rectified d-c to the hoist motor, the permanent armature shunt resistor becomes a standard feature.

In the lowering of overhauling loads with d-c dynamic braking control, as represented by the fourth quadrant of Fig. 2, one feature of the control is that it is capable of providing high-speed light-load lowering while maintaining satisfactory motor stability when lowering heavy loads. With the usual constant potential dynamic lowering control scheme, the maximum no-load-lowering speed must be limited to approximately 140% of rated value since with high armature current any further field weakening would cause sufficient armature reaction to affect motor stability adversely. However, when d-c power is derived from a rectified source, the circuit constants are quite different. The equivalent mesh circuit for the dynamic lowering hoist control with a rectifier power supply is shown in Fig. 3. The performance curves of Fig. 4 compare the results obtained when lowering loads at maximum speed with power from a 230-volt shop line and with a rectified 300-volt supply. Calculations for the data for the curves are on a per-unit basis. Note particularly the improved stability and the higher no load speed of the rectified d-c operation with respect to the shop line operation. The elementary wiring diagram of the complete control is illustrated in Fig. 5.

Referring to Fig. 3, calculations for a 3-mesh circuit involve the following equations:

$$R_{11}=R_A+R_{12} \tag{1}$$

$$R_{22}=R_{12}+R_2+R_{23}+R_F \tag{2}$$

$$R_{33}=R_F+R_{23}+R_3 \tag{3}$$

Solving for the three loop currents, using a method similar to that given in some detail in the succeeding analysis for a 2-mesh circuit,

$$I_1=1/D[(R_{12}R_{23}V)-(R_{22}R_{33}-R_{23}^2)E] \tag{4}$$

$$I_2=1/D[(R_{23}R_{11}V)-(R_{33}R_{12}E)] \tag{5}$$

$$I_3=1/D[(R_{11}R_{22}-R_{12}^2)V-(R_{12}R_{23}E)] \tag{6}$$

where

$$D=(R_{11}R_{22}R_{33})-(R_{11}R_{23}^2+R_{33}R_{12}^2) \tag{7}$$

$$I_{23}=I_3-I_2 \tag{8}$$

$$E=\frac{1/D(R_{23}R_{11}V)-1/D(R_{11}R_{22}-R_{12}^2)V+I_{23}}{1/D(R_{33}R_{12}-R_{12}R_{23})} \tag{9}$$

Finally, using values of K from the curves of Fig. 6,

$$T=KI_1 \tag{10}$$

$$S=\frac{E}{K[1-(R_A+R_F)]} \tag{11}$$

In solving for values of torque T and speed S it becomes apparent that the value of I_3 cannot become negative, i.e. regenerative, because of the blocking effect of the rectifier. Therefore, in solving for overhauling load values of T and S it should be clear that the equivalent circuit to the left of X-X, Fig. 3, should be used; this is equivalent to saying that the circuit to the right of X-X is open-circuited ($I_3=0$) and that the developed power for the 2-mesh circuit is provided by the overhauling load.

Referring to the 2-mesh circuit to the left of X-X in Fig. 3, the following equations may be written:

$$E+I_1R_{11}-I_2R_{12}=0 \tag{12}$$

$$-I_1R_{12}+I_2R_{22}=0 \tag{13}$$

from which

$$I_1=-E\left[\frac{R_{22}}{R_{11}R_{22}-R_{12}^2}\right] \tag{14}$$

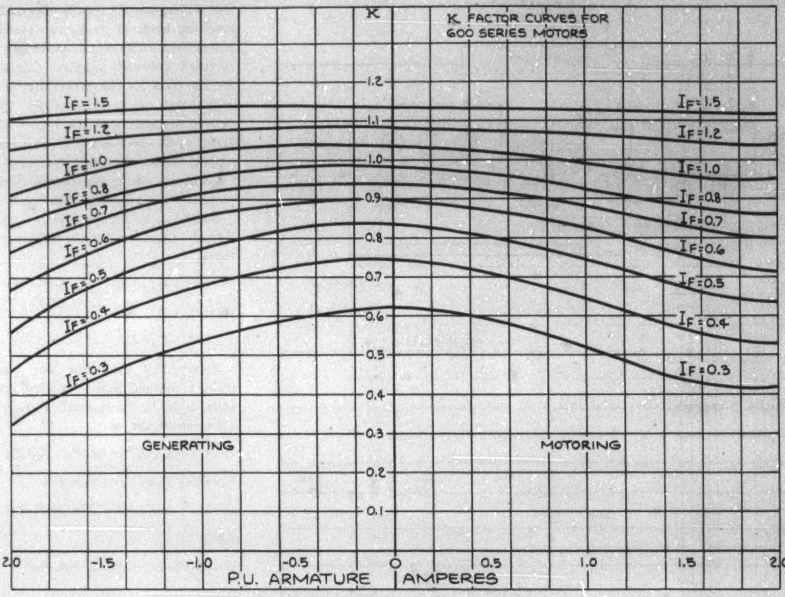

Fig. 6. K factor curves for 600-series mill-type motors

$$I_2 = -E\left[\frac{R_{12}}{R_{11}R_{22}-R_{12}^2}\right] \qquad (15)$$

The torque T and speed S values, equations 10 and 11, can then be determined as for the 3-mesh circuit.

After the calculation of any motor and control performance, it becomes highly desirable to test the calculated data under actual operation. The performance characteristics of Fig. 1 and Fig. 4 were confirmed from test data taken on the hoist test tower shown in Fig. 7. Whenever possible confirming data are also taken on field installations where the horsepower rating of the motor may be considerably higher than available with laboratory facilities. Fig. 8 shows a

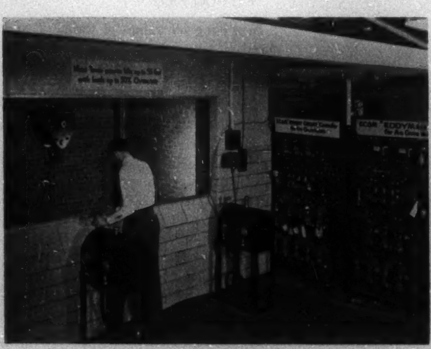

Fig. 7 (above). Experimental test hoist tower providing facilities for varied a-c and d-c circuit testing

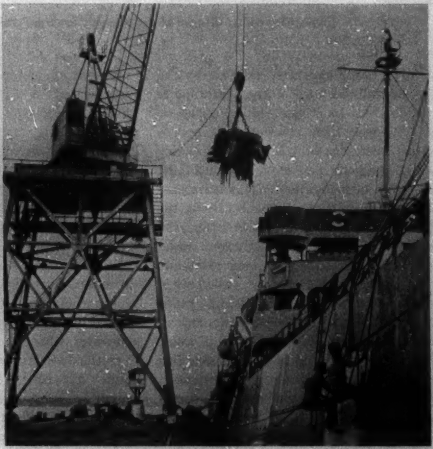

Fig. 8 (right). Whirler-type dock crane for scrap and general cargo handling. Power supply is a-c with rectifier d-c for hoist motor and control

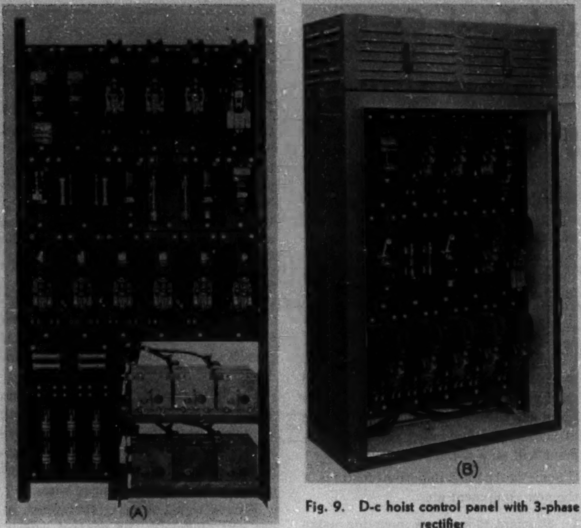

Fig. 9. D-c hoist control panel with 3-phase rectifier

A—Open panel construction
B—Enclosed panel construction

whirler-type crane handling the loading and unloading operations of a shipping dock. Here a rectifier power supply is ideally adapted for a d-c hoist motor and its control equipment.

Control panel construction may feature either open or enclosed control with rectifier mounted and wired as shown in Figs. 9(A) and (B) or the control may be similar but feature completely front-mounted and wired devices.

In the complete installation of crane control, many features affect mounting space, structure, weight, wiring, etc., and one costly and often difficult problem of mounting concerns trolley collector bars. In this connection it is particularly noteworthy that a rectifier power supply using a d-c motor and control requires but 4 collectors, whereas the usual a-c hoist control must have 10, 12, or more collectors depending upon the control schemes. For cranes with both main and auxiliary hoists this saving in both cost and complexity is indeed significant.

Finally, in any motor installation there is always the problem of line drop due to load current. Here again the rectified d-c supply has the advantage that the IR drop is a smaller per cent of the nominal 300-volt d-c system than is the same drop with the lower 230-volt d-c circuit thus giving improved load-speed regulation.

Summary and Conclusions

When a set of bridge-connected metallic rectifiers is used to supply power to a d-c series motor and its crane hoist control, the d-c output voltage will be about 1.3 times the line-to-line a-c 3-phase input voltage. This means that for a 230-volt a-c supply, a 230-volt d-c series motor will be energized from 300 volts, with a consequent increase in speed and horsepower ratings. In addition to the improvement in motor performance indicated, the following further advantages may be listed:

1. Faster hoisting and lowering speeds are obtainable.
2. Greater stability results when lowering heavy loads than is possible with a normal 230-volt d-c supply.
3. The d-c series motor develops better hoisting characteristics and faster acceleration than does the a-c wound rotor motor.
4. The d-c control scheme involving a series-wound motor, a series-wound brake, and a power-type overhoist limit switch provides maximum in safety and simplicity.
5. The d-c control scheme requires only 4 collectors, whereas the usual a-c hoist control must have 10 or more collectors.
6. Voltage regulation due to motor and lead drop is better on the 300-volt d-c system than with a normal 230-volt d-c shop line.

An All-Transistorized Trunk Carrier System

F. H. GARDNER
NONMEMBER AIEE

THE RAPID expansion of suburban and small urban communities has created such a demand for increased communication facilities that the telephone companies are hard pressed to supply the requirements. They find themselves required to supply not only house phones, business phones, etc., but new subscriber lines, new extended area trunks, and new toll trunks in order to handle the increased load.

Telephone companies are service organizations which are in business for the purpose of serving their customers quickly, efficiently, economically, and for making a profit for their stockholders. It is, therefore, necessary to provide added facilities which are reliable, quick and easy to install, simple to maintain, economical to operate, and require only modest investment in equipment.

Among the most expensive additions to a telephone company's plant are the new subscriber lines extended area service (EAS) trunk lines, and toll lines required to handle the increased traffic. The high cost of adding physical circuits may make it necessary to provide service by other means.

Discussion

The installation of subscriber carrier and trunk carrier equipment is often the most economical means of adding several lines since extensive plant wiring changes or additions are not required. As an answer to this problem Stromberg-Carlson has recently announced their All-Transistorized *565* Trunk carrier system as a companion to their *561* Subscriber Carrier system which has been on the market for several years. The *565* Trunk Carrier equipment is presently designed to provide five carrier channels for communication and *E&M* signaling. At this writing, the expansion of the system to a greater number of channels is contemplated.

DESCRIPTION

The equipment is of the amplitude-modulated double-sideband, transmitted carrier type. Fig. 1 shows a complete terminal. Those acquainted with the Stromberg *561* Subscriber Carrier Equipment will note the similarity.

Some of the most important features of the new equipment are:

1. Standard 19-inch rack mounting makes installation easy.
2. Plug-in major assemblies simplify service problems.
3. Test jacks in d-c, voice, and signaling circuits speed repairs.
4. Requires only 70 ma (milliamperes) per channel at −48 volts providing operating economy.
5. Operation from standard central office battery provides reliability.
6. Transmits over 150- or 600-ohm lines aleviating extensive plant changes.
7. Optional voice-frequency (v-f) termination increases utility, 600 ohms balanced 2 wire, 900 ohms balanced 2 wire, 600 ohms unbalanced to ground 4 wire are provided.
8. A per-cent make control makes 0% pulse distortion possible.
9. Wide bandwidth of 250 to 3,000 cps (cycles per second) extends area of application.

At the top of Fig. 1 is the line coil panel which mounts of v-f low-pass filter, a high-frequency (h-f) matching transformer for coupling to a 150- or 600-ohm circuit, and an inductance-capacitance (L-C) battery supply filter, and a 69-kc low-pass filter.

The lower five units are the five carrier channel units. These units each include 10 plug-in assembleis which are, from left to right:

1. Terminal card equipped with relay contact protection circuit, fuse, jacks to facilitate testing, etc.
2. Transmit band-pass filter card.
3. Receive band-pass filter card.
4. H-f card containing attenuating networks.
5. Transmitting card.
6. Crystal oscillator and hybrid coil and relay assembly.
7. Receiver card.
8. Signaling card containing filters, signaling oscillator, and signal amplifier.
9. V-f transmitting card containing attenuating networks (optionally a compressor may be used).
10. V-f receiving card containing attenuating networks (optionally an expandor may be used).

THE SYSTEM

Fig. 2 is a block diagram of a *565* Trunk Carrier system. The v-f, *E*, and *M* circuits are connected at the locations indicated.

The physical circuit is essentially no different from any other physical trunk circuit except that v-f low-pass filters have been inserted as shown to allow transmission of the additional five carrier channel signals on the same pair of wires.

The v-f signal entering the system at one end modulates the channel carrier. The *M* lead signal (−48 volts d-c) entering the system at *M* keys a 3,500-cps tone which in turn also modulates the channel carrier.

The modulated carrier of channels 3, 4, and 5 is fed directly to the line matching transformer. The carriers of channels 1 and 2, however, are fed to the line matching transformer through a 69-kc h-f low-pass filter which eliminates interference between low-frequency and high-frequency channels.

After the carrier signals arrive at the far end they are passed through trans-

VOICE TRANSMISSION

Looking at the voice transmission circuits, first note that the v-f signal enters at the v-f hybrid and travels to the transmitting v-f pad where the level is adjusted, thence through the 3-kc low-pass filter to the transmitter.

In the transmitter the voice-frequency signal modulates the carrier generated by the carrier oscillator which is transistorized and crystal controlled.

The modulated carrier amplified by two transistors in the transmitter card passes through the h-f pad where it may be attenuated as desired.

Next in its path is the band-pass filter which passes the carrier frequency and its sidebands only. The signal is thereby made available for transmission through additional filters and/or line matching transformers to a distant point over cable or wire lines.

Considering the lower half of Fig. 3 as the far-end receive section of the channel, the modulated carrier enters through a band-pass filter which rejects all other carrier frequencies. It then passes through the h-f pad to be attenuated as required to provide proper input level to the receiver.

The completely transistorized receiver amplifies, detects, and controls the output level within ±1 db (decibels) for carrier input levels varying between −13 and −28 dbm (decibels below 1 milliwatt).

From the receiver the voice signals are passed through a 3-kc low-pass filter which will stop any 3.5-kc signaling tones. In the receiving v-f pad the channel output may be adjusted to the desired level. Normal v-f input and output levels at

TONE SIGNAL TO TRANSMITTER

Fig. 5. Signaling card

the hybrid are 0 dbm and −4 dbm respectively.

SIGNALING

With the equipment wired for "tone off during seizure" (*X* wiring option) the tone oscillator continually feeds a 3.5-kc tone during idle time into the modulator circuit of the transmitter card. This tone modulates the carrier at a 16 db lower level than the voice frequency.

Transmission of the tone modulated signal is the same as previously described.

The 3.5-kc output from the receiver at approximately −12 dbm level is fed into the signaling card through a 3.5-kc band-pass filter (see Fig. 4 for band-pass characteristics) to be amplified, clipped, and converted to d-c to energize the coil of the signaling relay.

As long as the *M* lead at the near end is open (or grounded) the 3.5-kc tone will be transmitted and the signaling relay will be energized at the far end and no ground will appear on the *E* lead bus.

When −48 volts is applied on the *M* lead input the oscillator is biased to cut off. Subsequently, the signaling relay at the far end drops out placing a ground on the *E* lead bus seizing the trunk equipment at that end.

Other options for signaling are as follows:

1. −24 volts on the *M* lead (use *Z* wiring Fig. 5).
2. Tone on during seizure (use *Y* wiring Fig. 5).

Receiver and transmitter cards have been discussed in other literature,[1-3] however because of the novel characteristics of the signaling circuit a brief description of its operation follows. See the schematic shown in Fig. 5.

It will be noted that the card has five distinct sections which are:

1. Oscillator.
2. Tone amplifier.
3. 3.5-kc tone band-pass filter.
4. 3-kc low-pass filter for the v-f transmit signal.
5. 3-kv low-pass filter for the v-f receive signal.

The oscillator is of the L-C type employing a single transistor. The oscillator is shown in the upper left area of Fig. 5. The tone band-pass filter is at the lower left center with the v-f receive 3-kc low-pass filter located to the right of it. The v-f transmit 3-kc low-pass filter is shown at the upper right.

The filters are those shown in Fig. 3 and are located on the signaling card to improve system flexibility, for convenience

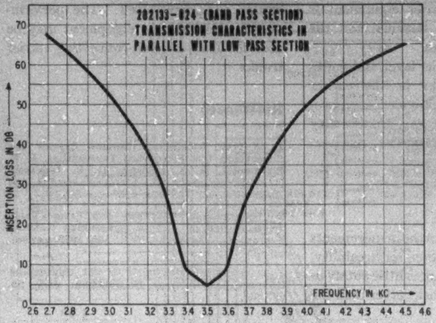

Fig. 6. Characteristics of 3.5-kc band-pass filter

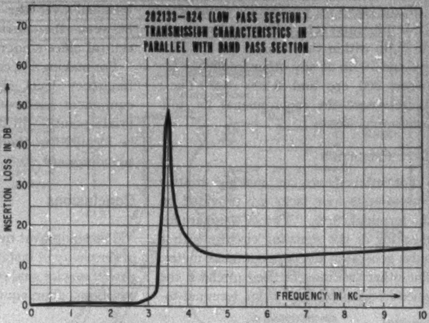

Fig. 7. Characteristics of 3-kc low-pass filter

of manufacture, and to reduce servicing problems.

For tone-on during idle, the tone oscillator transistor *Q*-15 is supplied with −48 volts through *R*64, *R*65, and transformer *ST*9. It will oscillate continuously until biased to cut off by the application of −24 to −48 volts on the *M* lead through *R*-67, *R*-66, and diode *CR*-25.

For tone-on during seizure, the oscillator receives all of its power fom the *M* lead and therefore will oscillate only during the time that voltage is supplied by it.

The 3,500-cps tone generated by the oscillator is fed to the transmitter at a level to produce sidebands 29 db below carrier level.

The signaling tone amplifier obtains its signal from the receiver through the 3.5-kc band-pass filter.

*Q*16 is a conventional common emitter amplifier. *Q*17 is an emitter follower which serves to match the output impedance of *Q*16 to the low input impedance of *Q*18. *Q*18 is a clipper to limit the magnitude of the signal before conversion to d-c in the last stage.

In order to understand the a-c-to-d-c conversion in the last stage, first consider it as an a-c amplifier with a controllable amount of feedback. As the feedback is increased the voltge available for conversion to d-c is reduced. The transistor may now be considered as a triode detector or a d-c amplifier. In either consideration the d-c output will be less as the a-c feedback is increased and will result in a slower operate time of the signaling relay. Rheostat *R*95 can therefore be used as a per-cent make control for dial pulses. It is possible to adjust the per-cent make of the signal receive relay to be equal to, greater than, or less than the per-cent make in the *M* lead at the transmitting terminal. The range of pulse conversion is ±4%.

In order to obtain reliable signaling and prevent talkdown, special characteristics were designed into the 3-kc low-pass filters and the 3.5-kc band-pass filter. These are as follows:

To insure perfect response to the 3.5-kc tone, the passband of the band-pass filter is 200 cycles wide. Outside the band the attenuation increases rapidly, particularly on the low-frequency side where the chances of talkdown are greater. Fig. 6 shows the attenuation characteristics of this filter.

The 3-kc low-pass filters also are of special design. They serve two purposes. The first requirement is to prevent 3.5-kc components of speech signals from entering the transmitter or signaling amplifier where they may cause eratic operation. The second requirement is to prevent the 3.5-kc signaling tone from getting out into the v-f line as an annoying whistle. Fig. 7 shows the attenuation of the 3-kc low-pass filter. Note the high attenuation characteristics of the filter at 3.5 kc. The use of these filters coupled with other special features of the system provide accurate signaling without pulse distortion in systems working over lines having losses exceeding 35 db at carrier frequencies (see Fig. 4). The filters in part make it possible to obtain F1A weighted noise levels lower than 15 dba (decibels adjusted).

The v-f band width of the system is 250 cps to 3,000 cps drop-to-drop with less than +1−3 db variation from the thousand cycle level. See Fig. 8 for drop-to-drop response curves of an actual installation at Merchants & Farmers Telephone Company of Montpelier, Va.

The design characteristics of the carrier frequency band-pass filters warrant some comment. Their passband approaches 3.5 kc each side of carrier in order to accommodate the sidebands of the signaling tone. They have an extremely flat passband, having a ripple of less than ±0.25 db.

The out-of-band attenuation characteristics are such that the channels may be spaced 12 kc apart at frequencies of 27, 39, ... 123, 135 kc without excessive crosstalk between channels.

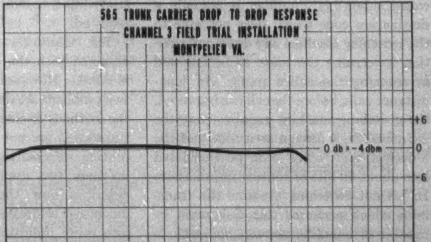

Fig. 8. Typical frequency response

Data taken on production equipments gave minimum return loss measurements of 22 db within the band of 500 to 2,500 cps and 19 db at any other frequency between 100 cps and 3,200 cps. These figures meet the requirements for toll-connecting trunks.

Test Facilities

For convenience in making routine system tests four jacks are provided on the terminal cards. Two of these are for checking of the signaling circuits with a pulse generator and per-cent make meter. The other two may be used to check the voice-frequency signal from terminal-to-terminal over the carrier equipment or between the carrier terminal and the central office equipment.

For making d-c, carrier level, and voice-frequency level checks in the carrier equipment, jacks are provided at appropriate points. In this way, trouble may be localized in the transmitter, receiver, signaling card, etc.

Conclusions

The equipment meets the requirements of simplicity of installation, serviceability, ease of service, and requires little outlay in additional plant equipment other than the carrier equipment itself. The performance is such that the equipment may be used for EAS and toll-connecting carrier trunks.

A Wired-Memory Translator with Shared Access

F. P. PACE
NONMEMBER AIEE

B. OSTENDORF, JR.
MEMBER AIEE

THIS PAPER describes the requirements, the circuits, and the design philosophy of a translator[1] developed in connection with experimental work on telephone and data-switching systems. The requirements called for a flexible translator of large capacity, with a nonvolatile memory, and for operation at speeds compatible with the present-day automatic telephone and telegraph switching systems. Moreover, the common translator must be made accessible to a large number of circuits which require translation service.

An important use of this translator is to convert destination-type codes or addresses into routing information. Two examples of this usage follow:

Example 1. In the telephone system a called subscriber's number is actually a destination code which does not give to the switching machine any direct information concerning the route to be followed in reaching the called party. In long-distance calls, before the call can be routed, the switching machine requires that the 3-decimal-digit foreign area code and the 3-decimal-digit office code be translated into about 60 bits of routing information. In present switching systems the translator which performs this task must be capable of handling about 1,200 such 6-digit codes. Also, the translator must be flexible in so far as code changes are concerned since the routing schemes are subject to frequent changes as the telephone traffic load changes. At present, this translation is handled by the card translator.[2]

Example 2. In certain data-switching systems messages are to be addressed by means of mnemonic codes which greatly facilitate the operator's task of memorizing many hundreds of station addresses. Also, in these systems group codes are used in such a way that a single message may be addressed to a large group of stations by means of a single group address. Again, there exists the need for translating these message addresses into route indicators which the switching machines can use for routing the messages to their proper destinations. In a switching system under study up to 2,000 such codes might be required.

The translator presented here was designed with the tasks described above in mind. However, some aspects of these two problems are different. For example, the methods of checking the results of the translation are not the same because the routing information is coded differently in these two applications. This paper describes how the translator converts mnemonic addresses and group addresses into route indicators for use by a data-switching system.

Consider the role of the translator functioning in a data-switching center, Fig. 1, in which the translator is designed to give service to a number of requesting machines. The translation of an address code into route indicators would proceed as follows: When a requesting machine has assembled the address to be translated it initiates a bid for translation service. This bid signal is detected by the translator, which operates an input access gate in the bidding requesting machine to allow the address which is to be translated to pass into the translator. Here it is converted into routing information. In the meantime, the translator also operates the output access gate in this requesting machine. In so doing, the results of the translation are transferred to the requesting machine. Then the translator proceeds to give service to the other bidding requesting machines in the order of their appearance on a scanner in the sequence circuit.

Translator Requirements

Translating Networks

The translating networks must be capable of accepting an address which consists of from two to eight alphabetical characters (five bits per character). Therefore, the input to the translator will be from 10 to 40 bits in increments of 5 bits.

Fig. 1. Common translator system, functional diagram

The maximum number of addresses which the translator must be capable of translating was set at 2,000. It was also required that there be no restrictions placed on the way in which these addresses are chosen.

The output of the translating networks is 300 bits of routing information on 300 leads. Because of power supply limitations the maximum number of ONES on the output leads (operated output relays) was limited to 100.

The 40 input bits give about 10^{12} possible input codes. Of these almost any 2,000 codes may be chosen. These codes may be translated into any of 4×10^{82} possible output combinations. These large numbers of possible input and output combinations make it apparent that any co-ordinate type of network matrix which even approaches full implementation would require an astronomical number of crosspoints. This makes it necessary to design a simple network scheme which requires almost no equipment for codes which are merely possible but not actually used. Equipment is then added to the network only on a per code used basis (job wiring).

Common Usage

The requirements call for one translator to give translation service to as many as 50 requesting machines in a data-switching center. Because of this common usage a lockout function must be provided to permit the requesting machines to have orderly access to the translator. An electronic scanner was chosen to perform this function. Also, some input access equipment is required to control the flow of addresses to be translated from the requesting machine to the translator. Likewise, output access equipment is required to control the flow of routing information from the translator to the requesting machine. For compatibility with present-day plant the translator holding time requirement was set at 35 milliseconds per translation.

Auxiliary Functions

Besides the essential features described above, the translator must provide check circuitry to evaluate the results of each translation. Also, in case of circuit failure, spare equipment must be provided as replacement for the circuit which has failed. Some means are needed for monitoring and testing the equipment in service and testing out-of-service or spare circuits.

Translator Circuits and Operations

The translator consists of two essential elements as follows.

The translating networks, whose functions are:

1. To receive the address to be translated.
2. To furnish the routing information.

The sequence and program circuits, whose functions are:

1. To detect the bids for translation service.
2. To operate the input access gate of the bidding requesting machine to allow the address which is to be translated to pass into the translating networks.
3. To pulse the translating networks.
4. To operate the output access gate of the bidding requesting machine to allow the resulting routing information to pass from the translating networks to the requesting machine.

5. To direct the check circuit to check the results of the translation.

TRANSLATING NETWORKS

When a bid has been detected and the input access gate in a requesting machine is operated, 40 address leads in the particular requesting machine are connected to the office multiple. This portion of the office multiple (the 40 address leads) is wired to the eight character translators in the translator. Each character translator has a 5-lead input (5 bits) and a 32-lead output. When the address leads are connected between a requesting machine and the translator, the ground or open conditions of these leads are used to operate or not operate the relays in each of the character translators in such a way that one and only one of the 32 output leads from each character translator has a ground condition on it instead of the usual +48 volts. For convenience each output lead of a character translator is labeled with the alphabetical character with which it corresponds. Therefore, the result of the translation up to this point is a one-out-of-32 selection for each of the eight alphabets represented by the eight character translators. This completes the first stage of a 2-stage translation.

The last stage of the translating networks consists of up to 2,000 code gates, one code gate for each address which is used in the system. Each code gate is a transistor-resistor AND gate with eight d-c inputs, one pulse input, and one pulse output. Each d-c input is cross-connected to an output from a different character translator. Where there are fewer than eight characters in an address to be translated, the unused inputs to the code gates are grounded.

When, in response to an input address the d-c inputs to a particular code gate are in the ground condition, the transistor of that gate becomes conducting and the 15 volts of back bias are removed from the output diode. The code gate is then said to be in an energized condition. Some time after one of the code gates has been energized by the receipt of an address, all the code gates are pulsed by the translate pulse. Only the one energized code gate out of the total number of gates will allow this pulse to proceed onward to its output lead. The output lead of each code gate is threaded through one or a number of rings, Fig. 2, in such a way that when a ring is pulsed, the flip-flop associated with it operates. This operates an output relay whose contact closes a low-resistance 7-volt path through the output access gate contacts which in the meantime have been operated, to operate a corresponding relay in the requesting machine which is being given translation service. When the relay in the requesting machine operates, a ground is returned to the output relay contact as an indication that the information has been properly stored in the requesting machine. This is used for check purposes.

CHECKING THE TRANSLATION

The checking plan chosen for this translator consists of the comparison of the numbers of output leads which ought to have ONES on them as the result of translation, with the number of output leads which actually do have ONES on them. However, because of the low density of addresses used (only 2,000 addresses may be used out of 10^{12} possible addresses) a full comparison was not necessary. The plan used checks for congruence modulo (4) between the expected output ONES and the actual output ONES. This is equivalent to the use of two parity bits or a 4-unit parity and is implemented as follows: The information concerning the number of expected ONES modulo (4) for a particular code is stored in the translator by also threading one out of the four check rings with the same wire with which a group of rings is threaded. This information is made available to the check circuit when the translating networks are pulsed. The information concerning the actual number of ONES modulo (4) resulting from the translation is obtained by scanning (Fig. 3) the 300 output leads for grounds indicating the successful transfer of ONES to the requesting machines, and counting these grounds on a recycling 4-stage check counter. The check consists in matching the state of the four check ring flip-flops with the final state of the check counter. A match indicates a check.

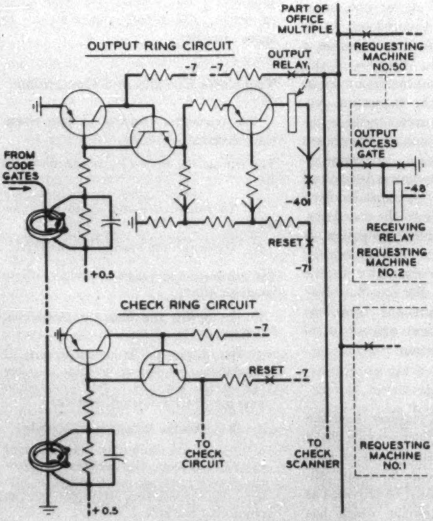

Fig. 2 (left). Ring operated flip-flops

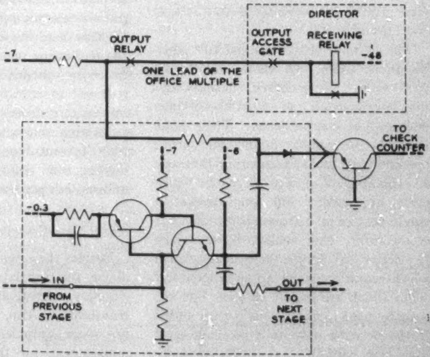

Fig. 3 (below). Check scanner stage

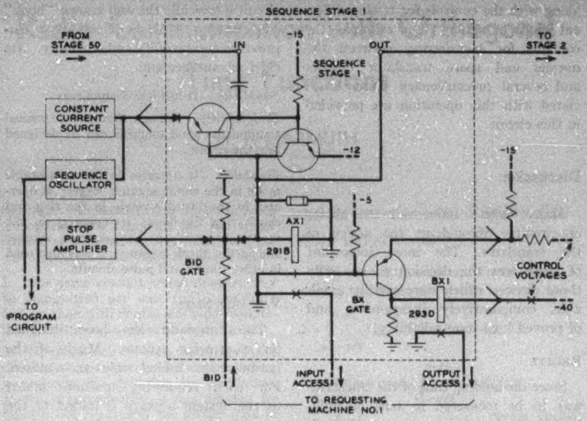

Fig. 4. Sequence scanner stage

Sequence Scanner

The purpose of the sequence scanner, Fig. 4, is to provide a means whereby the requesting machine may have orderly access to the translator with no preference given any of them. This task is accomplished by means of a 50-stage ring counter. Each stage is a series negative-resistance flip-flop. All stages have one terminal connected in common to a constant current supply which is sufficient to keep just one stage in the ON condition at a time. This ON condition has been designed to step along at a rate of 7,200 steps per second in response to pulses from a blocking oscillator (sequence oscillator) so long as the translator is not busy translating. When a stage is in the ON condition and bid gate of that stage is energized to detect the presence of a bid voltage (−48 volts) on the bid lead of the requesting machine associated with that particular stage of the sequence scanner. If a bid voltage is detected a STOP signal is sent to the program circuit. In turn, the program circuit stops the sequence oscillator and the ON condition remains at the stage where the bid signal was detected.

When the ON condition remains at a stage for more than 1 millisecond the mercury relay *AX* which is the load of that stage will operate. The *AX* make-contact operates the input access gate in the requesting machine, thus allowing the address which is to be translated to come into the translating networks. Also, the break contact of the *AX* relay is used to prime the *BX* gate so that, some time later, under control of the program circuit the *BX* relay of this stage will be operated. Operation of the *BX* relay operates the output access gate in the requesting machine and allows the routing information, which is the result of the translation, to proceed into the requesting machine.

Program Circuit

The various phases of a translation are directed by a wired-in program which consists of some flip-flops, timers, pulsers, and logic gates. A sequence chart shows when the various phases of translation occur with respect to one another; see chart of Fig. 5.

When the translator is not translating, the sequence scanner is scanning the 50-bid leads. As soon as a bid is detected an input access gate is operated; this operates the character translators, which in turn energize one of the code gates completing the encoding phase of the translation.

After sufficient time has elapsed to allow circuit transients to become negligible, all the code gates are pulsed. The output relays which have been assigned to this one energized code gate by means of the ring threadings are thus operated. In the meantime the output access gate of the requesting machine being given service has been closed, allowing the operating output relays to operate their associated relays in the requesting machine. This completes the translation phase of the over-all operation.

A time interval is again allowed for the circuit transients to disappear. At the end of this interval several operations occur simultaneously, as follows:

1. The translation results are checked and, after the check is completed, the output access gate of the requesting machine is released and the ring flip-flops, the check circuit, and the output relays are reset.
2. The input access gate of the requesting machine, the character translators and the code gates are released.
3. The sequence scanner is allowed to commence scanning.

If the next requesting machine is bidding, this will be immediately detected and the input access gate of this requesting machine will be operated. Thus the character translators and the code gates will be operated according to the new address to be translated, even while the output information is still being processed for the previous translation.

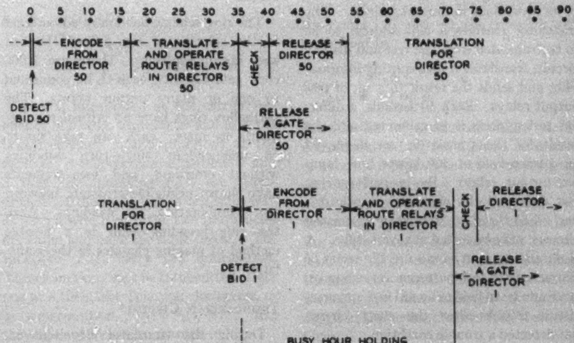

Fig. 5. Timing chart

At the time that the output portions of the translating networks have been reset, the input portions of the translating networks will have been energized so that the translator is ready to enter the translation phase of its operation for the second time.

Although a particular requesting machine is attached to the translator for about 53 milliseconds, by adopting the overlapping program described above the translator is able to complete a translation every 37 milliseconds. This gives to the translator an effective busy-hour holding time of 37 milliseconds.

DUPLICATED CIRCUITRY

Because this system is designed for real time operation those portions of the translator whose failure would result in total or nearly total communications breakdown were duplicated for quick substitution during emergencies. This includes the character translators, the program circuit, and the sequence circuit. These circuits can be transferred into service by operating a bank of transfer relays, the use of which also allows for routine exercising of the spare circuits.

TEST AND DISPLAY CIRCUIT

The test and display circuit contains the circuitry to perform the auxiliary functions described below.

By simulating portions of a requesting machine the test and display circuit is able to monitor the operation of the translator while it is in service. This is done as follows: Every 10 seconds, a test bid signal is initiated by the circuit. When this bid is detected by the sequence scanner, the translator proper proceeds in its operations in normal fashion. The translator receives a test address to be to be translated from the test and display circuit, translates it into routing information, and sends the result to a set of test output relays. Each 10 seconds, a different test address is so generated and the results of the translation are displayed on a lamp field of 300 lamps (one lamp per output relay). By properly wiring test codes all the character translators, and all of the rings with their associated circuits, may be tested automatically. A maintenance man would use the series of characteristic test patterns appearing on the route lamp field as an aid in diagnosing circuit trouble after the check circuit has detected a trouble condition.

Alarm features for indicating various types of circuit difficulties have been included in the test and display circuit along with the controls for testing different kinds of action. For example, the controls for transferring between the normal and spare translator circuits and several precautionary lamps associated with this operation are provided in this circuit.

Discussion

Many factors influenced the choice of circuitry throughout the design of the translator. The most important of these was the decision to use only those devices which were readily available, comparatively inexpensive, and of proved long-term reliability.

RELAYS

Since the holding time of the translator was to be measured in tens of milliseconds and not in microseconds, advantage could be taken of the more useful properties of relays. For example, the relay fan in the character translators originally consisted of about 130 diodes; these were replaced by eight relays and eight diodes. The relay fan is more economical and also has greater current-carrying capacity.

Diode gates were also considered for the input access gates and the output access gates which control the information flow to and from the translator. These gates would require about 35,000 diodes spread out over a 350-lead multiple which goes to 50 requesting machines. In view of the equipment costs and the vulnerability to diode damage on this complicated multiple, it was decided to use relays in this application also.

RINGS[3]

The ring scheme has many advantages in the solution of the difficult fan-out and fan-in problems: There are 2,000 code gate outputs, each to be connected to one or many output points. The permalloy rings have no critical requirements to meet, each can take up to 50 independent single-turn windings without crowding, and measurements have shown negligible crosstalk between any combination of windings. Also, the ring-threading plan is a flexible method of making changes in the translator.

TRUNCATED-N CIRCUIT[4]

During the translator development, a particularly interesting switching circuit was designed with an input characteristic which resembles a truncated N. This circuit is basically the well-known "hook" configuration with modifications to improve its designability and flexibility. Its chief advantages are:

Simplicity. It has few components.

Designability. Because there are no critical components good margins can be designed into the circuit.

Flexibility. It operates in the monostable mode in the check scanner stages; it operates in the bistable mode in the ring and check ring flip-flops; it operates in the multistable mode in the sequence scanner and in the check counter; it was also used in other timing and pulse circuits.

VARIABLE SIZE

The translator has been designed for a growing system. Much of the hardware is added only as required. For each requesting machine added to the system a stage is added to the sequence scanner. For each new address which the system has to handle a code gate is added to the translator. For each new bit required at the output of the translator a ring circuit and a check scanner must be added. When the message address format is expanded to include another character, a character translator is added. This growth aspect of the translator was needed to satisfy a variety of applications.

PRESENT STATUS

A laboratory "breadboard" model of the translator has been built in which all of the essential features of the translator have been tested and developed. A more complete model is being built for testing the circuits in their packaged environment and for evaluating the flexibility of the equipment arrangement for the ring circuits.

In conclusion, the translator is believed to be an economical balance of old art and new art techniques designed with sufficient flexibility to lend itself easily to the solution of various translation problems within the limitations of its requirements.

Radio Communication with Orthogonal Time Functions

H. F. HARMUTH
ASSOCIATE MEMBER AIEE

Synopsis: Communication systems using orthogonal time functions for the transmission of information over radio links are characterized by the following properties:

1. The same amount of information may be transmitted per unit (pu) bandwidth and pu time with double-sideband modulation as with single-sideband modulation.
2. No phase lock between the carriers produced at the transmitter and at the receiver is necessary for detection by correlation. Hence, communication is less affected by rapid phase changes of the carrier than in systems requiring phase lock.
3. It is possible to operate under conditions of large Doppler shift without changing the frequency of the carrier produced at the receiver, provided the Doppler shift varies sufficiently slowly.

CONSIDER a set of time functions $F_s(t)$, $s=1, 2, \ldots m$ which are orthogonal in the interval $-\tau/2 \leqslant t \leqslant +\tau/2$.

$$E^{-1}\int_{-\tau/2}^{\tau/2} F_i(t)F_k(t)dt=\delta_{ik}=\begin{cases}1 \text{ for } i=k\\ 0 \text{ for } i\neq k\end{cases} \qquad (1)$$

Consider further the set of functions obtained by multiplying $F_s(t)$ by -1:

$$F_{-i}(t)=-F_i(t) \qquad (2)$$

Both sets of functions form an extended set of orthogonal functions:

$$E^{-1}\int_{-\tau/2}^{\tau/2} F_i(t)F_k(t)dt=\delta_{ik}' = \begin{cases}1 \text{ for } i=k\\ -1 \text{ for } i=-k\\ 0 \text{ for } i\neq k, -k\end{cases} \qquad (3)$$

where τ is finite if the functions $F_s(t)$ are time limited and infinite if they are not.

Let the carrier $\sqrt{2}\cos\omega_1(t+t_1)$ be amplitude modulated by $F_i(t)$,

$$f_i(t)=\sqrt{2}F_i(t)\cos\omega_1(t+t_1) \qquad (4)$$

and the carrier $\sqrt{2}\cos\omega_2(t+t_2)$ by $F_k(t)$:

$$f_k(t)=\sqrt{2}F_k(t)\cos\omega_2(t+t_2) \qquad (5)$$

The correlation of equations 4 and 5 during the interval τ yields:

$$I=\int_{-\tau/2}^{\tau/2} f_i(t)f_k(t)dt=I_1+I_2+I_3+I_4$$

$$I_1=\cos(\omega_1t_1-\omega_2t_2)\int_{-\tau/2}^{\tau/2}F_i(t)F_k(t)\times \cos(\omega_1-\omega_2)tdt$$

$$I_2=-\sin(\omega_1t_1-\omega_2t_2)\int_{-\tau/2}^{\tau/2}F_i(t)F_k(t)\times \sin(\omega_1-\omega_2)tdt$$

$$I_3=\cos(\omega_1t_1+\omega_2t_2)\int_{-\tau/2}^{\tau/2}F_i(t)F_k(t)\times \cos(\omega_1+\omega_2)tdt$$

$$I_4=-\sin(\omega_1t_1+\omega_2t_2)\int_{-\tau/2}^{\tau/2}F_i(t)F_k(t)\times \sin(\omega_1+\omega_2)tdt \qquad (6)$$

It may be shown by partial integration that I_3 and I_4 are negligibly small if $\omega_1+\omega_2$ are large compared with the highest frequency components of $F_i(t)$ and $F_k(t)$ that one wants to transmit. Integral I_2 vanishes if the two carrier frequencies ω_1 and ω_2 are equal.

If, in addition, the two carriers are in phase one obtains:

$$E^{-1}\int_{-\tau/2}^{\tau/2} f_i(t)f_k(t)dt = E^{-1}\int_{-\tau/2}^{\tau/2} F_i(t)F_k(t)dt=\delta_{ik}' \qquad (7)$$

If ω_1 is interpreted as the carrier frequency of a radio transmitter and ω_2 as the beat frequency locally produced at the receiver, it follows from equations 7 and 3 that the functions $F_s(t)$ are transmitted via the radio link in the same way as with a wire line, if the two frequencies are equal and have the same phase. The functions $F_s(t)$ carry the information. These functions may be transmitted either one at a time, like Teletype characters, or as superposition $F_1(t)+F_2(t)+\ldots$, like the digits of Teletype characters.

In the following the transmission of only one function, $F_i(t)$, will be discussed. Due to the orthogonality of the functions $F_i(t)$ the results remain unchanged if one substitutes a sum $\Sigma F_i(t)$ for $F_i(t)$.

Synchronous Communication

Consider two transmitters both using carriers with the frequency ω but with a phase shift of 90 degrees between the two carriers. The amplitude modulation with $F_i(t)$ or $F_l(t)$ yields:

$$f_i(t)=\sqrt{2}F_i(t)\cos\omega t$$

$$f_l'(t)=\sqrt{2}F_l(t)\sin\omega t \qquad (8)$$

Assume that the frequency ω can be produced exactly at the receiver but that there is a phase difference between the transmitter carrier and the receiver carrier. (The terms "transmitter carrier" and "receiver carrier" will be used to indicate where the carrier is produced.) The received signal $f_i(t)+f_l'(t)$ is thus correlated with the following functions:

$$f_k(t)=\sqrt{2}F_k(t)\cos(\omega t+\phi)$$

$$f_m'(t)=\sqrt{2}F_m(t)\sin(\omega t+\phi) \qquad (9)$$

Neglecting terms which are small for large values of ω, one obtains the following correlations between $f_i(t)+f_l'(t)$ and the functions 9 (the neglected terms are of the form of I_3 and I_4 in equation 6):

$$I_{ik}=E^{-1}\int_{-\tau/2}^{\tau/2}[f_i(t)+f_l'(t)]f_k(t)dt \doteq \delta_{ik}'\cos\phi-\delta_{lk}'\sin\phi$$

$$I_{lm}'=E^{-1}\int_{-\tau/2}^{\tau/2}[f_i(t)+f_l'(t)]f_m'(t)dt \doteq \delta_{lm}'\cos\phi+\delta_{im}'\sin\phi \qquad (10)$$

The first terms on the right in equation 10 represent the transmitted information. $\delta_{lk}'\sin\phi$ gives the crosstalk from "sine channel" to "cosine channel" and $\delta_{im}'\sin\phi$ the crosstalk from "cosine channel" to "sine channel." Since the δ' may assume the values 1, 0, and -1, the crosstalk will be defined by:

$$C=\frac{|\sin\phi|}{|\cos\phi|+|\sin\phi|} \qquad (11)$$

Introduction of numerical values yields a crosstalk of 10% for a phase difference of about ±6 degrees between transmitter and receiver carrier.

In order to be able to distinguish between sine channel and cosine channel at the receiver one may transmit a certain function $F_i(t)$, say $F_1(t)$, all the time through the cosine channel but never through the sine channel. A typical signal in the cosine channel has, then, the form:

$$f_i(t)=\sqrt{2}[F_i(t)+F_1(t)]\cos\omega t \qquad (12)$$

where $F_i(t)$ stands for any number of func-

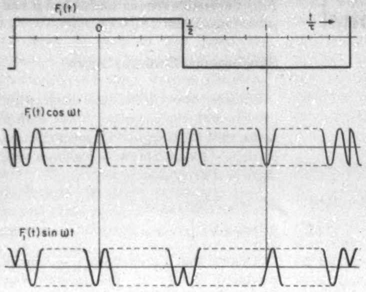

Fig. 1 (left). Modulation of cosine and sine carrier by square wave

tions of the set of equation 3. Since $F_1(t)$ is orthogonal to $F_i(t)$, $i\neq 1$, the integrals, equation 10, remain unchanged. Correlation of equation 12 with $\sqrt{2}\,F_1(t)$ sin $(\omega t+\phi)$ and $\sqrt{2}\,F_1(t)\cos(\omega t+\phi)$ yields:

$$I_{11}=2E^{-1}\int_{-\tau/2}^{\tau/2}[F_i(t)+F_1(t)]F_1(t)\times \cos\omega t\cos(\omega t+\phi)dt \doteq \cos\phi$$

$$I_{11}'=2E^{-1}\int_{-\tau/2}^{\tau/2}[F_i(t)+F_1(t)]F_1(t)\times \cos\omega t\sin(\omega t+\phi)dt \doteq \sin\phi \quad (13)$$

The output of the correlator producing integral I_{11}' may be used in a feedback loop to change the phase ϕ so that integral

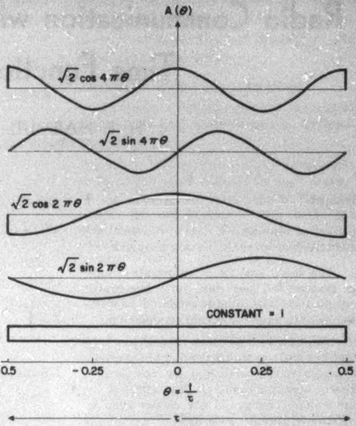

Fig. 2 (right). Set of orthogonal trigonometric time functions

I_{11}' vanishes. Information transmitted in the cosine channel will then be received in the cosine channel and the equivalent statement holds for the sine channel.

The integrals, 13, may be used to eliminate the crosstalk in equation 10 without feedback. Consider the correlation of $f_i(t)+f_i'(t)$ with the functions:

$$f_k'(t)=\sqrt{2}F_k(t)\sin(\omega t+\phi) \quad (14)$$

and

$$f_m(t)=\sqrt{2}F_m(t)\cos(\omega t+\phi)$$

$$I_{ik}'=E^{-1}\int_{-\tau/2}^{\tau/2}[f_i(t)+f_i'(t)]f_k'(t)dt = \delta_{ik}'\sin\phi+\delta_{lk}'\cos\phi$$

$$I_{lm}=E^{-1}\int_{-\tau/2}^{\tau/2}[f_i(t)+f_i'(t)]f_m(t)dt = -\delta_{lm}'\sin\phi+\delta_{im}'\cos\phi \quad (15)$$

A combination of equations 10, 13, and 15 yields δ_{ik}' and δ_{lm}' free of crosstalk:

$$I_{ik}I_{11}+I_{ik}'I_{11}'=\delta_{ik}'$$

$$I_{lm}'I_{11}-I_{lm}I_{11}'=\delta_{lm}' \quad (16)$$

Elimination of crosstalk by means of the phase information of equations 13 provides the same result as synchronization of the phase of the receiver carrier which would also be based on equations 13. Whether one prefers phase synchronization or elimination of the crosstalk with the help of equations 16 depends on how conveniently either method can be implemented under given conditions. There is, however, one important difference. The phase information obtained by the integration 13 during the time interval τ is used in equation 16 to eliminate crosstalk from the signals which were received during the same interval τ. If equation 13 is used to synchronize the receiver carrier, the phase information obtained during the interval τ will be used at a later time. This time lag makes phase synchronization undesirable if the phase of the transmitter carrier changes rapidly. Use of equations 13 for synchronization or crosstalk reduction by means of equations 16 is based on the assumption that phase shifts vary linearly with the frequency of the spectral components of $F_1(t)$ and $F_i(t)$.

It has been tacitly assumed so far that the period τ of the functions $F_i(t)$ is a multiple of the period of the carrier frequency. Modulation of a cosine or a sine carrier would then produce functions like $F_1(t)\cos\omega t$ and $F_1(t)\sin\omega t$ as shown by Fig. 1. To remove this undesirable requirement of synchronization between $1/\tau$ and ω, substitute $\cos\omega(t+t_1)$ and $\sin\omega(t+t_1)$ for $\cos\omega t$ and $\sin\omega t$. It follows from equations 6 for $\omega_1=\omega_2=\omega$ that t_1 and $t_2=t_1+\phi/\omega$ do not occur in the integrals. Furthermore, the functions $\cos\omega(t+t_1)$ and $\sin\omega(t+t_1)$ are only a different notation for $\cos(\omega t+\phi)$ and $\sin(\omega t+\phi)$. Only integrals I_3 and I_4 depend on the sum t_1+t_2 and these integrals vanish for large values of ω. Hence there is no need of making τ a multiple of $1/\omega$.

Single-Sideband Versus Double-Sideband Modulation

The following is a discussion of some specific sets of orthogonal functions. Fig. 2 shows the first five functions of a Fourier series. These functions can be produced by gating harmonic oscillators.

Vol.
Pt. 1
196

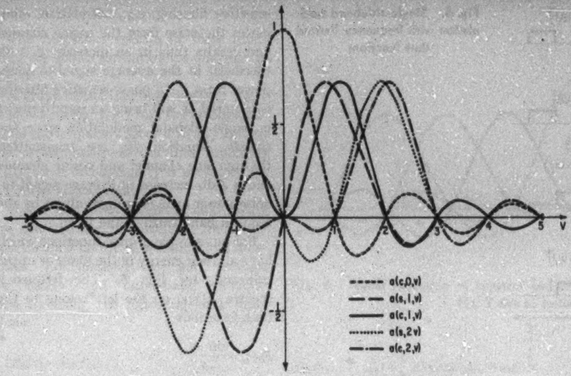

Fig. 4. Frequency spectra of trigonometric functions of Fig. 2

$$F_1(t) = -F_{-1}(t) = A$$

$$F_{2i}(t) = -F_{-2i}(t) = A\sqrt{2}\sin 2i\pi\theta$$

$$F_{2i+1}(t) = -F_{-2i-1}(t) = A\sqrt{2}\cos 2i\pi\theta$$

$$i = 1,2,3\ldots,\ \theta = t/\tau,\ -\frac{1}{2} \le \theta \le +\frac{1}{2} \qquad (17)$$

The frequency spectra of these functions have the following form:

$$a(c,0,\nu) = \frac{\sin \pi\nu}{\pi\nu}$$

$$a(s,i,\nu) = \frac{1}{2}\sqrt{2}\left[\frac{\sin \pi(\nu-i)}{\pi(\nu-i)} - \frac{\sin \pi(\nu+i)}{\pi(\nu+i)}\right]$$

$$a(c,i,\nu) = \frac{1}{2}\sqrt{2}\left[\frac{\sin \pi(\nu-i)}{\pi(\nu-i)} + \frac{\sin \pi(\nu+i)}{\pi(\nu+i)}\right] \qquad (18)$$

Graphs of these functions for $i=0$, 1, and 2 are presented in Fig. 2.

Modulation of the carrier $\sqrt{2}\cos\omega_1 t$ with the functions 17 produces the following frequency spectra ($\omega_1 = 2\pi f_1$, $\nu_1 = f_1\tau$):

$$a[\sqrt{2}F_1(t)\cos\omega_1 t,\nu]$$
$$= \frac{1}{2}\sqrt{2}[a(c,0,\nu-\nu_1)\underset{(-)}{+}a(c,0,\nu+\nu_1)]$$

$$a[\sqrt{2}F_{2i}(t)\cos\omega_1 t,\nu]$$
$$= (-)\frac{1}{2}\sqrt{2}[a(s,i,\nu-\nu_1)\underset{(-)}{+}a(s,i,\nu+\nu_1)]$$

$$a[\sqrt{2}F_{2i+1}(t)\cos\omega_1 t,\nu]$$
$$= \frac{1}{2}\sqrt{2}[a(c,i,\nu-\nu_1)\underset{(-)}{+}a(c,i,\nu+\nu_1)] \qquad (19)$$

The negative signs of the right members of equations 19 hold for the carrier $\sqrt{2}\sin\omega_1 t$.

To illustrate the effects of symmetry and skew symmetry of the modulating functions $F_{2i}(t)$, $F_{2i+1}(t)$ and the carrier the frequency spectra of $F_3(t)\cos\omega_1 t$, $F_3(t)\sin\omega_1 t$, $F_2(t)\cos\omega_1 t$, and $F_2(t)\sin\omega_1 t$ are plotted in Fig. 3.

It is seen from Fig. 4 that the frequency spectra of $F_{2i}(t)$ and $F_{2i+1}(t)$ are almost equal except that the 1's are skew symmetric and the others symmetric. Skew symmetry and symmetry becomes, for large values of i, the only difference between the frequency spectra. Sum or difference of the frequency spectra of $F_{2i}(t)$ and $F_{2i+1}(t)$ will have large values for $\nu>0$ or $\nu<0$ only. The orthogonal time functions belonging to these new frequency spectra are obtained by forming the sum and the difference of the functions $F_{2i}(t)$ and $F_{2i+1}(t)$.

$$F_i'(t) = \frac{1}{2}[F_{2i}(t) + F_{2i+1}(t)] = A\sin 2\pi\left(i\theta + \frac{1}{8}\right)$$

$$F_i''(t) = \frac{1}{2}[F_{2i}(t) - F_{2i+1}(t)]$$
$$= A\sin 2\pi\left(i\theta - \frac{1}{8}\right)$$

Frequency spectra $a[F_i'(t),\nu]$ of $F_i'(t)$ are shown in Fig. 5 for several values of i.

$$a[F_i'(t),\nu] = \frac{1}{2}\sqrt{2}\,\frac{\sin \pi(\nu-i)}{\pi(\nu-i)}$$

Modulation of the carrier $\sqrt{2}\cos\omega_1 t$ by $F_1'(t)$ yields the following spectra:

$$a[\sqrt{2}F_i'(t)\cos\omega_1 t,\nu]$$
$$= \frac{1}{2}\left[\frac{\sin \pi(\nu-\nu_1-i)}{\pi(\nu-\nu_1-i)} \underset{(-)}{+} \frac{\sin \pi(\nu+\nu_1-i)}{\pi(\nu+\nu_1-i)}\right]$$

The negative sign holds for the carrier $\sqrt{2}\sin\omega_1 t$.

Spectra of single-sideband modulation is not represented by $a[\sqrt{2}\ F_i'(t)\cos\omega_1 t,\ \nu]$ since the sign of i in the second term is the same as in the first term. The spectrum $a[\sqrt{2}\ F_i'(t)\cos\omega_1 t,\ \nu]$ belonging to the function $1/2[F_2(t)+F_3(t)]\cos\omega_1 t$ is shown in Fig. 3.

Single-sideband modulation is obtained by combining the function 17 with the carriers $\sqrt{2}\cos\omega_1 t$ and $\sqrt{2}\sin\omega_1 t$ in the following ways.

$$f_{2i}{}^{+}(t) = \frac{1}{2}\sqrt{2}[F_{2i+1}(t)\cos\omega_1 t - F_{2i}(t)\sin\omega_1 t]$$

$$f_{2i+1}{}^{+}(t) = \frac{1}{2}\sqrt{2}[F_{2i+1}(t)\sin\omega_1 t +$$
$$F_{2i}(t)\cos\omega_1 t]$$

$$f_{2i}{}^{-}(t) = \frac{1}{2}\sqrt{2}[F_{2i+1}(t)\cos\omega_1 t + F_{2i}(t)\sin\omega_1 t]$$

$$f_{2i+1}{}^{-}(t) = \frac{1}{2}[F_{2i+1}(t)\sin\omega_1 t -$$
$$F_{2i}(t)\cos\omega_1 t] \qquad (20)$$

Using the notation of equations 18 one may write the frequency spectra of the functions 20 in the following form:

$$a[f_{2i}{}^{+}(t),\nu] = a(c,i+\nu_1,\nu)$$

$$a[f_{2i+1}{}^{+}(t),\nu] = a(s,i+\nu_1,\nu)$$

$$a[f_{2i}{}^{-}(t),\nu] = a(c,i-\nu_1,\nu)$$

$$a[f_{2i-1}{}^{-}(t),\nu] = a(s,i-\nu_1,\nu) \qquad (21)$$

Fig. 6. Single-sideband modulation with frequency limited time functions

The functions 21 represent frequency spectra of single-sideband modulation with $f_{2i}^+(t)$ and $f_{2i+1}^+(t)$ having energy practically in the upper sideband only, and $f_{2i+1}^-(t)$ and $f_{2i}^-(t)$ in the lower sideband only. The spectra, equation 20, are shown in Fig. 3 for $i=1$. A comparison of equation 20 with equation 8 shows that single-sideband modulation is a practical implementation of the concept of transmission through sine channel and cosine channel. The functions $f_{2i}^+(t)$ and $f_{2i+1}^+(t)$ contain frequencies which occupy the same band but have a phase difference of 90 degrees. Hence, single-sideband modulation requires the same bandwidth for the same information rate as double-sideband modulation if the double-sideband modulation is performed in the way discussed.[1] It follows from equations 20 that single-sideband modulation may be performed by using two carriers with the same frequency but a phase difference of 90 degrees.[2,3] A double-sideband transmitter transmits all its energy either through the sine channel or the cosine channel of a certain frequency band; a single-sideband transmitter transmits its energy through the sine and cosine channel of half this frequency band; the power transmitted per bandwidth and per-phase channel is the same. As discussed in the Appendix, the components of white, normal noise may have the same frequency but a phase difference of 90 degrees and are then statistically independent.[4] If phase-insensitive filtering is used in a system which uses double-sideband modulation and transmits through the sine channel, the noise coming through the sine channel as well as through the cosine channel distorts the signal. Phase-sensitive filtering, e.g., correlation, eliminates the noise from the cosine channel and results thus in an increase of 3 db (decibels) in the average signal-to-noise-power ratio. No phase-sensitive filtering is required or will bring an improvement in single-sideband modulation since the signals, equation 20, are transmitted through sine channel and cosine channel and a 3-db increase in average signal-to-noise-power ratio is brought about by the reduced bandwidth of the filter.

For an example of time functions which have all their energy in the lower or upper sideband, see Fig. 6. The frequency spectra $A(n,\nu)$ on the left belong to the time functions

$$F_{00}(t)=\frac{\sin \pi\theta}{\pi\theta}$$

$$F_{10}(t)=\frac{\sin^2 \pi\theta/2}{\pi\theta/2}$$

$$F_{20}(t)=-\sin\frac{1}{2}\pi\theta\,\frac{\sin^2 \pi\theta/4}{\pi\theta/4}$$

$$F_{30}(t)=\cos\frac{1}{2}\pi\vartheta\,\frac{\sin^2 \pi\vartheta/4}{\pi\theta/4}$$

$$F_{40}(t)=-\cos\frac{1}{2}\pi\theta\,\sin\frac{1}{4}\pi\theta\,\frac{\sin^2 \pi\theta/8}{\pi\theta/8}$$

$$\vdots \qquad (22)$$

The following time functions with energy in the upper or lower sideband only may be derived from equation 22:

$$\frac{1}{2}\,[F_{00}(t)\sin\omega_1 t+F_{10}(t)\cos\omega_1 t]$$

$$\frac{1}{2}\,[F_{00}(t)\cos\omega_1 t-F_{10}(t)\sin\omega_1 t]$$

$$\frac{1}{2}\,[F_{20}(t)\sin\omega_1 t+F_{30}(t)\cos\omega_1 t]$$

$$\frac{1}{2}\,[F_{20}(t)\cos\omega_1 t-F_{30}(t)\sin\omega_1 t]$$

$$\vdots$$

$$\frac{1}{2}\,[F_{00}(t)\sin\omega_1 t-F_{10}(t)\cos\omega_1 t]$$

$$\frac{1}{2}\,[F_{00}(t)\cos\omega_1 t+F_{10}(t)\sin\omega_1 t] \qquad (23)$$

$$\vdots$$

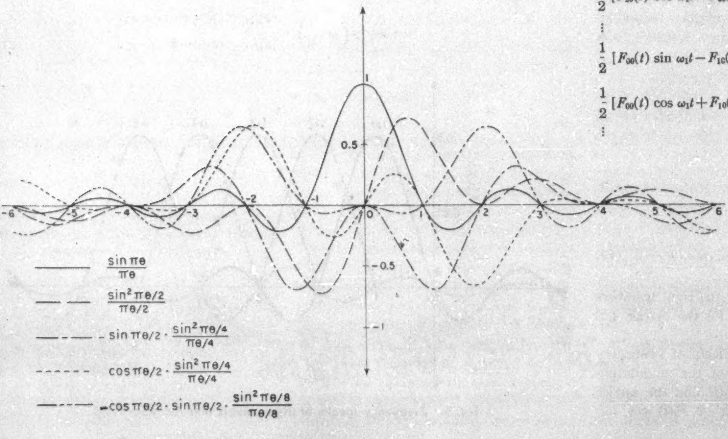

Fig. 7. Frequency limited time functions

The frequency spectra of these functions are shown on the right-hand side in Fig. 6.

A graph of the functions $F_{00}(t)$ to $F_{40}(t)$ is shown in Fig. 7. From the orthogonality of the frequency spectra $A(n,\nu)$ follows the orthogonality of the time functions $F_{n\nu}(t)$ since orthogonality is preserved by a Fourier transformation.

Upper and lower sideband modulation are special cases of arranging frequency spectra by a choice of suitable time functions. For instance, one may produce an "inner-" and "outer-band" modulation by using the following time functions:

$$\frac{1}{2}[F_{00}(t)-F_{20}(t)]$$

$$\frac{1}{2}[F_{10}(t)-F_{30}(t)]$$

$$\vdots$$

$$\frac{1}{2}[F_{00}(t)+F_{20}(t)]$$

$$\frac{1}{2}[F_{10}(t)+F_{30}(t)]$$

$$\vdots$$

The respective frequency spectra contain energy either in the inner band $-\nu_m/4 \leqslant \nu \leqslant +\nu_m/4$ or in the outer band $\nu_m/4 \leqslant |\nu| \leqslant \nu_m/2$ only, as may be inferred from Fig. 6.

Asynchronous Communication

If the frequencies ω_1 and ω_2 in equations 4 and 5 are not equal, the values of the integrals I_1 and I_2 in equations 6 depend on the particular set of orthogonal functions $F_*(t)$ used. Two sets of orthogonal functions will be investigated to outline the effects of frequency variations.

Consider first the set of trigonometric functions 17. Integral I_2 taken over the symmetric products $F_1(t)F_1(t)$, $F_1(t)F_{2i+1}(t)$, $F_{2i}(t)F_{2k}(t)$, and $F_{2i+1}(t)F_{2k+1}(t)$ equals zero; similarly, I_1 vanishes for the products $F_1(t)F_{2i}(t)$ and $F_{2i}(t)F_{2k+1}(t)$.

$$I_1=I_1(F_1,F_1)=\cos(\omega_1t_1+\omega_2t_2)\int_{-\tau/2}^{\tau/2}A^2\times \cos(\omega_1-\omega_2)tdt=A^2\tau\cos(\omega_1t_1-\omega_2t_2)\frac{\sin\pi\mu}{\pi\mu}$$

$$I_1(F_1,F_{2i+1})=-\frac{1}{2}\sqrt{2}A^2\tau\times \cos(\omega_1t_1-\omega_2t_2)\frac{\mu}{i}S(\mu+i)$$

$$I_1(F_{2i},F_{2k})=-\frac{1}{2}A^2\cos(\omega_1t_1-\omega_2t_2)\times \left[\frac{\mu}{i+k}S(\mu+i+k)+\frac{\mu}{i-k}S(\mu+i-k)\right]$$

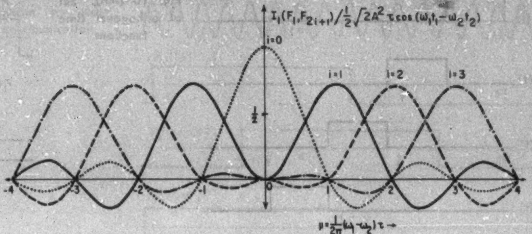

Fig. 8. Signal reduction of constant and crosstalk between constant and even functions of Fig. 2 due to carrier frequency variations

$$I_1(F_{2i+1},F_{2k+1})=\frac{1}{2}A^2\tau\cos(\omega_1t_1-\omega_2t_2)\times \left[\frac{\mu}{i+k}S(\mu+i+k)-\frac{\mu}{i-k}S(\mu+i-k)\right]$$

$$I_2(F_1,F_{2i})=\frac{1}{2}\sqrt{2}A^2\tau\cos(\omega_1t_1-\omega_2t_2)S(\mu+i)$$

$$I_2(F_{2i},F_{2k+1})=A^2\tau\sin(\omega_1t_1-\omega_2t_2)[S(\mu+i+k)+S(\mu+i-k)]$$

$$\mu=\frac{1}{2\pi}(\omega_1-\omega_2)\tau$$

$$S(\mu+i+k)=\frac{\sin\pi(\mu+i+k)}{\pi(\mu+i+k)}-\frac{\sin\pi(\mu-i-k)}{\pi(\mu-i-k)} \qquad (24)$$

Plots of the functions $I_1(F_1, F_{2i+1})$ are shown in Fig. 8. It may be seen that a frequency difference $\mu=\pm 1/2$ results in a crosstalk $I_1(F_1, F_3)$ from $F_3(t)$ to $F_1(t)$ which is almost as strong as the desired information $I_1(F_1, F_1)$.

For a Teletype system the period τ is the time required to transmit one character, $\tau=166.6$ ms (millisecond). The normalized frequency difference $\mu=\pm 1/2$ corresponds in this case to an actual frequency difference $f_1-f_2=\tau/\mu=\pm 3$ cps (cycles per second).

Time functions $F_i(t)$ which permit larger frequency differences may be obtained by transmitting, for instance, the function $F_1(t)+F_3(t)$ instead of $F_1(t)$. The permissible frequency difference μ is, in this case, increased to about $\mu\pm 3/2$, but the bandwidth required for a certain information rate is also increased.

Of more practical interest is the change of sign of $I_2(F_1, F_2)$ at $\mu=0$ in Fig. 9 which permits automatic tuning of the receiver carrier to the transmitter carrier.

The second set of orthogonal time functions to be considered is shown in Fig. 10. Superposition of these functions and the functions $F_{b,-i}(t)=-F_{b,i}(t)$, $i=1$, 2, 3, 4, 5, yields the 32 time functions produced by a balanced teletypewriter. The "worst" superpositions of these funtions, e.g., $F_{b1}(t)+F_{b2}(t)-F_{b3}(t)+F_{b4}(t)+F_{b5}(t)$ require about five times the bandwidth (measured by the first zero crossing of the frequency spectra) of any superposition of the five functions of Fig. 2. In return, these functions do not pro-

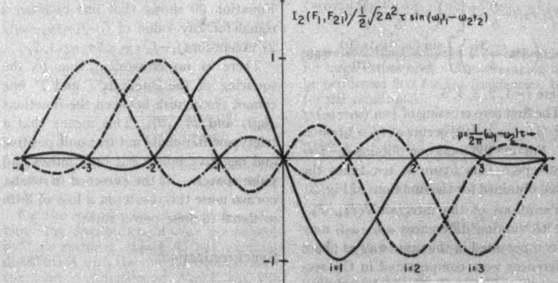

Fig. 9. Crosstalk between constant and odd functions of Fig. 2 due to carrier frequency variations

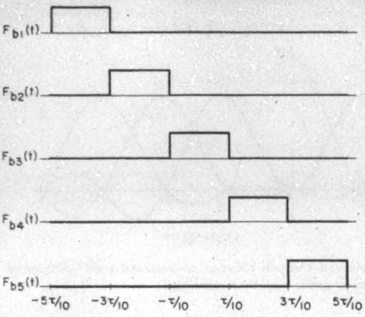

Fig. 10 (left). Set of orthogonal time functions

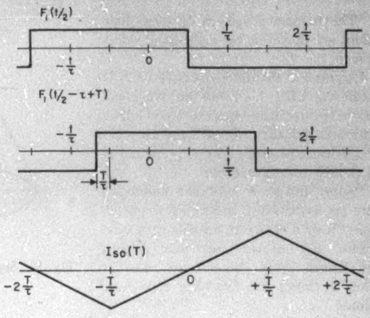

Fig. 11 (right). Synchronization for wire communication

duce any crosstalk due to differences of phase or frequency between transmitter and receiver carrier; peak power and average power are the same for any superposition of these functions whereas the superposition of the five functions of Fig. 2 produces peak powers which equal almost five times the average power. Integrals I_1 and I_2 of equations 6 may be readily computed. One obtains, for instance:

$$I_1=I_1(F_{b3},F_{b2})=\cos(\omega_1 t_1-\omega_2 t_2)\times \int_{-\tau/10}^{\tau/10}\cos(\omega_1-\omega_2)t\,dt=\frac{\tau}{5}\times \cos(\omega_1 t_1-\omega_2 t_2)\,\frac{\sin(\omega_1-\omega_2)\tau/10}{(w_1-w_2)\tau/10}$$

$$I_2=I_2(F_{b3},F_{b3})=-\sin(\omega_1 t_1-\omega_2 t_2)\times \int_{-\tau/10}^{\tau/10}\sin(\omega_1-\omega_2)t\,dt=0 \quad (25)$$

There are no crosstalk integrals.

$$I_1(F_{bi},F_{bk})=I_2(F_{bi},F_{bk})=0,\ i\neq k$$

Of interest are the sums

$$I(F_{bi},F_{bi})=-I(F_{bi},F_{b,-i})=I_1(F_{bi},F_{bi})+I_2(F_{bi},F_{bi})$$

$$I(F_{bi},F_{bi})=\frac{\tau}{5}\cos\left[\omega_1\left(t_1+\frac{i-3}{5}\tau\right)-\omega_2\left(t_2-\frac{i-3}{5}\tau\right)\right]\frac{\sin(\omega_1-\omega_2)\tau/10}{(\omega_1-\omega_2)\tau/10} \quad (26)$$

where $i=1, 2, 3, 4, 5$.

The first zero crossing of $[\sin(\omega_1-\omega_2)\tau/10]/[(\omega_1-\omega_2)\tau/10]$ occurs at $(f_1-f_2)\tau=\pm 5$. For $\tau=166.6$ ms one obtains $f_1-f_2=\pm 30$ cps. This figure is ten times the value obtained for the functions of Fig. 2.

Variations of the integrals $I(F_{bi}, F_{bi})$ due to varying differences $\omega_1 t_1-\omega_2 t_2$ may be compensated in the same way as phase differences were compensated in the section "Synchronous Communications." Let the received signal, equation 4, be correlated with:

$$f_k'(t)=\sqrt{2}F_k(t)\sin\omega_2(t+t_2) \quad (27)$$

One obtains:

$$I'=\int_{-\tau/2}^{\tau/2} f_i(t)f_k'(t)dt=I_1'+I_2'+I_3'+I_4'$$

$$I_1'=I_1'(F_i,F_k)=-\sin(\omega_1 t_1-\omega_2 t_2)\times \int_{-\tau/2}^{\tau/2}F_i(t)F_k(t)\cos(\omega_1-\omega_2)t\,dt$$

$$I_2'=I_2'(F_i,F_k)=-\cos(\omega_1 t_1-\omega_2 t_2)\times \int_{-\tau/2}^{\tau/2}F_i(t)F_k(t)\sin(\omega_1-\omega_2)t\,dt \quad (28)$$

I_3' and I_4' are of the form of I_3 and I_4 in equations 6 and vanish for large values of $\omega_1+\omega_2$.

The sums:

$$I'(F_{bi},F_{bi})=-I'(F_{bi},F_{b,-i})=I_1'(F_{bi},F_{bi})+I_2'(F_{bi},F_{bi}) \quad (29)$$

yield the values equations 26 except that cos in front of the bracket is replaced by −sin.

One obtains from equations 26 and 29:

$$I^2(F_{bi},F_{bi})+I'^2(F_{bi},F_{bi})=I^2(F_{b,i}F_{b,-i})+I'^2(F_{bi},F_{b,-i})=\left(\frac{\tau}{5}\right)^2\left(\frac{\sin(\omega_1-\omega_2)\tau/10}{(\omega_1-\omega_2)\tau/10}\right)^2 \quad (30)$$

Equation 30 shows that one receives a signal for any value of $f_1-f_2=(\omega_1-\omega_2)/2\pi$ except for $(f_1-f_2)\tau=\pm 5n$; $n=1, 2, \ldots$

There is no crosstalk. Due to the squaring of the integrals I and I' one cannot distinguish between the functions $F_{bi}(t)$ and $F_{b,-i}(t)$. This means that a teletypewriter could not transmit positive and negative pulses but only pulses and pulse spaces. In the presence of white, normal noise this results in a loss of 3 db in signal-to-noise-power ratio.

Synchronization

Orthogonal time functions may be constructed which permit a certain amount of time shift between $F_i(t)$ and $F_k(t)$ without invalidating relation 3. In general, however, one will try to avoid such a shift and synchronize $F_i(t)$ and $F_k(t)$. The principle of a synchronization method based on correlation will be explained with reference to Fig. 11.

The function $F_1(t/2)$, which has twice the duration of $F_1(t)$ in equation 17, and the function $F_{-1}(t/2)=-F_1(t/2)$ are transmitted alternatingly. At the receiver the same square wave delayed by τ is produced. Multiplication of the two square waves and integration from $-\tau/2$ to $+3\tau/2$ yields zero. If, however, the square wave of the receiver is advanced, the integration will produce a positive output; on the other hand, a negative output will be obtained if the receiver is retarded. I_{so} represents the output of the integrator for any time difference between the two square waves. The point $T/\tau=0$ is stable and the points $T/\tau=\pm 2$ are unstable if a positive value of I_{so} is used to retard the receiver and a negative one to advance it.

The information carrying functions $F_{2i}(t)$ and $F_{2i+1}(t)$ of equation 17 are orthogonol to $F_1(t/2)$, for $T=0$ they are also orthogonal to $F_1(t/2-\tau+T)$. A synchronization error produces crosstalk between the information carrying functions and $F_1(t/2-\tau+T)$. Hence, the integral I_{so} should be averaged over several periods τ to prevent the crosstalk from affecting the synchronization.

For the discussion of the application of the synchronization technique to radio communication refer to Fig. 12. The transmitter carrier $\cos\omega t$ is modulated by the square wave $F_0(t/2)$. At the receiver the two carriers $\cos(\omega t-\tau+T)$ and $\sin(\omega t-\tau+T)$ are modulated by the functions $F_0(t/2-\tau+T)$ and $F_0(t/2+T)$. One obtains the following correlations:

$$I_{s1}(T)=\int_{-(\tau/2+\tau)}^{3\tau/2-\tau}F_0(t/2)F_0(t/2-\tau+T)\times \cos\omega t\cos\omega(t-\tau+T)dt\doteq T\cos\omega T$$

$$I_{s2}(T)=\int_{-(3\tau/2+T)}^{\tau/2-T} F_0(t/2)F_0(t/2+T)\times$$
$$\cos \omega t \cos \omega(t-\tau+T)dt \doteq (\tau-T) \cos \omega T$$

$$I_{s3}(T)=\int_{-(\tau/2+T)}^{2\tau/2-T} F_0(t/2)F_0(t/2-\tau+T)\times$$
$$\cos \omega t \sin \omega(t-\tau+T)dt \doteq T \sin \omega T$$

$$I_{s4}(T)=\int_{-(3\tau/2+T)}^{\tau/2-T} F_0(t/2)F_0(t/2+T)\times$$
$$\cos \omega t \sin \omega(t-\tau+T)dt \doteq (\tau-T) \sin \omega T \quad (31)$$

$$I_{s1}(T)I_{s2}(T)+I_{s3}(T)I_{s4}(T) \doteq T(\tau-T);$$
$$0 \leqslant T \leqslant \tau \quad (32)$$

The sum 32 for any value of T is shown in Fig. 12. This function has only one half the period of the function $I_{s0}(T)$ in Fig. 11 but may otherwise be used in the same way for synchronization. For the phase synchronization of the receiver the function $I_{s3}(T)$ is better suited than the function 32 since it is subject to fewer mathematical operations.

Appendix

The following is a discussion of error probability due to white, normal noise.

Let the function $F_m(t)$ in the interval $-\tau/2 \le t \le \tau/2$ be represented by a superposition of the functions 17; that is, by a Fourier series.

$$F_m(t)=\sum_{k=-\infty}^{\infty} a_{mk}e^{2ik\pi t/\tau} \quad (33)$$

$$a_{mk}=\frac{1}{\tau}\int_{-\tau/2}^{\tau/2} F_m(t)e^{-2ik\pi t/\tau}dt$$

$$\int_{-\tau/2}^{\tau/2} F_m(t)F_m{}^*(t)dt=\tau\sum_{k=-\infty}^{\infty} a_{mk}a_{mk}{}^*=E \quad (34)$$

Consider white noise in the frequency domain. Let the frequency band be divided into intervals $\Delta f=f_l-f_{l-1}$. The probability that a sample of noise has a frequency component between f_l and f_{l-1} is independent of l. The amplitudes of the frequency components in any interval have a normal distribution. A sample of noise can be represented by a Fourier series:[4]

$$g(t)=\sum_{l=-\infty}^{\infty} A_l e^{2il\pi\Delta f t} \quad (35)$$

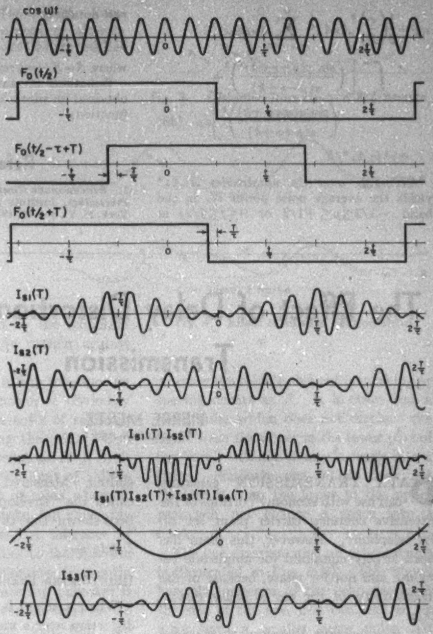
where the A_l have a normal distribution.

If a signal $\phi(t)$ is transmitted through a noisy channel it arrives at the receiver in the form $\phi(t)+g(t)$. The correlation of this signal with $\sqrt{2}F_m(t)\cos(\omega t+\phi)$ yields:

$$\sqrt{2}\int_{-\tau/2}^{\tau/2}[\phi(t)+g(t)]F_m(t)\cos(\omega t+\phi)dt$$

The contribution $N_m\tau$ of the noise to this integral is obtained with the help of equations 33 and 34.

Fig. 12. Synchronization for radio communication



$$N_m\tau=\sqrt{2}\int_{-\tau/2}^{\tau/2} g(t)F_m(t)\cos(\omega t+\phi)dt$$
$$=\frac{1}{2}\sqrt{2}\tau\sum_{k=-\infty}^{\infty}\sum_{d=-\infty}^{\infty} A_l a_{mk}\times$$
$$\{\cos\phi\, S(\mu-\nu+k)-i\sin\phi S'(\mu-\nu+k)\}$$

$$\mu=\tau l\Delta f, \nu=\tau f$$

$$S(\mu-\nu+k)=\frac{\sin \pi(\mu-\nu+k)}{\pi(\mu-\nu+k)}+\frac{\sin \pi(\mu+\nu+k)}{\pi(\mu+\nu+k)}$$

$$S'(\mu-\nu+k)=\frac{\sin \pi(\mu-\nu+k)}{\pi(\mu-\nu+k)}-\frac{\sin \pi(\mu+\nu+k)}{\pi(\mu+\nu+k)} \quad (36)$$

where μ becomes a continuous variable for $\Delta f \rightarrow 0$ and the sum over l becomes an integral.

For the computation of the error probability the distribution of $N_m\tau$ normalized by E is required. Since A_l has a normal distribution with the average equal to zero the joint distribution of $N_l\tau/E$ has the form:

$$W(N_l\tau/E)=(2\pi)^{-1/2}\sigma^{-1}\times \exp[-(N_l\tau/E)^2/2\sigma^2]$$

A component of $g(t)$ with amplitude A_λ and frequency $\mu=\lambda\Delta f\tau$ correlated with $\sqrt{2}F_m(t)\cos(\omega t+\phi)$ produces the term for $l=\lambda$ in equation 36. The square of this term divided by E is the square deviation $\sigma_{A\mu}{}^2$ for a particular amplitude and a particular frequency from the average $\overline{N_l\tau/E}=0$.

$$\sigma_{A\mu}{}^2=\frac{1}{2}\left(\frac{\tau}{E}\right)^2 A_\lambda A_\lambda{}^*\sum_{k=-\infty}^{\infty} a_{mk}\zeta\sum_{k=-\infty}^{\infty}\times a_{mk}{}^*\zeta^*$$

$$\zeta=\cos\phi S(\mu-\nu+k)-i\sin\phi S'(\mu+\nu+k) \quad (37)$$

where σ^2 is the average of R deviations $\sigma_{A\mu}{}^2$ for large values of R. The averaging may be performed first for the frequencies, then for the amplitudes.

$$\sigma_A{}^2=\frac{1}{2}\left(\frac{\tau}{E}\right)^2 A_\lambda A_\lambda{}^*\sum_{k=-\infty}^{\infty} a_{mk}a_{mk}{}^*\times \int_{-\infty}^{\infty}[\cos^2\phi S^2(\mu-\nu+k)+\sin^2\phi S'^2(\mu-\nu+k)]d\mu$$

For large values of ν the terms:

$$2\frac{\sin \pi(\mu-\nu+k)}{\pi(\mu-\nu+k)}\,\frac{\sin \pi(\mu+\nu+k)}{\pi(\mu+\nu+k)}$$

of $S^2(\mu-\nu+k)$ and $S'^2(\mu-\nu+k)$ may be neglected and one obtains:

$$\sigma_\lambda^2 \doteq \frac{1}{2}\left(\frac{\tau}{E}\right)^2 A_\lambda A_\lambda^* \sum_{k=-\infty}^{\infty} a_{mk}a_{mk}^* \times$$
$$\int_{-\infty}^{\infty}\left[\left(\frac{\sin \pi(\mu-\nu+k)^2}{\pi(\mu-\nu+k)}\right)^2 + \left(\frac{\sin \pi(\mu+\nu+k)}{\pi(\mu+\nu+k)}\right)^2\right]d\mu \quad (38)$$
$$\doteq \tau^2 A_\lambda A_\lambda^*/E$$

Averaging over the amplitudes $A_\lambda A_\lambda^*$ yields the average noise power N_n in the band $-1/2 \leq \mu \leq +1/2$ or $0 \leq f \leq 1/2\tau$ in real notation.

$$\sigma^2 = \tau N_n/E = N_n/S \quad (39)$$

where $S = E/\tau$ = average signal power.

Equations 38 and 39 are the same as obtained for wire transmission of orthogonal functions.

The Effect of Delay Distortion on Data Transmission

PIERRE MERTZ
NONMEMBER AIEE

DATA TRANSMISSION generally can use with economy portions of the extensive common carrier plant set up for telephony. However, this plant has been largely equalized for amplitude response and not for phase, because of the insensitivity of the ear to phase distortion.

It is important therefore to consider the effects of phase and delay distortion on the data signal. The paper starts with a brief review of the relations between phase shift and delay, and goes on to a general appraisal of possible tolerances on distortions in these characteristics.

Phase Shift and Delay in Transmission

When an unmodulated wave is transmitted over a distance its phase is shifted. The shift can be measured in degrees or radians, or also as a delay in seconds. The radian shift ϕ is equal to

$$\phi = \omega t \quad (1)$$

where

ω = radian frequency, radians/(second) = $2\pi\times$cyclic frequency, cps (cycles/sec)
t = time, sec

When an amplitude-modulated wave is transmitted, the phase of its carrier is similarly shifted. Also its envelope is shifted. Measured in seconds, this is called the "envelope delay" D. It has been shown[1] that this is equal to

$$D = d\phi/d\omega \quad (2)$$

Undistorted Transmission

When a signal is transmitted without distortion over a medium, the amplitude response of the medium is independent of frequency in the utilized band, and the phase shift is proportional to the frequency. In Fig. 1 signal B is a delayed replica of A and the amplitude response and phase shift respectively of the medium appear in dotted lines at the right.

Distorted Transmission

Where medium characteristics show a ripple or other deviation as in the solid lines at the right of Fig. 1 the signal is distorted in transmission.[2] In the case shown the distortion consists of an echo C. Often it is convenient in the phase characteristic to show only the departure from linearity as indicated in the lower right of the figure.[3]

Coarser or finer ripples in the medium characteristics indicate respectively closer-in or more remote echoes, as shown in Fig. 2.

A badly distorting circuit can be improved by the use of an "equalizer." This adds extra loss or phase shift respectively at the frequencies where these are low in the circuit, and as little as possible where they are high. Generally the further discussion in the paper holds equally for the phase distortion in the untreated circuit and for the residual distortion left after phase correction. However, usually the departures in characteristics for the untreated circuit follow broad sweeping curves; in the residuals they tend to follow fine-grained ripples.[4]

Distortion Tolerances on Data Signals

Objectives

In engineering a transmission system it is often necessary to place a tolerance limit on the distortion to be permitted in the signal. It is very simple if this tolerence can be merely set as plus and minus limits on some specific measurement on the medium. This is analogous to dimensional tolerances, say in machining a sample. It is especially desirable

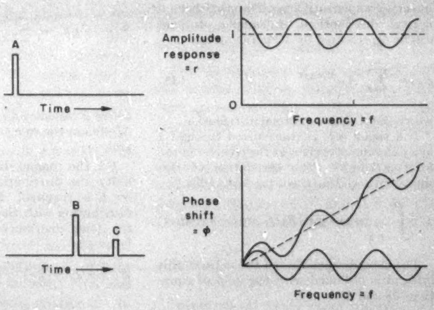

Fig. 1. Echo description in time and frequency

Paper 60-27, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted October 26, 1959; made available for printing November 13, 1959.

Pierre Mertz is with the Rand Corporation, Santa Monica, Calif.

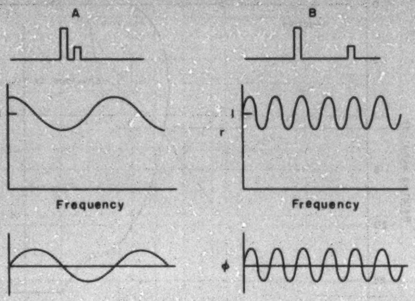

Fig. 2 (left). Comparison of close-in and remote echoes

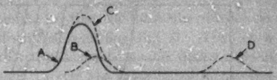

Fig. 3. Distortion from close-in and remote echoes

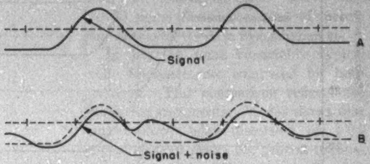

Fig. 4. Effect of noise in causing error

for this plus and minus tolerance to be independent of the exact shape of the departure. For example, in Fig. 2 it is desirable for the same tolerance to hold for coarse or fine ripples.

While there is an advantage in having this invariability exact, it is to be recognized that in a complicated system an approximation is often really sufficient. The penalty for transgressing tolerances slightly is not always catastrophic, and unless this is the case a reasonable approximation will do.

Thus the objective in appraising signal distortion is to find some measurement of the medium which is related to the penalty for the distortion in a manner that does not depend too much on the specific shape of the distortion.[5]

Echo Effects on Noise Tolerance

Fig. 3 illustrates an original signal at *A*, a close-in echo at *B*, and a remote echo at *D*. It shows that *B* distorts *A* into *C*. *C* differs from *A* chiefly by being larger, but also because the shape is changed a little. The size would be readjusted by a gain change in lining up the system; but to bring the shape back is another problem. One would guess that the close-in echo *B* would cause less penalty than the remote echo *D*. Also the effect from *B* is probably more sensitive to exact delay than that from *D*.

The nature of the penalty is suggested in Fig. 4. Here in row *B* one sees how noise can cause errors in the interpretation of a signal. Thus in the space after the first mark the added noise shown changes the space into a mark. The original signal can stand some noise before an error is caused. That is, the noise peak has to be about half the signal amplitude before an error is likely. It is clear, however, that this margin can be reduced by an echo which distorts the signal.

Thus the important penalty of a signal distortion is measured by the reduction which it causes in the margin against noise.

It is difficult to set a firm tolerance on this noise penalty because it obviously depends upon relative costs of reducing the noise and reducing the echo.[6] One may consider noise penalties of 1, 3, 6, and 10 db (decibels). A limit of 1 db is severe, to be applied in cases where it is easy to remove the echo, but expensive to eliminate the noise. A tolerance of 10 db is lax, and applies to the opposite extreme cases. A tolerance frequently used for general engineering purposes is 3 db. Of course, even if there is no noise at all, extreme distortion can cause error. This represents the maximum possible echo tolerance.[7] It is about 6 db down from the signal amplitude for the remote echoes.

A diagram which permits a simple evaluation of the noise penalty in specific cases is shown in Fig. 5(A). Here *A*, *B*, *C*, and *D* each shows three consecutive signal elements,[8] and depicts all the transitions which can occur between the middle element and the outer two. At *E* all four transitions are superimposed, together with the all mark and all space cases. The receiver sampling to detect whether the middle element is marking or spacing occurs at *F*. It is clear that a noise pulse which does not displace the signal from the upper to the lower part of the "eye" will not change a mark into a space. Similarly one which does not displace it from the lower to the upper part will not change a space into a mark.

The eye diagram with an echo present is illustrated in Fig. 5(B). This shows how the presence of the echo decreases the size of the eye, and can lead to an error with a smaller noise pulse. It also displaces slightly the best time for sampling.

By constructing diagrams such as this it is possible to plot curves of the nature shown in the solid lines of Fig. 6. These cover positive echoes i.e., where whites are echoed as whites, and blacks as blacks, in an AM (amplitude-modulation) system. In Fig. 6 the 3-db curve shows the relative echo amplitude giving a 3-db noise penalty at various echo delays measured in signal elements. The curve follows the trend which was guessed earlier. That is, larger echo

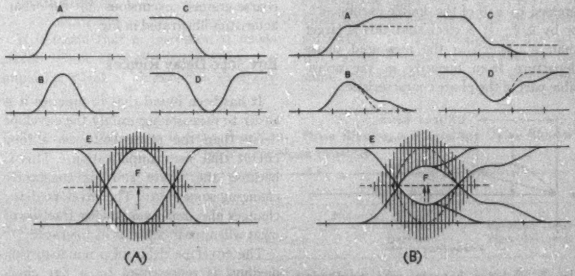

Fig. 5. "Eye" diagram

A—For undistorted signal B—With echo

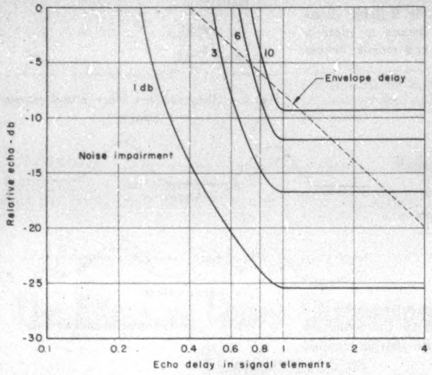

Fig. 6. Noise impairment from positive echoes of varying amplitudes and delays

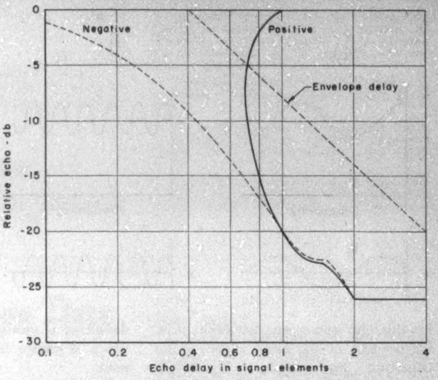

Fig. 8. Echo amplitude versus echo delay for measured departure from phase linearity of 1/10 radian

amplitudes are permissible for a close-in than for a remote echo, for a given noise penalty.

Noise impairment curves for 1, 6, and 10 db, all for positive echoes, are also plotted in Fig. 6.

ECHO VERSUS RIPPLE AMPLITUDES

In Fig. 1 it turns out that if a is the relative echo amplitude, then a is also the ripple amplitude in the response characteristic if this is plotted in radians. This is independent of the fineness of the ripple. Because of such independence it does not appear at first glance that the ripple amplitude can characterize echo penalty, which has just been shown to vary with echo delay.

However it is to be noted that when the echo delay is less than one signal element, less than one whole wave of the ripple will appear within the utilized frequency band, in the medium characteristics. This is illustrated in Fig. 7

Here the real echo amplitude is expressed by half of the double excursion h, or by $h/2$. It is clear that this is larger than h', which is the measured phase departure from linearity in the accessible part of the phase characteristic.

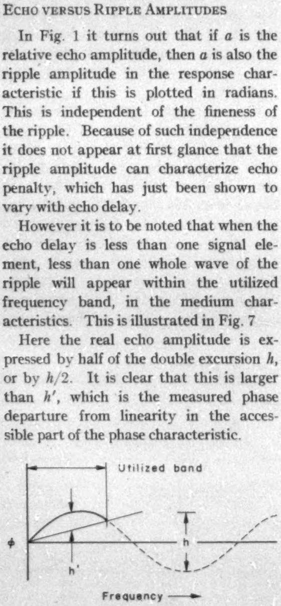

Fig. 7. Relation between echo amplitude and measured phase distortion for very-close-in echo

Thus if one sets a specific tolerance h' at all echo delays, it will correspond to larger and larger real echo amplitudes as the echoes get closer and closer in. The curve actually obtained for positive echoes is plotted in Fig. 8, for a measured h' of 1/10 radian. The curve for a negative echo is somewhat different.

SELECTION OF DISTORTION TOLERANCE

The positive curve in Fig. 8 does not really match the 1-db curve of Fig. 6, but it does show the same trend. In practice it is close enough to say that the phase departure from linearity within the utilized frequency band represents a fairly good index of the noise penalty incurred from the phase distortion, and is a good measurement on the medium upon which to place a tolerance.

It is possible in principle to set echo tolerances from the amplitude response, as well as the phase shift. In practice, however, it is found more difficult, especially say in handling the very coarse-grained excursions in the characteristics illustrated in Fig. 7.

Envelope Delay Ripples

It has been found that in practice it is easier to measure accurately the envelope delay than the phase shift, on a long circuit that uses amplification. This is because the phase shift is constantly changing somewhat. The envelope delay changes also, but by a smaller fraction of what will appear below as its tolerance.

The envelope delay of a nondistorting medium is represented by a flat characteristic, independent of frequency.

The envelope delay of the distorting medium has ripples in it which correspond in wavelength (in the frequency plot) to those in the phase shift, as shown in Fig. 9. The phase departure from linearity appears at the left, and the envelope delay at the right, for the three echoes A, B, and C.

Since the envelope delay is a derivative of the phase, the amplitude of its ripples is affected both by their fineness of structure and by the echo amplitude. In the figure the envelope delay ripples all show the same amplitude. This corresponds to a large close-in echo A, and a much smaller remote echo C. The phase departure ripples in each case are proportional in amplitude to the echoes.

ENVELOPE DELAY TOLERANCES

In the plot of Fig. 6, a fixed tolerance on envelope delay ripple corresponds to

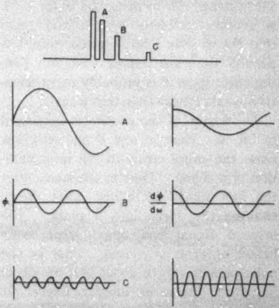

Fig. 9. Comparison between ripples in phase and in envelope delay for close-in and remote echoes

Vol.
Pt. 1
196

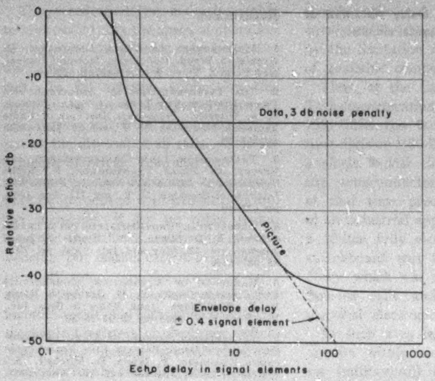

Fig. 10. Comparison of echo tolerances for data and picture transmission

a large close-in echo, but a much smaller remote echo. The course is shown by the diagonal dotted line. For fractional ripples within the utilized frequency band, i.e., at the extreme left of the plot, an additional up-turn would be experienced as discussed for the phase ripples. It is left out of the figure for simplicity.

Toward the right of the figure the fixed envelope delay tolerance for finer and finer grained ripples specifies smaller and smaller remote echo amplitudes. For echo delays of over one signal element this means smaller and smaller noise penalties. Thus a rigidly applied fixed envelope delay tolerance tends to over-engineer the system with respect to fine-grained ripples.

In practice it has been found that tolerances on the envelope delay ripples in general represent a reasonably good measure of the noise penalty, with an important proviso. The tolerance cannot be applied slavishly to fine-grained ripples, and these can be allowed larger excursions.

Two-Parameter Specfications

An envelope delay distortion characteristic represents an infinite continuum of values over some utilized frequency range. A tolerance on excursions from flatness gives a one-parameter characterization of noise penalty. It does not, however, even suggest a possible remedial or equalizing characteristic.

In unpublished memoranda of 1948, K. W. Pfleger, of Bell Telephone Laboratories, described the rather small delay distortion of wide-band filters in portions of their pass bands by two parameters. These were respectively the "slope" of the delay curve between the extremes of the utilized portion of the pass band (in the given voice channel), and the "sag" at midpoint below the straight line slope.

This description has been extended by Gibbey and Fowler[9] to cover much larger distortions occurring in voice band width transmission lines of appreciable lengths. The two-parameter description permits the advantage of a "prescription" type of equalization, i.e., based only on the parameters and not requiring a complete delay-frequency characteristic. This assumes a parabolic curve for the characteristic, as approached frequently in practice. In such cases the equalizers are chosen to have exactly the negative slope and sag, in envelope delay, of the untreated medium.

The principal weakness of the two-parameter specification, according to the authors, lies in an undue sensitivity of the noise penalty to minor variations in the exact shape of the characteristic when the penalty runs over some 3 db.

Comparison with Pictorial Transmission

It is found that in television or news-picture grade facsimile transmission the impairing effect of an echo[10] is generally similar to that for data transmission as discussed regarding Fig. 3. That is, a remote echo can be smaller than a close-in echo to give the same impairment—but after a sufficient separation the variation ceases. However, for pictorial transmission the transition comes after some 20–50 signal elements instead of merely one or two for the data transmission.

In Fig. 10 some reasonably typical echo tolerances are compared for both systems. This comparison reflects the foregoing statements. It also shows that an envelope delay distortion of ±0.4 signal element meets the general requirements for both. However, it is additionally clear that the envelope delay criterion has significance much farther into the remote echoes (or the fine structure distortion) for the pictorial than for the data transmission. By the same token the fine-structure phase departure from linearity is not as useful for the pictorial transmission.

Conclusions

It has been shown that phase or delay distortion in a propagating medium results in a noise penalty for the transmission of a signal. This penalty can be reasonably well measured in terms of the departures of the phase from linearity in the utilized frequency band; or, with precautions, in terms of the envelope delay distortion.

A tabulation, for AM transmission, of the basic tolerances on echo amplitude, phase ripples, and envelope delay ripples is given in Table I, for various noise penalties. The phase ripple magnitudes are measured in radians and degrees, and the envelope delay ripples in signal elements.

In AM systems, the figures are roughly applicable to either baseband or carrier (single or double sideband). At the very edges of the band, where signal energy is quite low, the tolerances can be relaxed somewhat. For FM (frequency-modulation) systems under approximately the same as double sideband conditions

Table I. Basic Tolerances in Echo Amplitude, Phase Ripples, and Envelope Delay Ripples for Various Noise Penalties

		Ripple Magnitude		
		Phase		
Noise Penalty, Db	Relative Echo Amplitude, Db	Radians	Degrees	Envelope Delay Signal Elements
1	−25	±0.06	± 3.5	±0.15
3	−17	±0.15	± 9	±0.4
6	−12	±0.26	±15	±0.7
10	− 9	±0.34	±20	±0.9

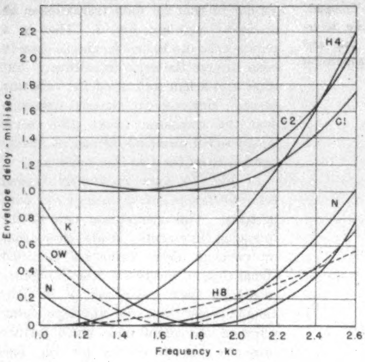

Fig. 11. Delay distortion of typical circuits

practical experience indicates the tolerances to be somewhat tighter. For FM systems where the edges of the band are appreciably cut into, i.e., leaving a total less than double sideband width, the tolerances become even tighter.

For general information the envelope delay distortions of a few typical circuits are plotted in Fig. 11. These are generally only approximate in any specific case, the exact value being subject to the precise composition of the circuit in terms of possible filters, networks, coils, wire line conductors, etc. In part they are taken from reference 9.

The circuits illustrated are:

H4 = 400 miles *H44* loaded cable
H8 = 20 miles *H88* loaded cable
K = 5 links *K* carrier
N = 4 links *N* carrier
OW = 8 repeater sections *VF* open wire
C2, *C1* = 1 link *C5* carrier, maximum and and minimum distorting channels, respectively

The *C5* carrier varies in distortion from channel to channel, mostly because of directional separating filters. The data assume no intermediate repeater; addition of these for greater lengths increases the variation among channels.

The data are plotted to displaced axes, with minimum delay equal to zero or 1 millisecond.

A 240-Line Fully Electronic Telephone Switchboard

G. GOUDET
NONMEMBER AIEE

THE EVOLUTION of electromechanical switching systems shows a trend toward specialization of their functional elements and tends to their separation into two categories:

1. Those elements the function of which is to establish a connection between the calling and the called subscriber; they constitute the speech circuit.
2. Those elements the function of which is to give the instructions necessary for the operation of this circuit; they constitute the control circuit.

The latter is nothing more than a special computer and as such it must include, on the one hand, memories which contain at least the information describing the condition of the system, and on the other hand, a logical circuit which is capable, according to the previous and present data, of preparing the instructions to be given to the speech circuit. A modern switching system is therefore divided into speech circuit, logical circuit, and memories.

From the functional point of view these three parts have quite different characteristics, particularly if one compares the minimum time which each of them should devote to the communication between two subscribers. The logical circuit intervenes essentially for the establishment or the release of connections. Its action has therefore a transitory character and the duration of its interventions depends only on its own speed of operation. The situation is different with certain memories, for instance, those which register the number of a called line. This recording lasts, in fact, during the entire time necessary for dialing; it cannot be suppressed if one wants to give the logical circuit all the desirable flexibility and speed.

As for the speech circuit, it is known that, with electromechanical systems, its elements providing a path for a given conversation remain busy for its duration.

Paper 60-233, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted October 30, 1959; made available for printing December 30, 1959.

G. Goudet is with the Laboratoire Central de Télécommunications, Paris, France.

The preceding analysis makes it possible to understand that the speed of operation of electronic components may be particularly well utilized within the logical circuit. In its extreme application this speed avoids any duplication of elements, one single logical circuit being successively put at the disposal of all calls. It is the principle known as "time sharing."

Naturally, the electronic components may be introduced with benefit also into the memories, if for no other reason than for the sake of uniformity of components, but in this case it is impossible to apply completely the preceding principle. Just as a crossbar central office includes a relatively high number of electromechanical registers, an electronic switchboard must include several electronic memories for the recording of several calls simultaneously in progress.

Finally, for the speech circuit, one may envisage three different types of solutions,[1] as follows:

Semielectronic Switching System: The first type consists in keeping mechanical contacts chosen with a sufficiently high speed and low power requirement to make them operable from an electronic control circuit; one then obtains a semielectronic switching system.[2,3]

Space-Division Electronic Switching System. The second solution consists in utilizing electronic contacts according to the same schemes as those of mechanical contacts. The establishment of a connection is then performed by choosing a conducting path between the calling and called line in a complex network of contacts. Here one obtains a space-division electronic switching system.[4]

Time-Division Electronic Switching System. The third solution consists in applying to the speech circuit the time-sharing principle such as is currently used in the time-division multiplex links: samples of each conversation signal are periodically taken, the different sets of samples are interleaved, and, finally, the complex train of pulses is sent over a transmission channel. Thus, a number of simultaneous conversations can be handled on a single circuit. Following this principle one obtains a time-division electronic swiching system.[5]

Previous Development Work

It follows that several types of electronic switchboards may be conceived, differing by the extent to which the time-sharing principle is applied, from a single one-at-a-time control and a time-sharing speech circuit, to space-division speech paths and many logical control circuits. The choice is heavily influenced by the limitation in speed of operation of available components.

Thus, at the Laboratoire Central de Télécommunications, was constructed in 1951–1952 the laboratory model of a time-division 100-line switchboard with a single logical circuit. Unfortunately, the semiconductor elements available at that time precluded the feasibility of an industrial application; but in 1957 a 20-line fully electronic space-division switchboard was built for the French Navy which was capable of two simultaneous calls and which required two identical electronic registers.

In such a system no assembly need operate within times smaller than one ms (millisecond) which is very easily satisfied by the electronic components used, especially by the silicon junction diodes utilized as crosspoints in the speech circuit. This equipment has already been described.[6] It has proved its ruggedness and its perfect reliability under the very severe operating conditions met with on board a battleship. It applies only to a small extent the principle of time sharing, certain parts of the logical circuit being permanently assigned to each of the 20 lines and other parts to each of the two registers. However, this was justified by the very small capacity of the equipment.

On the contrary, the realization on the same basis of central offices up to several thousands of lines would be economically inadmissible. It would lead to too high a multiplicity of identical elements, whereas the semiconductor devices presently available make it possible to replace them by a single central logical circuit.

It is precisely to demonstrate this possibility that a 240-line PABX was built, conceived in such a way that the applied solutions can be extended to offices of up to several thousands of lines. This equipment will now be described, with the help of the general block diagram of Fig. 1 and the detailed diagrams mentioned in the course of the text.

The 240-Line PABX

SPEECH CIRCUIT

The Crosspoint. The speech circuit utilizes as an electronic crosspoint a cold cathode gas diode. This diode is similar to a tube developed at the Bell Telephone Laboratories.[7] Its firing voltage V_F is about 170 volts and its sustaining voltage V_S is about 107 volts.

This type of crosspoint is advantageous for switching because of the following property: If a set of tubes is permanently supplied at a voltage V_0 comprised between V_S and V_F, it is sufficient, for firing one of them, to apply temporarily between its terminals an additional voltage greater than $V_F - V_0$. After the suppression of this marking voltage the tube will remain fired; for this reason it is considered a crosspoint provided with a memory. This property is essential for performing the marking by the horizontal and vertical wires in a matrix of tubes. Furthermore, the gas diode used possesses a current-voltage characteristic, the slope of which is negative around the operating point, 107 volts, 11 ma (milliamperes).

The average dynamic impedance is that of a resistance of −80 ohms and of an inductance of 18 millihenrys. Advantage has been taken of the negative resistance

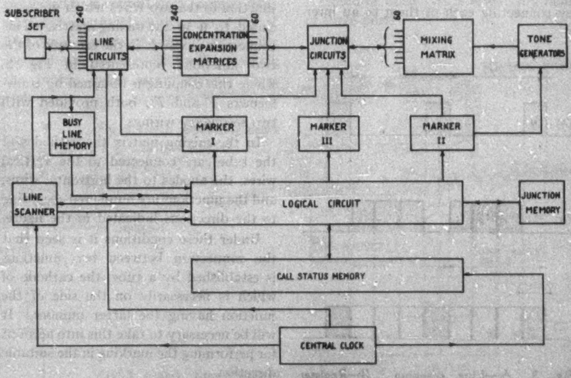

Fig. 1. General block diagram

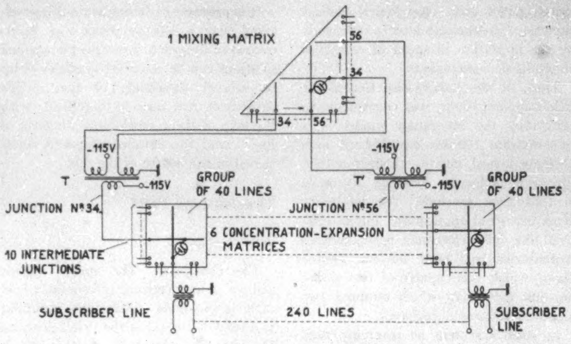

Fig. 2 Block diagram of speech circuit

for compensating the unavoidable losses in connection with the other parts of the speech circuit. At rest, the tube is equivalent to a capacity of 3 picofarads, which makes it possible to maintain cross-talk between lines at a sufficiently low level.

Structure of Speech Circuit. The speech circuit block diagram is shown in Fig. 2. It is a 1-wire circuit comprising two selection stages. In the first stage the lines are subdivided into six groups of 40 lines each. Each group of lines enters into a rectangular matrix of $40\times10=400$ gas tubes which gives access to ten outgoing intermediate junctions. There are therefore a total of 60 such junctions. Any two of these junctions can be interconnected, thanks to a triangular matrix comprising $(60\times59)/2=$ 1,770 tubes.

The communication between two subscriber lines can therefore be established by connecting each of them to an intermediate junction of its group and by interconnecting the two chosen junctions.

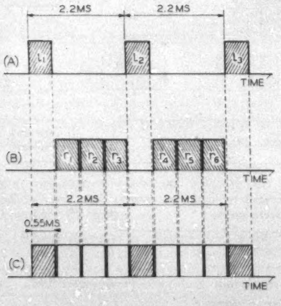

Fig. 3. A—Line scanning. B—Register scanning. C—Line and register scanning

Therefore, the first stage fulfills the functions of both concentration and expansion of the lines. The second stage fulfills the function of mixing the junctions. Each stage possesses its own d-c supply. In the matrices of concentration-expansion, the anodes of the tubes are connected to the ground through wires represented vertically in Fig. 2. The cathodes are connected through the horizontal wires to a d-c supply of -115 volts.

In the mixing matrix an intermediate junction must be connected to a horizontal and a vertical wire in order that there may be one intersection between any two junctions.

The need to give a determined bias to the horizontal wires, on one hand, and to the vertical wires, on the other, leads to utilizing a transformer for coupling a given junction to the two wires which are associated to it in the mixing matrix. This connection is visible in the example of the two junctions represented in Fig. 2, where this coupling is obtained by transformers T and T', both provided with two secondary wirings.

In the mixing matrix the cathodes of the tubes are connected to the vertical wires, the anodes to the horizontal wires, and the junctions are numbered according to the directions indicated in the figure.

Under these conditions it is seen that the connection between two junctions is established by a tube, the cathode of which is necessarily on the side of the junction having the larger number. It will be necessary to take this into account for performing the marking in the suitable direction.

With the preceding description, it may be seen that 30 simultaneous communications can be established. The possible traffic amounts to 9 erlangs with a loss probability of 1.0%.

CONTROL CIRCUIT

Main Functions. The main functions of the control circuit are:

1. Scanning of the lines to detect any new calling line.
2. For each call, recording of the called number.
3. Determination of a free path between the calling and the called lines.
4. Establishment of the connection by firing the three gas tubes chosen.
5. Supervision and release of the connection.

To these main functions must be added auxiliary functions, especially the sending in proper time of various tones: dialing tone, busy tone, ringing, and ringing back.

Scanning of Lines and of Registers. The principle of time sharing applied to a single logical circuit naturally leads it to perform a permanent scanning of the lines, one after the other, to detect a call after a waiting time which must be imperceptible for the subscriber. It may be assumed that the time necessary for the subscriber to pick up the handset is greater than 500 ms. In fact, 528 ms has been taken as the period between two scannings of a given line. The time interval comprised between two consecutive line scannings is therefore: $528/240=2.2$ ms; see Fig. 3(A). This concerns only the detection of new calls. It should be noticed that the situation is different as soon as a calling subscriber begins to dial and that it depends upon the type of signals used for this function.

Except for particular reasons resulting from the use of electronics, it has been considered undesirable to modify the conventional subscriber set. Therefore the conventional dial producing current pulses of 33 ms every 100 ms has been retained. For recording these pulses it was necessary to perform at least one line scanning within 33 ms during the dialing and to record the result obtained. For this purpose, when a line is identified as calling, it is connected to a register

made of a row of ferrite cores. The register is an extremely simple device; it is not necessary to free it as soon as the dialing is finished in order to put it at the disposal of other calls. On the contrary it is advantageous to allow it to be assigned to a calling line for the whole duration of the conversation, while it gathers all the information concerning the conversation. This disposition facilitates the supervision, and especially the release, and for this reason the equipment includes a number of registers equal to the number of possible simultaneous conversations, namely, 30. The registers are permanently scanned. According to the preceding, less than $33/30=1.1$ ms should be devoted to each. Therefore, during a line-scanning period, i.e., 2.2 ms, more than two registers must be scanned. A number of three has been chosen, which leads to interleaving a line scanning and three register scannings; see Fig. 3(B). The duration of each scanning is then $2.2/4=0.55$ ms; see Fig. 3(C). During this time the logical circuit not only identifies the condition of the scanned element, but also carries out orders with a view towards making the system evolve in the desirable direction.

The following may be cited as examples: the order to look for a free junction, the order to test the called subscriber, the order to fire or to switch off a gas tube, etc.

An order is, in general, a complex operation which is subdivided into a determined sequence of elementary steps. For this reason each scanning interval is subdivided into 16 equal parts of 34 μsec (microseconds) which shall be called "time positions"; see Fig. 4. Each of these is devoted to an elementary step initiated by a 20-μsec pulse called "timing pulse" followed by a rest interval of 14 μsec.

Central Clock and Decoding Matrices: The preceding indicates that the operation of the whole control circuit is synchronized by a central clock, permanently running; see the block diagram of Fig. 5. The clock is made of a 29 kc/sec (kc per second) sine wave oscillator from which the timing pulses are derived. These pulses are recorded in binary code in a set of four flip-flops mounted as a counter. The counter is connected to two sets of flip-flops also mounted as counters. In the first one the line numbers appear successively according to the scanning rhythm indicated in Fig. 3. One line number is made of three decimal digits: the first one indicates the group number (1 to 6); the second and the third indicate the individual line number within its group (00 to 39). Each decimal digit is separately coded in binary. This results in three bits for the group number, two bits for the tens number of the line, and four bits for the units number of the line, making a total of nine bits.

In the second counter the register numbers (01 to 30) appear also in accordance with the scanning rhythm indicated in Fig. 3. Here the number is translated into binary as a whole; therefore a capacity of 5 bits is needed.

Each of the three preceding counters is connected to a diode decoding matrix which has as many outlets as elements to be counted. The designation of a line or of a register to be scanned during a given 0.55-ms interval is therefore made by marking the outlet which bears its number in the corresponding decoding matrix. The timing pulses are treated in a similar way: thanks to the decoding matrix assigned to them, each of these, $t_1, t_2, \ldots t_{16}$ is sent in proper time on an outgoing wire which is reserved for it and, through this wire, goes to a number of diode gates in the logical circuit in order to open them and to provoke the execution of an elementary step which depends on an order number indicated elsewhere.

Line Scanner. The first role of the line scanner is to examine whether a line is closed or open. It is essentially made of three parts:

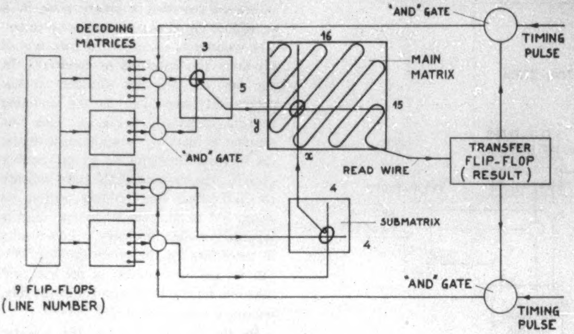

Fig. 8. Busy-line memory

1. The line number decoding matrix mentioned in the preceding paragraph.

2. The individual test circuit making it possible to pick up in each line the wanted information.

3. A flip-flop known as "line condition" in which the information CLOSED or OPEN is registered at each line scanning.

To take account of the fairly high number of lines, the decoding is made in several stages; see Fig. 6.

The individual test circuit attributed to a subscriber line is represented in Fig. 7. When the line is closed a voltage V appears across resistor r. An AND gate receives this information and the marking signal of the line, as well as a timing pulse which goes through only if the line is marked and closed. This pulse then places the flip-flop line condition in position 1. The flip-flop is common to all lines; for this reason it is driven through a set of OR gates. It is brought back to 0 by a timing pulse at the beginning of each scanning.

Busy-Line Memory, Provisional Store. It is evident that the parts described above are not sufficient for the identification of the new calls. In fact, for identifying a line as newly calling, one must recognize not only that it is closed at a scanning but also that it was free at the preceding scanning. It is therefore necessary to make use of a memory, in which the busy condition of lines is recorded; this is the "busy-line memory." It is made of 240 ferrite cores, one per line, arranged according to a rectangular matrix of 16×15. The address of the core on which either a writing or a reading must be performed is recorded in a set of nine flip-flops connected to the line flip-flops of the central clock. For economical reasons, this address is decoded in several stages comprising four diode matrices followed by two ferrite core submatrices; see Fig. 8.

During the reading operation of a core, its content is transferred to the flip-flop "result" where it is utilized. In fact, the information contained in this flip-flop is directed towards an AND gate which is also connected to the flip-flop line condition. It is only in the case of simultaneously 0 (where the line is free at the preceding scanning) in the first flip-flop, and one (closed line) in the second, that a timing pulse is permitted to go through the gate, and place it in position 1 a third flip-flop called "new calling line."

Then, if the flip-flop new calling line is in condition 1, a timing pulse produces the transfer of the line number inscribed in the input flip-flops to a new set of nine flip-flops called "provisional store," where this number remains as long as a register scanning does not indicate a free register. Of course, means are provided for writing or rewriting after reading in the main ferrite core matrix.

Registers, Call Status Memory. When a new line is indentified as calling, the first operation to be carried out is to assign to it a register. As already mentioned, a register consists only of a row of ferrite cores in a number such as to record all information useful for the establishment, the supervision, and the release of a conversation.

A register is then destined to contain information which may be tabulated as follows:

Items	Bits
Calling line number	9
Called line number	9
Units digit of junction connected to calling subscriber (number of tens not needed; in fact, each group possessing ten junctions, the tens number is identical to the group number of the calling line)	4
Units digit of junction connected to called subscriber	4
Number of order which must be carried out by the logical circuit (there is a total of 38 orders)	6
Position of duration counter utilized for temporization and for time measurements	3
Condition of line of calling or of called subscriber at time of last scanning	1
Indication that one dialing train was in course at time of the last scanning	1
Total	37

To permit possible improvements after further experience, provision is made for a capacity of 40 bits. The 30 registers therefore constitute a rectangular matrix of 30×40 elements which possess naturally the usual means of writing and reading. This assembly, known as "call status" memory, is represented in Fig. 9. It is seen that a horizontal wire goes through the 40 cores of a register; it

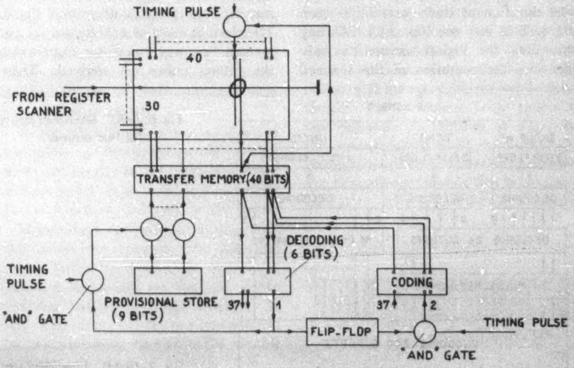

Fig. 9. Call status memory

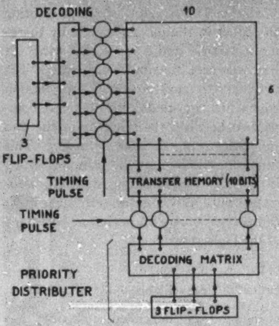

Fig. 10. Busy junction memory and priority distributor

comes from the register scanner, i.e., it is one of the 30 outlets of the decoding matrix represented in Fig. 5. A timing pulse sent on this wire at the beginning of each scanning provokes the reading which is the transfer of the information to a set of 40 flip-flops called "transfer memory," where it will be utilized. The operations to be carried out depend essentially upon the number of the order inscribed. For this reason the six flip-flops attributed to the order are connected to a 37-outlet decoding matrix (one outlet per order). In fact, there are 38 orders, but the first, called "order 0" is the order to detect a new call and, as already noted, it is executed at the beginning of each line scanning, without intervention of a register.

A free register is characterized by the presence of order number 1, called "take register." The marking voltage which then appears on the corresponding order wire causes a timing pulse to open gates which connect the provisional store (where a new calling line number is kept) to the nine first flip-flops of the transfer memory. The line number is then recorded in this memory.

It is then necessary to replace, in the transfer memory, the order number 1 by order number 2. For this purpose, one utilizes first a timing pulse for wiping out the inscribed order, then a coding matrix, having 37 inlets and 6 outlets connected to the order flip-flops, intervenes. Outlet number 1 of the decoding matrix is connected to the inlet number 2 of the coding matrix through a flip-flop and an AND gate. A timing pulse goes through this gate when the order wire 1 is marked and it produces the inscription of order number 2. Similar arrangements are utilized for all sequences of orders irrespective of whether or not their numbers are consecutive.

The next step consists in marking reversely the horizontal wire, and in opening, by a timing pulse, the input gates of the matrix in order to copy the contents of the transfer memory in the register which, then containing the order number 2 and the calling line number, is reserved from that time on to the call carried out by this line.

At each further scanning of the register, the calling line number is reproduced in a set of nine flip-flops of the line scanner. These, which are different from the line flip-flops of the central clock, are represented in the right-hand section of Fig. 5. The presence of these flip-flops makes it possible for the line to be tested at each scanning of the register namely every 22 ms.

Busy Junction Memory, Priority Distributor. The next order (number 2) is the search for a free junction within the group of the calling subscriber. It is performed by a third ferrite core memory, the "busy-junction" memory. It is made of a matrix of 6×10 cores, a row of 10 cores being attributed to each group of 10 junctions, and it possesses means of writing and reading similar to those of the preceding memories. In the block diagram represented in Fig. 10, observe the following:

1. A set of three flip-flops in which the order number 2 provokes the inscription of the group to be explored.
2. A decoding matrix which marks the corresponding row of cores.
3. A transfer memory comprising ten flip-flops.

At the beginning of the scanning, a timing pulse initiates the reading of the row marked by the decoding matrix. The content of this row then passes to the transfer memory. It is then necessary to make a choice from among the free junctions and to avoid showing a consistent preference which would make some gas tubes work more often than others.

The choice is performed by the priority distributor represented in the lower part of Fig. 10. It is a 4-bit counter which progresses by one unit at the beginning of each scanning, i.e., every 550 μsec, and contains a number comprised between 0 and 9, thus designating a preferred junction. This number is detected by a 10-outlet matrix connected to ten AND gates. These gates are also connected to the ten outlets of the transfer memory. If a junction is both preferred and free, the corresponding gate allows a timing pulse to go through and to produce the inscription of its number in the register. If the preferred junction is not free, a suitable coupling device between the flip-flops inscribes the number of the next one and so on, up to the moment where a preferred junction is found free. The junction being thus chosen, it is recorded as busy in the transfer memory; then, this information is copied in the busy-junction memory, the flip-flops of the transfer memory are brought back to 0, and finally the order number 3 is inscribed in the register.

Marker I. From that time, the register assigned to the conversation contains all information necessary for connecting the calling line to a junction by firing the gas tube located at the intersection in the concentration-expansion matrix. This is the role of marker I when it carries out order 3. The block diagram of marker I is shown in Fig. 11, where the line and the junction flip-flops of the supervision mem-

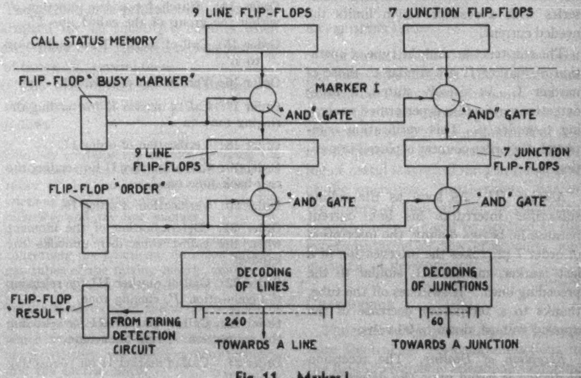

Fig. 11. Marker I

ory have been reproduced. The numbers inscribed here are first copied in the marker's own flip-flops. On account of the duration of the marking, which is normally 2 ms, the input flip-flops of the marker are protected by AND gates placed under control of the flip-flop register busy which allows the signals to go through only in case the marker is free. Then a flip-flop order intervenes, provoking the decoding of the two numbers and therefore the marking of the line and of the junction in order to fire the suitable tube. Certain precautions, described in the Appendix, have been taken in the marking process.

The result of the marking operation is verified, according to order 4, by a firing detection device, which sends an order END OF MARKING bringing back to 0 all the flip-flops of the marker. If this signal has not appeared within 20 ms, a delay device places the flip-flop result in position 0 which means that the marking has failed. One proceeds in this case to the search for a new free junction in order to perform the marking on another tube. This operation is repeated until a satisfactory result is obtained.

Marker II and Tone Generators. Marker I having carried out its work, the calling subscriber is connected to a junction and the order counter is placed in position 5. In this situation, a new marker, marker II, receives the order to connect the junction to the dialing tone generator. The four tone generators are connected to the 60 intermediate junctions thanks to an auxiliary matrix of $60\times4=240$ gas tubes. In this matrix the 60 vertical wires are those of the mixing matrix and the four horizontal wires are peculiar to the generators. To provide for the possible firing of several tubes in the same row, each tube is connected in series with a resistor which limits the needed current.

The construction and the type of operation of marker II are similar to those of marker I. As already stated, a firing detection verification is performed, according to order 6. This verification completed, the order counter is placed in position 7.

Marker III. As soon as the calling subscriber interrupts his line current because he begins dialing, the inscription of order 7 provokes the intervention of a last marker, marker III, similar to the preceding ones. It switches off the tube, thanks to a temporary decrease of the applied voltage, down to 90 volts.

Reception of Dialing. The reception of dialing is based upon the detection of the current interruptions in a line. Of course, it is necessary to compare at each register scanning, the flip-flop line condition, with the transfer flip-flop associated with the core of the register where the line condition was registered at the time of the previous scanning. The current pulses are recorded in the called subscriber flip-flops reserved for that purpose.

The order numbers 8, 9, and 10 correspond respectively to the recording of the hundreds, the tens, and the units. A duration counter is used for verifying the length of the pulses in each train as well as the time interval between two different trains. Due to this counter, release is also obtained in case of incompleted dialing.

Test of Called Subscriber. This operation is the object of order 11. The number of the called line is transferred into the input flip-flops of the busy-line memory in order to determine its idle or busy condition If it is found idle, the logical circuit records it as busy from then on and places the order counter in position 14. If it is busy the logical circuit places the order counter in position 12 and wipes the called line number of the register in order not to cut off, at the time of the release of the calling subscriber, the conversation in which the called party is engaged.

The Following Orders. The first orders have been described in detail to introduce the various constitutive parts of the PABX. For the following orders, in general, the description will be limited to citing their object without comment.

Order 12: Call of marker II in order to connect the calling junction J to the busy-tone generator.

Order 13: Verification of order 12.

Order 14: Search for a free junction J' within the group of the called line L'.

Order 15: Call of marker I for connecting J' to L'.

Order 16: Verification of order 15.

Order 17: Call of marker II for sending the ringing tone on J'.

Order 18: Verification of order 17.

Order 19: Call of marker II for sending the ring-back tone on J.

Order 20: Verification of order 19.

Order 21: Determination of the moment when the called subscriber unhooks the handset.

Order 22: Call of marker III for releasing the connection J', ringing tone.

Order 23: Call of marker III for releasing the connection J, ring-back tone.

Order 24. Call of marker II for connecting J and J'.

Marker II is, in fact, in charge of firing the tubes in the mixing matrix by marking a vertical and a horizontal wire. It has been seen that in this operation it is necessary to mark positively the junction which has the smaller number. A comparison between the numbers of the two junctions must therefore be made. This function is fulfilled by the ordinator which is a set of seven decoding matrices associated with diode gates. It makes the comparison bit by bit beginning with that of the highest rank.

Order 25. Verification of order 24.

Order 26. Surveillance of the conversation.

As soon as the called subscriber has answered, the logical circuit proceeds to the alternate surveillance of the two lines, devoting to each of them one register scanning out of two. This allows the provocation of the release by either of the two correspondents.

Orders 27–30. Operations of release, permitted by marker III.

Orders 31 and 32. Connection to the public network.

Orders 33 through 36. Repeated marking in case of failure of one tube.

Order 37: Sending of the ring-back tone to a subscriber calling the operator.

It is seen that the establishment of a conversation requires the execution of 25 orders which lasts $22\times25=550$ ms. The release is made in four orders representing a total duration of $22\times4=88$ ms.

In the preceding it will be noticed that the marking of the gas tubes has been performed stage by stage, whereas one could have imagined an end marking made over an assembly of three distinct stages. The first solution was chosen because it was the only one capable of providing for a sufficient operating reliability, taking into account the scattering of the gas tube characteristics and of their evolution in the course of time.

SUBSCRIBER'S SET

The subscriber's set, developed in cooperation with Standard Electric Lorenz, Stuttgart, Germany, involves an original ringing device. The sound signals are produced by an ordinary telephone receiver driven by a 1-transistor amplifier. They are made of 0.5-sec trains of two musical notes alternating 20 times per second. Their respective frequencies are 1,000 and 1,600 cps (cycles per second). An integrating circuit including one transistor provides for protection against line noise. Thanks to this arrangement, the ringing power has been decreased down to 1 milliwatt.

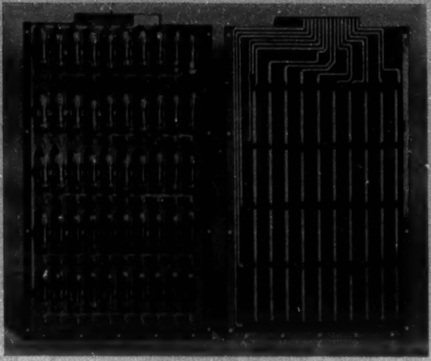

Fig. 14. Gas tube card

CONNECTION WITH PUBLIC TELEPHONE NETWORK

Three orders are devoted to the connection of subscribers to the public telephone network. This connection is not automatic. A subscriber who wants to be connected to the public network should therefore signal to the operator; he obtains this result by dialing 0. The process according to which the control circuit acts is therefore the same as in the case of an internal call, up to the dialing.

The calls coming from the exterior are directly handled by the operator, who disconnects the called subscriber from the PABX when she plugs in, and at the same time identifies him as busy. Such a process of connection with the intervention of an operator has been adopted mainly because of the experimental character of the equipment.

Fig. 13. Example of technology: boxes and cards

TECHNOLOGY

The whole circuitry is included in three adjoined bays, represented in Fig. 12. The over-all dimensions are: height 2 meters; width, 3.4 meters; depth, 0.4 meter. Each bay comprises six cases and each case contains insulating cards of approximately 20×30 centimeters, placed vertically and bearing the elementary functional circuits; see Fig. 13. On these cards the wiring is of the conventional type except for those which contain the gas tubes where the connections are made of printed circuits on both sides; see Fig. 14. The different cards are interconnected by a cabling fixed on the base, the connection between the cards and the cabling being made by plug-in connectors. The technique of printed wiring has been utilized for all repetitive circuits when they have been repeated a large number of times, i.e., several tens.

The distribution of the different circuits among the bays and cases is as follows:

One bay contains the circuits grouping the subscriber lines: the line circuits, the gas tubes of the concentration-expansion matrices as well as the marker I, the busy line memory, and the line scanner.

The second bay includes all the circuits concerning the junctions: junction circuits, gas tubes of the mixing matrix, marker II, marker III, and tone generators.

In the third bay are the main elements of the control circuit, i.e., the logical circuit which occupies a whole case, the call status memory, the busy-junctions memory, and the central clock.

Two cases in this bay are devoted to the circuits necessitated by the connection to the public network. The supplies draw their energy from a 50-cycle 3-phase power network; they take two cases respectively located in the first and in the third bay. The total power consumption is 1 kilovolt-ampere.

SOME NUMERICAL DATA

Some numerical data follow:

Over-all loss from subset to subset
  At 1,000 cps, less than 0.5 db (decibel)
  Between 300 and 3,000 cps, less than 2 db

Crosstalk level, less than −70 db

Power consumption, 1 kilovolt-ampere

Traffic with loss probability of 1%, 9 erlangs

Total number of diodes,* 7,000

Total number of transistors,* 1,500

Total number of ferrite cores,* 1,300

* Without circuits of connection to the public network.

EXPERIMENTATION

The PABX described has recently been put into operation at the Laboratoire Central de Télécommunications. Its capacity has been chosen to correspond to the present need of this organization. It is sufficiently large to permit the collecting of useful statistical data in the course of the operation. Furthermore, one of the groups of lines will not be connected to subscribers but will be devoted to the experimentation of new crosspoints now in course of development.

Conclusions

The work already done by the Laboratoire Central de Télécommunications in the field of electronic telephone switching demonstrates that it is technically possible to realize, at present, small PABXS and even large offices. It is now known that the former possess a reliability which surpasses that of electromechanical devices, in particular when severe climatic or mechanical conditions should be met. They are especially promising for military applications.

Large electronic offices are mainly destined for civil applications in which they must successfully compete with the electromechanical exchanges, i.e., with equipment which has been experienced for years and has reached a very high level of quality.

The comparison between the two kinds of solutions must be made from different angles such as: first cost, maintenance cost, reliability, flexibility, bulk and weight of equipment. Their respective capability of offering to the subscriber additional services should also be discussed.

Another important point concerns the noise generated, in particular in its relation to the problem of data transmission.

With regard to transmission, an important question concerns the methods of switching best adapted to the most modern transmission techniques such as pulse code modulation.

It must be recalled that there is no single way to electronic switching, but a variety of approaches including the semielectronic ones, which must be compared with each other. This increases tremendously the complexity of the problem of large electronic exchanges, which will not be solved without much exploratory work, theoretical as well as experimental.

It is hoped that the 240-line fully electronic PABX will be a valuable contribution to this problem, and will give the possibility of making an evaluation of great interest for the future.

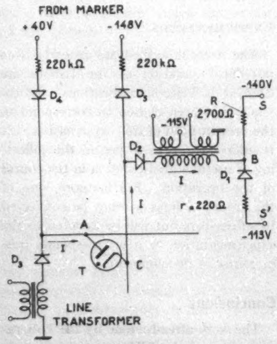

Fig. 15. Supply and marking of a tube

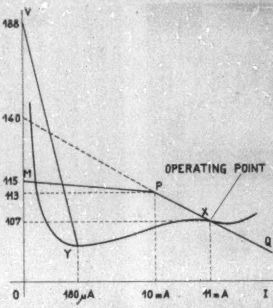

Fig. 16. Voltage-current characteristic of a gas diode (The proportions are not respected)

Appendix I. Marking Process

With a view toward understanding certain precautions taken in the marking process, it seems useful to indicate here the main numerical characteristics of the gas diode used. These are:

Firing voltage, 160 to 175 volts
Voltage applied for firing, 188 volts
Corresponding firing time, 10 ms
Sustaining voltage, 105 to 109 volts
Voltage applied for switching off, 90 volts
Corresponding switch-off time, 200 μsec

The d-c supply of the tube is described by Fig. 15 where it may be seen that the anode A is connected to ground and that the cathode C is connected indirectly to two supply sources furnishing −112 and −140 volts respectively.

To understand the roles of these two sources as well as that of resistors r, R and of diode D_1, it is sufficient to plot the curve representing the potential $-V$ of point B against current I arriving at this point. With the numerical data indicated, this curve is made of two linear segments MP and PQ. For currents I larger than 10 ma the voltage of B is superior to −113 volts and the diode D_1 is blocked. Therefore, segment PQ is located on the load line of the source of −140 volts in series with resistor R alone. On the contrary, for currents inferior to 10 ma the voltage of point B is smaller than −113 volts and the two sources supply current. Segment MP has a slope much smaller than PQ; it is approximately located on the load line of the source of −113 volts in series with resistor r alone.

For a current $I=0$, there is only a current circulating through the loop $S'BS$ and the voltage of B is $-V=-115$ volts. Therefore, when at rest the tube is submitted to a voltage $V=115$ volts.

Now if the tube is fired, thanks to a voltage temporarily larger than the firing voltage, the operating point X is located at the intersection of the V-I characteristic of the tube and of the curve made of the two preceding segments. Thus one obtains the average values indicated above ($V=107$ volts; $I=11$ ma). It should be noted in particular that when the tube is operating, diode D_1 is blocked and the supply is provided by the source S of −140 vlots only.

However, the advantage of complicating the circuit by the introduction of source S' lies in the fact that after extinction the voltage does not go up more than 115 V. There is thus a larger safety margin against spontaneous firing of tubes whose firing voltage would be abnormally low.

For performing the firing, the marker is introduced in parallel with the main supplies, care being taken to provide for the necessary decoupling, thanks to diodes D_2, D_3, D_4, and D_5. The line wire of the marker introduces a marking voltage of +40 volts, whereas the junction wire of the marker goes down to −148 volts. Therefore the marking produces temporarily a voltage of 188 volts across the tube, which primes the firing through a high resistance (440,000 ohms) to limit the current supplied by the marker. At the beginning of the marking the operating point of the tube is in Y, Fig. 16, the current supplied being only 180 per μampere. Then, in the course of a transient it moves towards the final point X already indicated. For completing the description of marker I, note lastly that the decoding of the line numbers is performed in several stages, according to Fig. 17.

The final stage, which has 240 outlets, is made of a matrix comprising diodes and resistors, and not diodes only, in view of reducing the current consumption. It can be demonstrated, in fact, that an AND gate made of two diodes is supplied at a low current only in the case when it performs the logical operation $1\times1=1$. On the contrary, an AND gate consisting of one diode and one resistor can be made so as to be supplied at a low current in all three other numerical cases of the logical multiplication. Now, in a decoding matrix, one single outlet is marked at a time. If the first type of AND gate has been used, this outlet is the only one to be supplied

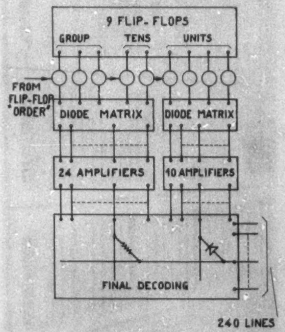

Fig. 17. Block diagram of line decoding matrix of marker I

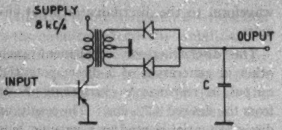

Fig. 18. Amplifier of the decoding matrices of marker I

at a low current, whereas it is the only one to be supplied at a high current if the second type has been used. With respect to current consumption, this second type is therefore much more advantageous.

The circuit of Fig. 17 involves amplifiers. They are realized according to the scheme of Fig. 18. One may remark an 8-kc power supply and the existence of a coupling transformer between the transistor and the output. This has the advantage of providing for d-c insulation and to facilitate the obtaining of fairly high output voltages with common transistors.

A Test Set for Measurement of Envelope Delay Distortion at Audio Frequencies with 1-Microsecond Precision

W. ALFRED CODD
MEMBER AIEE

THE accelerating use of transmission facilities for data transmission requires an increased knowledge and control of phase characteristics of the facilities and associated networks. These are commonly controlled by specification of a related quantity designated as envelope delay. Specifications have been encountered calling for control or equalization of a switching link to limits of ±10-μsec (microsecond) envelope delay over a frequency range of 1,000 to 2,600 cps (cycles per second). Such requirements call for measuring equipment capable of accurately and rapidly measuring envelope delay.

Control of phase characteristics is necessary in order to minimize distortion of signal waveforms in transmission. Distortionless transmission requires constant attenuation and constant envelope delay, resulting from insertion of a network, for all frequency components of the signal to be transmitted. If the signal in question is transmitted directly (not modulating a carrier), it also requires that the intercept of the phase characteristic on the phase axis at zero frequency be zero or an integral multiple of $\pm\pi$ radians. For a signal modulated on a carrier the latter condition is not required.

Envelope delay is equal to the derivative of the phase characteristic in radians with respect to frequency in radians per second; i.e., $d\phi/d\omega$. Audio-frequency measurements of envelope delay have been made indirectly by measuring ϕ, the insertion phase shift, at successive frequencies throughout the range of interest with sufficiently small frequency intervals so that calculations of $\Delta\phi/\Delta\omega$ from measurements at adjacent frequencies may be used as an approximation of $d\phi/d\omega$. A commercially available phasemeter which has been used for determination of envelope delay in this manner is capable of giving phase readings in a range of 30 to 20,000 cps with a precision of 0.1 degree. Changes of phase angle, at a given frequency, within a range of ±1 degree may be measured to a precision of 0.01 degree.

Determination of $d\phi/d\omega$ with the foregoing phasemeter method is very time-consuming, largely because measurement of phase at each frequency must be preceded by a multistep balancing procedure. The method has the added disadvantage that to yield a specified precision in $\Delta\omega$, it is necessary to have a higher order of precision for each test-frequency setting. Thus, a given per-cent error in the test frequencies may result in as much as 100 times this per-cent error in the resultant determination of envelope delay. This paper describes a test set which has been developed to overcome these disadvantages for envelope delay measurements in the audio-frequency range and to yield a precision of 1 μsec for measurements of envelope delay distortion up to 166 μsec.

Basic Arrangement

The test method incorporated in this test set was adopted as a direct attack on the disadvantages noted in connection with point-by-point single-frequency measurements of insertion phase shift. A means of overcoming the disadvantage arising from time-consuming rebalancing of the phase meter at each test frequency is to translate all test frequencies in a suitable manner to a single frequency at the phasemeter input, thus eliminating the need for rebalancing. Now, if a pair of test frequencies is provided which differ from each other by a suitably small increment, Δf, and arrangements are made to hold this increment constant as the test frequencies are swept through the desired test range, a basis for making the desired frequency translation is available.[1] Translation is then accomplished by passing the pair of test frequencies simultaneously through the network under test and intermodulating the pair of frequencies as they appear at the input and also at the output of the network in suitable modulator circuits. The difference frequency from each of these modulations is then used at the phasemeter inputs. Thus the desired constant frequency is provided at the phasemeter input while

Y., January 31–February 5, 1960. Manuscript submitted November 2, 1959; made available for printing February 10, 1960.

W. Alfred Codd is with the Stromberg-Carlson Company, Rochester, N. Y, a Division of General Dynamics Corporation.

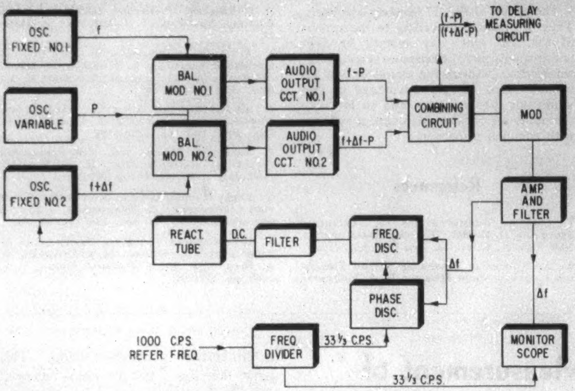

Fig. 1. **Test signal generator and control circuit**

the frequency at the test circuit is varied over the required range of measurement. With this arrangement also, the need for a high order of precision for the individual test frequencies is obviated, the requirement for precision being in maintenance of the difference between the two test frequencies which may be controlled directly.

The several components of this test set will be considered in more detail in the following sections.

Generator of Test Frequencies

The required pair of test audio frequencies is derived from three high-frequency oscillators; see Fig. 1. Two of these are "fixed" oscillators, one generating a nominal frequency of 250 kc (f) and the other a frequency, $(f+33^{1}/_{3}$ cps). The third high-frequency oscillator is variable by manual control over a range from $(f-500)$ to $(f-3{,}200)$ cps. The required audio frequencies are derived from two balanced modulators. The first fixed oscillator and the manually variable oscillator constitute the input to one modulator from which is derived an audio frequency manually variable over the range of 500 to 3,200 cps. The second fixed oscillator and the manually variable oscillator provide input to the second modulator and produce an audio frequency manually variable from $533^{1}/_{3}$ to $3{,}233^{1}/_{3}$ cps. Thus, the pair of audio frequencies is swept through the test range by the same manual control with a nominal difference between them of $33^{1}/_{3}$ cps. Although the frequency generator described provides a pair of frequencies of nominally constant difference ($33^{1}/_{3}$ cps), the difference is not maintained with adequate precision as thus generated.

The Control Circuit

The precision required for Δf is of the order of 1 in 10^4. To meet this requirement, an electric control circuit is used which measures the difference between Δf and a $33^{1}/_{3}$-cps reference frequency at any instant and provides a control voltage which is used to correct Δf by changing the frequency of the second fixed high-frequency oscillator. The arrangement of the control circuit is shown in block diagram form in Fig. 1 in relation to the generator of test frequencies.

The projected physical arrangement for the test set embodies a test signal generator assembly which incorporates the three high-frequency oscillators, the two balanced modulators and their associated audio output circuits, and the reactance-tube circuit for control of fixed oscillator no. 2. A control circuit assembly includes the other components of Fig. 1.

The combining circuit shown in this diagram is a 600-ohm resistance bridge with the two audio frequencies introduced in conjugate arms and two 600-ohm adjustable pads, feeding the control circuit modulator and the test circuit, constituting adjacent arms of the bridge.

The control circuit modulator uses a semiconductor diode to derive the difference frequency, Δf, from the pair of test frequencies for input to the discriminator elements. Two stages of amplification and associated filtering deliver this difference frequency with suitable level and waveform to the discriminator input circuits.

The discriminators supplement each other in generation of a direct-potential output in response to variations of Δf from the desired $33^{1}/_{3}$ cps. The resultant direct potential is used as a varying bias supply to the reactance-tube control element. In response to the changed bias, the reactance tube effectively alters the tuning of the tank circuit of the fixed oscillator tube thereby altering its frequency to adjust Δf in the required direction.

Initially in the design, the control circuit used a single discriminator. The phase discriminator was chosen because it has a much higher sensitivity to frequency error than has the frequency discriminator arrangement. The two circuits are basically different in principle of operation. The frequency discriminator functions by comparison of the Δf frequency input to the frequencies of resonance of a pair of tuned circuits whose geometric mean is the desired frequency to which Δf is to be controlled. It produces a direct-potential output proportional to the frequency error. It can never reduce the frequency error to zero.

The phase discriminator does not employ tuned circuits. As indicated in Fig. 1, it has two inputs, Δf and a precise $33^{1}/_{3}$-cps reference frequency derived from an accurately controlled frequency standard. It produces a direct-potential output proportional to the phase difference between Δf and the $33^{1}/_{3}$-cps reference. Considering the condition with Δf exactly equal in frequency to the $33^{1}/_{3}$-cps reference, the phase relation between the two signals is constant and the discriminator output, is supplying exactly the direct potential needed to maintain Δf at its control value. If, then, a change in Δf is somehow induced, though extremely small, its phase relation to the reference wave will change and thus produce a correcting change in direct-potential output. A stable point is reached only when the phase relation of Δf and $33^{1}/_{3}$-cps reference is static, i.e., when there is zero-frequency difference. It is seen that the phase discriminator circuit continues correction to the point of zero-frequency error. A disadvantage in use of the phase discriminator is in difficulty of adjusting for stable operation. Also, its range of control is limited from 0- to 180-degree phase difference. When the phase difference goes beyond this range, the slope of the control curve reverses and control is lost. This also permits the undesirable possibility, in initial adjustment, of lock-in of fixed oscillator no. 2 at either $(f+33^{1}/_{3})$ or $(f-33^{1}/_{3})$ cps.

Addition of the frequency discriminator to the circuit is effective in stabilizing the operation and in limiting lock-in to $(f+33^1/_3)$ cps. The frequency and phase discriminators are driven in parallel at their inputs. Their direct-potential outputs are connected in series to the bias circuit of the reactance-tube grid. This connection is through a resistance-capacitance network which serves to filter out Δf and its harmonics to prevent production of spurious frequencies in the test-frequency output by frequency modulation of the fixed oscillator. The network also serves to control the time constant of the control circuit.

The $33^1/_3$-cps reference frequency input for the phase discriminator is derived from a high-precision 1,000-cps frequency standard maintained in the testing laboratories. A 2-stage multivibrator frequency divider circuit is used to divide this down to a precise $33^1/_3$-cps output. This is in the form of short-duration pulses with $33^1/_3$-cps repetition rate.

Monitor and Adjustments for Control Circuit

The oscilloscope in Fig. 1 is provided to enable observation of the control circuit operation and facilitate adjustment to secure lock-in. The oscilloscope used is a conventional unit with horizontal and vertical deflecting systems. Input to the horizontal amplifier is the Δf signal taken from a suitable point in the control circuit amplifier. Input to the vertical amplifier is the $33^1/_3$-cps pulse signal derived from the frequency divider. When the circuit is in control with Δf equal precisely to the $33^1/_3$-cps reference, the oscilloscope pattern will show a stationary vertical pulse. When the circuit is not in control the pulse will move back and forth across the screen.

To establish control it is necessary first to adjust the input level of Δf to the frequency discriminator and also the levels of Δf and the $33^1/_3$-cps reference to the phase discriminator to specified levels. These values are not critical. In normal operation control is then established by adjustment of the voltage of a direct-potential bias in series with the discriminator output circuits until the pulse pattern on the monitor becomes stationary. This adjustment may be made with the manual frequency control of the variable oscillator set at any point on the frequency scale. With control established the dial may then be swept back and forth over the full available audio-frequency range and the difference in the pair of test frequencies delivered to the delay-measuring circuit will remain at precisely $33^1/_3$ cps.

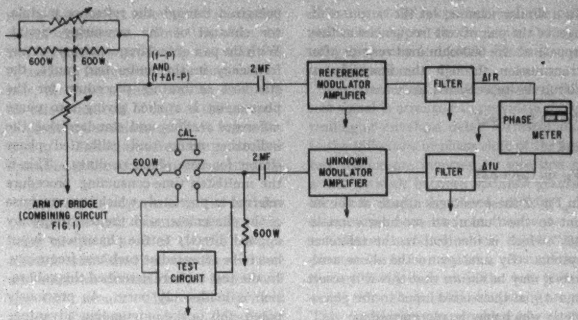

Fig. 2. Envelope delay measuring circuit

The Measuring Circuit

The pair of controlled test frequencies as delivered from the combining circuit to the measuring circuit is used as a generator voltage which is fed through a desired value of generator resistance to a specified load resistance. These are usually 600 ohms each. Switching is provided so that after initial adjustment any 4-terminal unbalanced audio-frequency network for which envelope delay measurements are desired may be inserted between the generator and load. The complete measuring circuit arrangement in block-schematic form is shown in Fig. 2. In this circuit the phasemeter is the same unit that was previously used in the indirect method of determination of envelope delay. Capabilities of the unit are those given earlier in the paper. The present arrangement as exemplified by Figs. 1 and 2 enables use of the unit to make available its incremental precision of 0.01 degree in direct measurement of envelope delay distortion as set forth in the following development.

The broad outline of the method by which this circuit provides a measurement of envelope delay has been given under the heading "Basic Arrangement." This will now be considered in more detail. Let the pair of test frequencies $(f\text{-}p)$ and $(f+\Delta f-p)$ composing the generator voltage feeding the test circuit be represented as

$$V_{11}\sin(\omega_1 t+\phi_{11})$$

and

$$V_{21}\sin(\omega_2 t+\phi_{21})$$

As indicated in Fig. 2, this voltage appears also at the input to the "reference modulator-amplifier." The basic element in this unit is a square-law modulator which, as previously indicated, derives the difference frequency, Δf_R, between the pair of test frequencies and presents this to one input circuit of the phasemeter. The circuit also includes a cathode follower input stage to provide high input impedance while permitting volume control at a relatively low impedance level to minimize effects of level adjustments on phase shift. A stage of amplification follows to provide optimum level at the modulator input. The modulator stage is a cathode-follower reflex type. A stage of amplification follows the modulator to provide a suitable level in the range required for the phasemeter input. Filtering is incorporated in and follows the modulator-amplifier to provide a pure $33^1/_3$-cps wave with necessary freedom from potentially error-producing components. Harmonics of $33^1/_3$ cps are suppressed to a level at least 40 db (decibels) below the $33^1/_3$-cps signal.

With further reference to the representation of the test frequencies, it may be shown that one product of the intermodulation process in the modulator stage can be represented as

$$kV_{11}V_{21}\sin(\omega_1 t+\phi_{11})\sin(\omega_2 t+\phi_{21})$$

By trigonometric transformation this is shown to be equal to

$$(1/2)\,kV_{11}V_{21}\cos(\omega_1 t+\phi_{11}-\omega_2 t-\phi_{21})-(1/2)kV_{11}V_{21}\cos(\omega_1 t+\phi_{11}+\omega_2 t+\phi_{21})$$

The first term of this latter expression is retained after filtering as the Δf_R output of the reference modulator–amplifier–filter system, feeding one phasemeter input. It may be written as

$$(1/2)\,kV_{11}V_{21}\cos[(\omega_1-\omega_2)t+(\phi_{11}-\phi_{21})]=(1/2)\,kV_{11}V_{21}\cos[2\pi(\Delta f_R)t+\phi_R]$$

In a similar manner, let the output voltages of the pair of test frequencies as they appear at the 600-ohm load resistor after transmission through the inserted test circuit be represented as

$$V_{12} \sin (\omega_1 t+\phi_{12})$$

and

$$V_{22} \sin (\omega_2 t+\phi_{22})$$

In Fig. 2 these voltages appear at the input to the "unknown modulator-amplifier" which is identical to the reference system. By analogy to the above analysis it may be shown that this will result in a Δf_U at the second input to the phasemeter which may be represented as

$$\begin{aligned}(1/2)\ kV_{12}V_{22} \cos\ &[(\omega_1-\omega_2)t+(\phi_{12}-\phi_{22})]\\ &=(1/2)\ kV_{12}V_{22} \cos\ [2\pi(\Delta f_U)t+\phi_U]\end{aligned}$$

Now, the functioning of the phasemeter is such that for input signals of identical frequency at its two inputs it provides a measure of the difference in the phase of the two input signals, which in the above instance will be $(\phi_R-\phi_U)$. From the foregoing development this is seen to be equal to

$$(\phi_{11}-\phi_{21})-(\phi_{12}-\phi_{22})$$

This may be rewritten as

$$(\phi_{22}-\phi_{21})-(\phi_{12}-\phi_{11})$$

From an examination of these last forms, it is seen that $(\phi_{12}-\phi_{11})$ is the phase shift incurred by f_1 as a result of insertion of the test circuit and $(\phi_{22}-\phi_{21})$ is the corresponding phase shift for f_2. Thus,

$$(\phi_R-\phi_U)=(\phi_{22}-\phi_{21})-(\phi_{12}-\phi_{11})=\Delta\phi$$

where $\Delta\phi$ is the required difference of insertion phase shift for frequencies f_1 and f_2, differing by the controlled Δf value. Since Δf is constant for all pairs of test frequencies, the phasemeter reading, $(\phi_R-\phi_U)=\Delta\phi$ in degrees, is converted to envelope delay by multiplying by a constant $=1/360\ \Delta f$. Thus, if desired, the meter may be calibrated directly in terms of envelope delay, recognizing as previously indicated that $\Delta\phi/\Delta\omega$ approximates $d\phi/d\omega$ when $\Delta\omega$ is small.

Calibration of the Measuring Circuit

Prior to use of the circuit for measurement of a test circuit, the calibrate-test key is placed in calibrate position. The phase of the signal at the input of the reference and unknown modulator channels is then identical and the phasemeter must show zero phase difference over the test-frequency range. Calibration may be accomplished by first setting up the phasemeter with both of its channels energized through the reference modulator channel of the measuring circuit. With the pair of test frequencies set at any frequency in the audio test range, the standard calibrating procedure for the phasemeter is applied giving zero phase difference reading and standardizing the indicating meter and calibrated phase shifter for true phase readings. This is the multistep time-consuming procedure referred to previously which in normal use of the phasemeter with the test frequency applied directly to the phasemeter input has to be repeated at each test frequency. In the test set here described this calibration is made only once. As previously noted, this is the outstanding advantage of this test set. It reduces testing time to the order of one tenth the time required by the measurement of phase shift at successive single frequencies, in addition to eliminating considerable amount of calculation for determination of envelope delay values.

In normal operation, when the phasemeter calibration has been completed with the pair of test frequencies at any point in the test range it is maintained over the whole range of test frequencies. This is readily checked by sweeping the manual frequency control through the range.

The next step in calibration is to return to the condition shown in Fig. 2, i.e., the reference and unknown modulator channels connected separately to the two phasemeter inputs. The phasemeter should still show zero phase difference over the test range. This may again be checked by sweeping through the test-frequency range. An adjustable decade capacitor is provided in the $33^1/_3$-cps output amplifier stage of the reference modulator-amplifier channel to use for zero adjustment when required. This completes the calibration of the test set.

Characteristics and Precision of the Measuring Circuit

The basis of the large reduction in testing time which results by the test arrangement here described has already been discussed. Another advantage also accrues directly from the translation of the variable test frequencies to a single constant frequency at the phasemeter inputs. This lies in the fact, previously noted, that the incremental technique available in the phasemeter may be used for measurement of differences in delay, thus providing a precision of 0.01 degree for measurement of changes of $\Delta\phi$ with test frequency. This may be used over a range of 2 degrees of $\Delta\phi$. With $\Delta f=33^1/_3$ cps, 0.01-degree phase difference is equivalent to 0.833, or approximately 1-μsec envelope delay. Thus, with Δf held to a precision of 1 in 10^4, envelope delay distortion up to 166 μsec may be measured with a precision of 1 μsec. When differences in phase over the frequency range are greater than 2 degrees, the incremental technique of the phasemeter cannot be applied and the precision of delay measurements is then the equivalent of 0.1 degree or 10 μsec.

It is seen that precision of 1 in 10^4 for Δf contributes, per se, negligible error in delay measurement in comparison with the figures determined by the phasemeter precision. However, this order of precision in Δf is necessary in order to maintain balance of the phasemeter because of the high envelope delay value of the internal phasemeter circuits at $33^1/_3$ cps.

To realize the potential precision given, requirements must be met at several points in the circuit relative to purity of signal in order to avoid error due to spurious signals.

It has already been noted that the harmonic content of the Δf signals at the phasemeter inputs is limited to a level lower than 40 db below the fundamental. Another potential source of error is any spurious $33^1/_3$-cps component. Assuming the extreme condition of spurious Δf being present in one phasemeter input in 90-degree phase relation to the true Δf while being absent in the other input, or in phase with true Δf, the level of the spurious component must be at least 75 db below the true component to produce no more than 0.01-degree error. Points at which such components may arise are the signal generator and the test circuit. In general, any pair of frequencies other than the test pair differing by $33^1/_3$ cps will produce a spurious $33^1/_3$-cps component by intermodulation in the measuring circuit modulators. Harmonics of the test frequencies are not a source of this type of error since they would produce harmonics of Δf when modulated. These will be eliminated by the filter circuits in the modulator channels.

It should be noted that spurious Δf components being of the same frequency as the true Δf cannot be eliminated by filtering after they have been produced and must, therefore, be controlled by control of the frequency or frequency pairs which would produce them before they arrive at the modulator stages of the measuring circuit. A means by which spurious pairs with Δf separation may arise in the signal generator is by frequency modulation of fixed oscillator no. 2 by $33^1/_3$ cps from the control circuit discriminators entering the grid circuit of the reactance tube. As previously noted, this is controlled by filtering of this component in the discriminator outputs.

The frequency of $33^{1}/_{3}$ cps should be controlled in the signal source to sufficiently low level. Unbalance in the two modulators of the signal source will produce a $33^{1}/_{3}$-cps component. This is controlled by limiting this unbalance and is further suppressed by $33^{1}/_{3}$-cps twin-T reactance-capacitance filters in the grid circuits of the modulators of the measuring circuits. Another precaution found to be desirable in the signal generator is use of d-c heater supply for the reactance tube to avoid 60-cps modulation of the oscillator encountered with 60-cps heater supply. This would produce an audio component $26^{2}/_{3}$ cps below $(f\text{-}p)$, rather than $33^{1}/_{3}$ cps. This is too close to $33^{1}/_{3}$ to be suppressed adequately by filtering and so must be kept negligible in the signal generator output.

As previously noted, spurious Δf components may also arise in the circuit under test. These also must be limited in level or suppressed by filtering out the frequency components which would give rise to them before entering the measuring circuit modulators. Note that when the two frequencies producing the spurious Δf are both frequencies other than the test pair, the level of each need be only 37.5 db below the level of each of the test pair to produce a spurious Δf 75 db below the true Δf. This follows from the square-law operation of the measuring circuit modulators.

Error which might arise in the modulator-amplifier-filter channels of the measuring circuit is avoided by the balance which is established between the reference and unknown channels before insertion of the test circuit. This was described under "Calibration of the Measuring Circuit."

Conclusions

A test set has been described which enables direct measurement of envelope delay distortion at audio frequencies with a precision of 1 μsec. This result has been obtained by generation of an audio test signal composed of a pair of audio frequencies which can be swept through the audio-frequency range with a constant difference of $33^{1}/_{3}$ cps between the pair maintained by an electric control circuit using frequency and phase discriminators in combination.

The measuring circuit employing this test signal is arranged to provide a direct reading of envelope delay corresponding to the difference in phase shift of the two test frequencies incurred by insertion of a test network between specified generator and load. Increased rapidity of measurement results from the frequency translation involved which enables the phasemeter to be used at a constant frequency ($33^{1}/_{3}$ cps) while the test pair is swept through the audio-frequency range. This translation also enables use of the incremental technique of the phasemeter employed in this set. This provides the 1-μsec precision for delay distortion up to 166 μsec. The test set has been developed in breadboard construction and has been found to perform as set forth here in measurement of several typical networks.

Intermodulation Effects in FM and PM Systems

B. E. LOVE
NONMEMBER AIEE

WITH THE increasing use of radio relay systems to transmit a large variety of time and frequency division information signals, noise and signal distortions that tend to reduce the information-carrying capacity of such systems take on added importance. In any multiplex system for either speech or data-type signals, noise produced by nonlinear elements carrying the active channels generally limits the maximum signal-to-noise ratio that can be obtained. Nonlinearities in baseband amplifiers, frequency modulation generators, discriminators, and distortions of the delay characteristic are the principal contributors of this modulation noise. Thermal or first circuit noise in any part of the radio system can be readily calculated. The following discussion is concerned primarily with the measurement, evaluation, and correction of delay distortion, klystron pulling effects, and the determination of optimum system loading. A number of references are included to assist in a further study of the subject.[1–7]

Review of Repeaters

Repeaters for microwave radio systems will fall in one of two categories, either baseband or intermediate frequency. Fig. 1 illustrates the two generic types. It should be noted that the i-f (intermediate-frequency) repeater eliminates two baseband amplifiers, a discriminator, and a directly modulated klystron along with any distortion inherent in these units. However, for short haul systems, the baseband repeater equipment offers the ad-

vantage of easily dropping or adding information channels since the output of the receiver is at the multiplex frequencies. For systems several thousand miles in length designed for high capacity message service, it is necessary to use i-f type repeaters and equip the system with discriminators and FM (frequency-modulated) generators at message-dropping points only.

Noise Versus Loading

It will be of interest to examine the connection between thermal or first circuit noise and intermodulation noise produced by system nonlinearities. If the modulating voltage level to the FM generator is increased from some low value, and attenuators used to keep the over-all system gain constant, thermal noise will predominate. As the sending level is increased with the attendant increase in frequency deviation of the system, the noise as measured at the output of the receiver will decrease db (decibel) for db with the increase in send level. As the frequency deviation is further increased, a point is reached at which the intermodulation noise begins to override the thermal noise. The optimum deviation is usually taken as the point at which the thermal noise and modulation noise is equal during the maximum busy hour loading. Any further increase in deviation will result in an increase of modulation noise. The noise variation with FM deviation is shown graphically in Fig. 2.

Delay Characteristics

Delay characteristics may be classed into three general shapes: parabolic, sinusoidal, and slope. Parabolic shapes tend to produce third order distortion products while slope produces second order products. The distortion products resulting from sinusoidal shapes depend upon the ripple period and amplitude as well as the phase with respect to the frequency position of the unmodulated carrier. The shapes found in practice will generally be some combination of the three basic shapes.

Ideally, the delay in a channel should be constant with frequency. The absolute delay is usually of little consequence. A typical delay characteristic of a repeater is shown in Fig. 3. The vertical scale here is such that 10 millimicroseconds is equivalent to one degree. Since this shape is quite consistent between repeaters, it is readily reduced by providing an equalizer with a complementary shape in each repeater. Variations due to the *Q* of cavities, broadness of filters, etc., at different frequencies can be controlled by adding or removing equalizers. As an example, Fig. 4 shows an overequalized channel about 500 miles long. It was necessary to remove the parabolic equalizers from about one third of the repeaters for the best equalization.

Figs. 5(A) and (B) show delay characteristics having a general long-period sinusoidal shape with some residual slope. These irregular shapes were caused by mismatched impedances in the i-f circuits at a number of repeaters. The signal-to-noise ratio on these channels was about 30 db during busy periods. The objective would be in the order of 55 db.

Fig. 6 shows the effects of waveguide echoes on the delay characteristic. This channel is about 250 miles long. The ripple configuration suggests that there are at least two and possibly three individual echoes represented. Such echoes may be produced by poor antenna terminations, foreign material in the waveguide, mismatched impedances between the waveguide and the receiver crystal converter, etc.

The amplitude of the ripple in the delay characteristic depends upon the sum of the return losses at the two ends of the waveguide or coaxial cable. In many cases, it is not practicable to improve the

return loss by obtaining better impedance matches because of design or other limitations. An example is the feed for a parabolic antenna. Another example is the receiver crystal converter. Here the impedance looking into the crystal cavity is dependent upon the individual crystal characteristics as well as the current through them.

Ferrite devices, such as isolators, are very useful in either improving impedance matches or improving the operation of some units of equipment. As an example, an isolator may be used at a crystal converter to improve the return loss as seen by the waveguide. Since the isolator has little attenuation in the forward direction and high attenuation in the backward direction, the return loss from the waveguide side will be improved by some amount.

The impedance reflected by an antenna into the frequency-determining cavity of a directly modulated klystron oscillator often produces a frequency deviation that is not solely a function of the modulating voltage. This effect is commonly termed klystron pulling. An isolator placed very close to the klystron is very effective in controlling this condition. It is now common practice to design the microwave equipment using directly modulated klystrons to include an isolator.

Some systems exhibit a delay characteristic that has a slope either increasing or decreasing with frequency. This shape is readily controlled by appropriate slope equalizers. The principal control over sinusoidal variations in the delay characteristic is by control of the impedance matches as implied in the discussion above. This control can be exercised by appropriate maintenance procedures and the provision of the necessary equipment such as isolators. The characteristic of a well-equalized channel is shown in Fig. 7.

Modulation Noise Versus Delay Distortion

The modulation noise resulting from sinusoidal variations in the delay characteristic can be calculated with a fair degree of accuracy. The curves shown in Fig. 8 were calculated for a number of different amplitudes and noise plotted against the ripple period for a 600-message circuit load. Order of magnitude estimates of the noise produced by a complex characteristic can be obtained by breaking it up into component sinusoids of constant amplitude at the various periods and determining the resultant noise contribution of each. These may then be added on a power basis to obtain the final result. The broad peak of each of the curves in the neighborhood of 6 to 8 mc (megacycles per second) is quite apparent. The peaks occur at a ripple period that is a little more than twice the frequency of the top message channel. Some characteristics, as seen in Figs. 5 and 6, have been found with ripple periods in the vicinity of 7 mc. The message circuit noise as measured on these channels demonstrated the existence of the broad peaks.

Evaluation Methods

The curves of Fig. 8 show the modulation noise resulting from delay distortion having a particular shape. Even with an exact knowledge of the noise contributed by delay irregularities, no information is conveyed about the contributions from nonlinearities in baseband amplifiers, FM generators, and discriminators. Some method of evaluating the over-all system performance is therefore desirable. Two methods have been used. The first method uses a broad-band source of white noise to simulate the desired number of active message channels. The other uses the common 2-tone intermodulation test procedure.

The broad-band noise source is first filtered to restrict the bandwidth to that occupied by the multiplex system. Two slots, each about 3 kc wide, are made free of noise by appropriate rejection filters. Frequency-wise, the slots are located near the extremes of the noise spectrum. This filtered noise source is then used to modulate the system. At the receiving end of the system, some type of selective power-measuring equipment must be provided to measure the modulation products that now are found in the slots that were cleaned out at the transmitting end. The two slots are equivalent to two idle message channels. The noise power measured in them is the summation of all possible combinations of modulation products occurring as a result of system nonlinearities acting on the noise-modulated signal.

The intermodulation method makes use

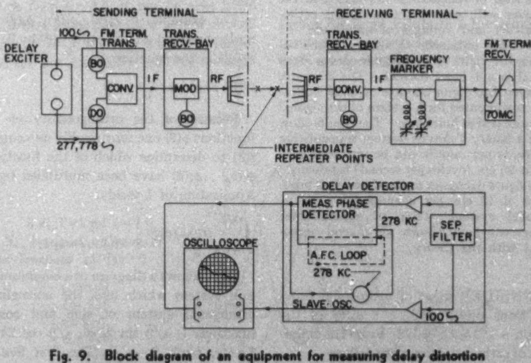

Fig. 9. Block diagram of an equipment for measuring delay distortion

of two tones having frequencies separated by perhaps 100 kc and having equal amplitudes. The system is then modulated with the two tones and suitable measuring equipment provided to determine the level of the second and third order modulation products. Measurements should be made using several pairs of tone frequencies which are not harmonically related.

With either method, the deviation is increased in small increments, say 2 db, from some small value considerably below the maximum rated deviation of the equipment. By keeping the system gain constant with attenuators, a plot of the results will yield results similar to Fig. 2. The results using the noise method may be applied almost directly to message systems while the intermodulation method requires the development of an empirical relationship for such application.

Delay Distortion Measurement

The block schematic of one type of equipment for measuring delay distortion is shown in Fig. 9. The carrier frequency is swept back and forth through the i-f pass band at a 100-cycle rate. This carrier is modulated at a low index, about 0.3, at a frequency of 277.778 kc. At the receiver, the recovered 100-cycle voltage is used to drive the horizontal deflection of an oscilloscope. The 278-kc voltage is continuously compared in a phase detector with a local oscillator of similar frequency. This local oscillator is locked in step with the incoming 278 kc through an automatic frequency control circuit having a long time constant. The output of the phase detector then represents the phase error, caused by differences in delay, continuously as the carrier is moved from one edge of the pass band to the other. The voltage representing the phase error is applied to the vertical deflection plates of the oscilloscope. Marker pips may be introduced by absorption wavemeters for the purpose of determining band edges, ripple periods, etc. The oscilloscope presentation then represents the delay variations across the band in terms of phase error versus frequency. At 277.778 kc, the delay for one degree of phase change is 10 millimicroseconds. The measurement can thus be considered in terms of time or phase as desired.

On the Transmission of Information by Orthogonal Time Functions

H. F. HARMUTH
ASSOCIATE MEMBER AIEE

Synopsis: In a digital communication system each digit of a character may be represented by one function of an orthogonal set of functions. This function is multiplied by +1 or −1 if binary digits are being used. All functions of the character are added and transmitted in parallel. This sum of functions is correlated in the receiver with each function of the orthogonal set and voltages of amplitude +1 or −1 are obtained. No interference between the digits of a character occurs if the signal is not band limited. The crosstalk between the digits because of band limitation is computed for a system of orthogonal sine and cosine functions. The results show that a binary Teletype system transmitting 60 words per minute can be operated with about 25 cps (cycles per second) bandwidth. This figure decreases to the theoretical minimum of 15 cps per channel for a multichannel system. Tests of experimental equipment have shown very good agreement with the theory.

CONSIDER a set of orthogonal functions $\phi_1(\theta)$, $\phi_2(\theta)$, $\ldots$ $\phi_l(\theta)$ in the region $-1/2 \leqslant \theta \leqslant +1/2$. From the definition of orthogonal functions follows

$$\int_{-1/2}^{1/2} \phi_l(\theta)\phi_m(\theta)d\theta \begin{cases} =K \text{ for } l=m \\ =0 \text{ for } l\neq m \end{cases} \qquad (1)$$

K is assumed 0 normalized to 1.

If the functions $\phi(\theta)$ are multiplied by 1 or 0 and added, one obtains a function $f(\theta)$.

For example, if $\phi_1(\theta)$, $\phi_2(\theta)$, $\phi_3(\theta)$ are multiplied by 1 and all other $\phi(\theta)$ by 0, the result is the function

$$f(\theta)=\phi_1(\theta)+\phi_2(\theta)+\phi_3(\theta) \qquad (2)$$

Because of the orthogonality of the functions $\phi(\theta)$ one may readily decompose $f(\theta)$ to determine which of the functions $\phi_1(\theta)\ldots\phi_l(\theta)$ have been multiplied by 1. Application of 1 yields

$$\int_{-1/2}^{1/2} f(\theta)\phi_l(\theta)d\theta \begin{cases} =1 \text{ for } l=1,\,2,\,3 \\ =0 \text{ for } l=4,\,5,\,\ldots \end{cases}$$

Fig. 1 shows a diagram of a communication system which uses the normalized orthogonal system of sine and cosine functions 1, $\sqrt{2}\sin 2k\pi\theta$, $\sqrt{2}\cos 2k\pi\theta$; $\theta=t/\tau$, $k=1,\,2,\,\ldots$. The first five of these functions are shown in Fig. 2. Assume that the five digit character 11001 is to be transmitted. The switches (multipliers) in the transmitter let through 1, $\sqrt{2}\sin 2\pi\theta$, and $\sqrt{2}\cos 4\pi\theta$, but not $\sqrt{2}\cos 2\pi\theta$ and $\sqrt{2}\sin 4\pi\theta$. The transformers add the voltages and yield

$$f(\theta)=1+\sqrt{2}\sin 2\pi\theta+\sqrt{2}\cos 4\pi\theta \qquad (3)$$

The function $f(\theta)$ varies continuously with time and is similar to a voice signal. It may be transmitted by amplitude or frequency modulation, or any other type of modulation suitable for the transmission of continuously varing time functions.

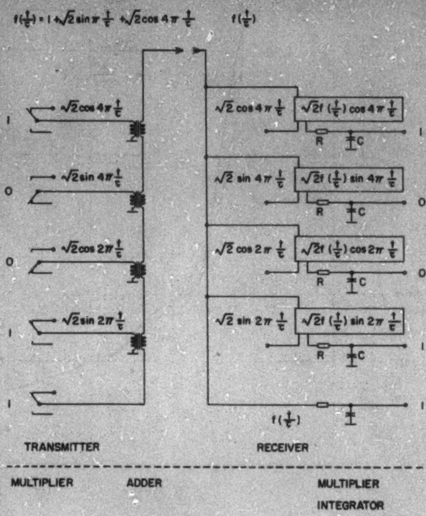
In the receiver $f(\theta)$ is multiplied by the same five functions which were used in the transmitter, the integral over the period τ is taken and the character 11001 multiplied by τ is recovered

$$\tau\int_{-1/2}^{1/2} f(\theta)(1)d\theta=\tau$$

Paper 59-1076, recommended by the AIEE Communication Theory Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting Chicago, Ill., October 11–16, 1959. Manuscript submitted May 25, 1959; made available for printing December 17, 1959.

H. F. HARMUTH is with the Research Division of the Stromberg-Carlson Company, Rochester, N. Y., a Division of the General Dynamics Corporation.

The author wishes to express his gratitude to Mr. R. C. Clark, Mr. W. Brouillette, Mr. C. Nielsen, and Mr. H. Putschi of the General Electric Company, Electronics Laboratory, Syracuse, N. Y., for several helpful discussions on the subject.



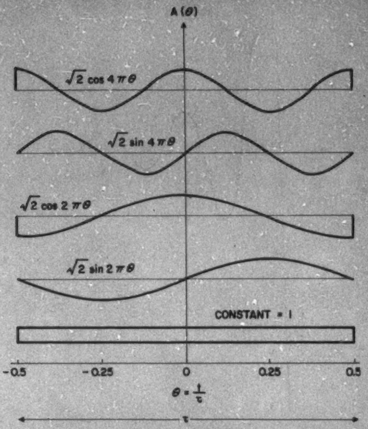


Fig. 1 (left). Communication system using a set of orthogonal trigonometric functions

Fig. 2 (above). Set of orthogonal trigonometric functions

$$\tau\int_{-1/2}^{1/2} f(\theta)\sqrt{2}\sin 2\pi\theta d\theta=\tau$$

$$\tau\int_{-1/2}^{1/2} f(\theta)\sqrt{2}\cos 2\pi\theta d\theta=0$$

$$\tau\int_{-1/2}^{1/2} f(\theta)\sqrt{2}\sin 4\pi\theta d\theta=0$$

$$\tau\int_{-1/2}^{1/2} f(\theta)\sqrt{2}\cos 4\pi\theta d\theta=\tau$$

In the following only trigonometric functions are considered but there is no difficulty other then computational in applying other sets of orthogonal functions.

Transmission Through a Noise-Free Channel

The bandwidth required for the communication system may be derived as follows: $f(\theta)$ is the sum of several sine and cosine terms; hence its frequency spectrum is the sum of the frequency spectra of the sine and cosine terms. The frequency spectra a ν for 1, $\sqrt{2}$ sin $2k\pi\theta$, and $\sqrt{2}$ cos $2k\pi\theta$, $(-1/2\leqslant\theta\leqslant+1/2)$, may be readily computed

$$a(\nu_1 1)=\int_{-1/2}^{1/2}\cos 2\pi\nu\theta d\theta=\sin\pi\nu/\pi\nu \qquad (4)$$

$$a(\nu_1\sqrt{2}\sin 2k\pi\theta)=$$
$$\frac{1}{\sqrt{2}}\left(\frac{\sin\pi(\nu-k)}{\pi(\nu-k)}-\frac{\sin\pi(\nu+k)}{\pi(\nu+k)}\right) \qquad (5)$$

$$a(\nu_1\sqrt{2}\cos 2k\pi\theta)=$$
$$=\frac{1}{\sqrt{2}}\left(\frac{\sin\pi(\nu-k)}{\pi(\nu-k)}\right)+\frac{\sin\pi(\nu+k)}{\pi(\nu+k)} \qquad (6)$$

Fig. 3 shows the frequency spectra of the first five orthogonal trigonometric functions. It can be seen that most of the energy is concentrated at low frequencies. For the comparison with standard PCM systems the dot frequency f_d is introduced

$$f_d=1/2T=n/2\tau \qquad (7)$$

T is the average time available for the transmission of one digit, τ the average time available for the transmission of one character, and n the number of digits in one character. For five digit characters follows $f_d\tau=\nu_d=2.5$, it can be seen from Fig. 3 that a low pass filter with a cut-off frequency $\nu=3$, which is only 20% larger then the dot frequency, will let through almost all energy. A communication system using n-digit characters requires for $n=2l+1$ or $n=2l$ the bandwidth

$$w\tau=\nu=l+\frac{1}{2}+\alpha=\nu_d+\alpha \qquad (8)$$

α is a constant determined by the tolerable distortion of the characters because of band limitation; in the foregoing example α was chosen equal to 1/2. Introduction of equation 7 into equation 8 yields

$$w=\left(1-\frac{\alpha}{l+1/2}\right)/2T \quad \text{for } n=2l+1 \qquad (9)$$

$$w=\left(1+\frac{\alpha+1/2}{l}\right)/2T \quad \text{for } n=2l \qquad (10)$$

Hence for large values of l the required bandwidth approaches its theoretical limit $w=f_d=1/2T$.

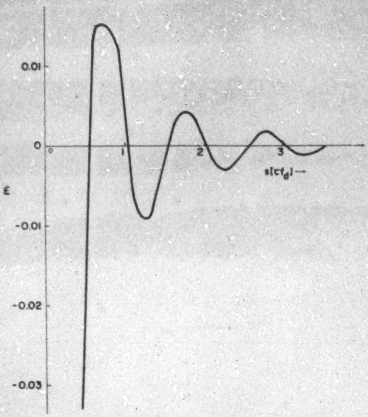

Fig. 4 (left). Error versus cutoff frequency for the constant term, $E=2\pi^{-1}(\sin 2\pi s+\cos 2\pi s/2\pi s)$. The ideal limit of the bandwidth corresponds to $s=1/2$

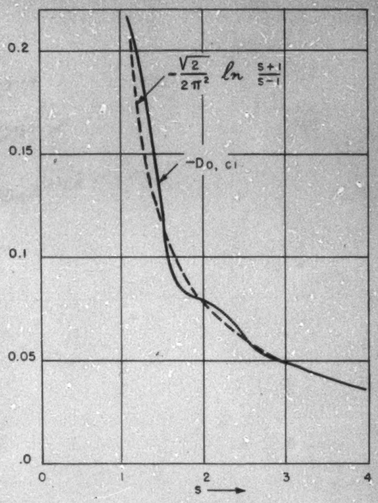

Fig. 5 (right) Crosstalk from the digits transmitted by $\sqrt{2}\cos 2l\pi\theta$ to the digit transmitted by the constant voltage

$D_{o,ci}=-1/2\sqrt{2}\,\pi^{-2}\{-\mathrm{ci}\ 2\pi(s-1)+\mathrm{ci}\ 2\pi(s+1)-\ln[(s+1)/(s-1)]\}$

The value of α may be determined by cutting off all frequencies $\nu>s$ and investigating the resulting distortions of $f(\theta)$. The assumption of an ideal low-pass filter is only made to illustrate the effects of band limitation. The filter is not used to suppress noise. It is possible to study the distortions of the individual sine and cosine functions which make up $f(\theta)$. The inverse Fourier integral taken over the frequency spectrum equation 4 yields, if no frequencies higher then s are passed

$$F_0(\theta)=\int_{-s}^{s}\frac{\sin\pi\nu}{\pi\nu}\cos 2\pi\nu\theta d\nu$$
$$=\frac{1}{\pi}[\mathrm{Si}\ \pi s(2\theta+1)-\mathrm{Si}\ \pi s(2\theta-1)] \quad (11)$$

where Si x is the sine integral

For the sine and cosine terms equations 5, 6 one obtains

$$F_{s,k}(\theta)=\frac{\sin 2k\pi\theta}{\sqrt{2}\pi}[\mathrm{Si}\ \pi(s-k)(2\theta+1)-$$
$$\mathrm{Si}\ \pi(s-k)(2\theta-1)+\mathrm{Si}\ \pi(s+k)(2\theta+1)-$$
$$\mathrm{Si}\ \pi(s+k)(2\theta-1)] \quad (12)$$

$$F_{c,k}(\theta)=\frac{\cos 2k\pi\theta}{\sqrt{2}\pi}[\mathrm{Si}\ \pi(s-k)(2\theta+1)-$$
$$\mathrm{Si}\ \pi(s-k)(2\theta-1)+\mathrm{Si}\ \pi(s+k)(2\theta+1)-$$
$$\mathrm{Si}\ \pi(s+k)(2\theta-1)] \quad (13)$$

$$\mathrm{Si}\ x=\frac{\pi}{2}+\mathrm{si}\ x=\int_0^x\frac{\sin y}{y}dy$$

The band-limited function $f(\theta)$ is represented as sum of $F_0(\theta)$, $F_{s,k}(\theta)$, and $F_{c,k}(\theta)$. For instance the $f(\theta)$ corresponding to the character 11001 has now the form

$$f(\theta)=F_0(\theta)+F_{s,1}(\theta)+F_{c,2}(\theta) \quad (14)$$

instead of the form of equation 3. The distortion of the received character may be obtained by multiplying equations 11, 12, 13 with the various sine and cosine functions and integrating over the period τ. Two kinds of integrals have to be distinguished: First, the "information integrals" with a value close to 1

$$\int_{-1/2}^{1/2}F_0(\theta)d\theta;\ \int_{-1/2}^{1/2}F_{s,k}(\theta)\sqrt{2}\sin 2k\pi\theta d\theta;$$
$$\int_{-1/2}^{1/2}F_{c,k}(\theta)\sqrt{2}\cos 2k\pi\theta d\theta \quad (15)$$

Second, the "crosstalk" integrals, which will be 0, unless the frequency limitation produces some crosstalk between the digits of a character

$$\int_{-1/2}^{1/2}F_{s,k}(\theta)d\theta;\ \int_{-1/2}^{1/2}F_{s,k}(\theta)\sqrt{2}\times$$
$$\sin 2m\pi d;$$
$$\int_{-1/2}^{1/2}F_{s,k}(\theta)\sqrt{2}\cos 2l\pi\theta d\theta \quad (16)$$

$$\int_{-1/2}^{1/2}F_{c,k}(\theta)d\theta;\ \int_{-1/2}^{1/2}F_{c,k}(\theta)\sin 2l\pi\theta d\theta;$$
$$\int_{-1/2}^{1/2}F_{c,k}(\theta)\sqrt{2}\cos 2m\pi\theta d\theta$$

$$\int_{-1/2}^{1/2}F_0(\theta)\sqrt{2}\sin 2l\pi\theta d\theta;$$
$$\int_{-1/2}^{1/2}F_0(\theta)\sqrt{2}\cos 2l\pi\theta d\theta;$$
$$k,\ l,\ m=1,\ 2,\ 3\ldots \quad k\neq m$$

The first integral of equation 15 yields by partial integration

$$\int_{-1/2}^{1/2}F_0(\theta)d\theta=1+\frac{2}{\pi}\left(\mathrm{si}\ 2\pi s+\frac{\cos 2\pi s}{2\pi s}\right)$$
$$=1+E \quad (17)$$

The second term in equation 17 yields the distortion of the received digit because of band limitation. Using the asymptotic expansion

$$\mathrm{si}\ x\approx -0!\frac{\cos x}{x}-1!\frac{\sin x}{x^2}+2!\frac{\cos x}{x^3}+$$
$$3!\frac{\sin x}{x^4} \quad (18)$$

E may be written in the following form

$$E\approx-\frac{2}{\pi}\left[\frac{\sin 2\pi s}{(2\pi s)^2}-2\frac{\cos 2\pi s}{(2\pi s)^3}\right] \quad (19)$$

If α is chosen equal 1/2 in equation 9, it follows $s=w\tau=1$ and therefore

$$E\doteq\frac{2}{\pi}\frac{2}{(2\pi^3)}\doteq 0.005$$

Hence the error is only one-half per cent. E is plotted versus $s=1/2+\alpha$ in Fig. 4, according to equation 17.

The second and third integral of equation 15 yield

$$\int_{-1/2}^{1/2}F_{s,k}(\theta)\sqrt{2}\sin 2k\pi\theta d\theta$$
$$=\int_{-1/2}^{1/2}F_{c,k}(\theta)\sqrt{2}\cos 2k\pi\theta d\theta=1+E$$
$$(20)$$

$$E=\frac{1}{\pi}\left[\mathrm{si}\ 2\pi(s-k)+\frac{\cos 2\pi(s-k)}{2\pi(s-k}+\right.$$
$$\mathrm{si}\ 2\pi(s+k)+\frac{\cos 2\pi(s+k)}{2\pi(s+k)} \quad (21)$$

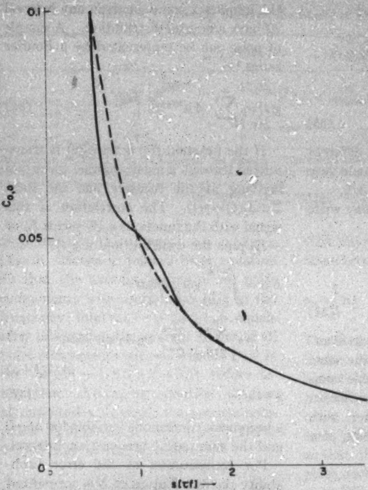

Fig. 6 (left). Crosstalk between the constant terms of two adjacent characters. The ideal limit of the bandwidth corresponds to s=1/2

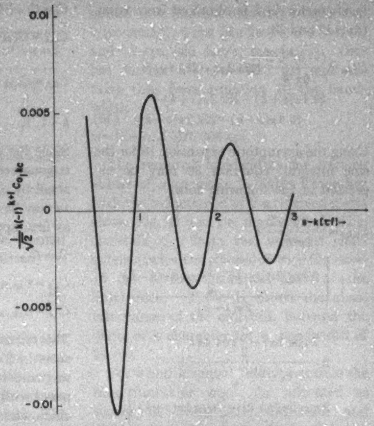

Fig. 7 (right). Crosstalk between the constant term of character l and the cosine terms of character l+1. The ideal limit of the bandwidth corresponds to s=1/2

$2^{-1/2}k(-1)^{k+1}C_{0,kc}=\sin\ 2\pi(s-k)/2\pi(s-k)\quad [2+\cos\ 2\pi(s-k)]$

In first approximation E is represented by the graph of Fig. 4 if $s-k$ is substituted for s.

The interference between the digits of one character (digit crosstalk) is determined by evaluating the integrals of equation 16. No crosstalk occurs between symmetric and skew symmetric functions. Only the following integrals are unequal zero

$$D_{0,cl}=\int_{-1/2}^{1/2} F_0(\theta)\sqrt{2}\cos 2l\pi\theta d\theta$$

$$=\frac{1}{2}\sqrt{2}\,\frac{(-1)^l}{\pi^2 l}\Big[-\mathrm{Ci}\,2\pi(s-l)+\mathrm{Ci}\,2\pi(s+l)-\ln\frac{s+l}{s-l}\Big]$$

$$D_{ck,0}=\int_{-1/2}^{1/2} F_{c,k}(\theta)d\theta$$

$$=\frac{1}{4}\sqrt{2}\,\frac{(-1)^k}{\pi^2 k}\Big[-\mathrm{Ci}\,2\pi(s-2k)+\mathrm{Ci}\,2\pi(s+2k)-\ln\frac{s+2k}{s-2k}\Big]$$

$$D_{ck,cm}=\int_{-1/2}^{1/2} F_{c,k}(\theta)\sqrt{2}\cos 2m\pi\theta d\theta$$

$$=\frac{(-1)^k}{2\pi^2}\,\frac{k}{(k+m)(k-m)}\Big[-\mathrm{Ci}\,2\pi(s-2k)+\mathrm{Ci}\,2\pi(s+2k)-\ln\frac{s+2k}{s-2k}\Big]$$

$$D_{sk,sm}=\int_{-1/2}^{1/2} F_{s,k}(\theta)\sqrt{2}\sin 2m\pi\theta d\theta$$

$$=\frac{(-1)^{k+1}}{2\pi^2}\,\frac{k}{(k+m)(k-m)}\Big[-\mathrm{Ci}\,2\pi(s-2k)+\mathrm{Ci}\,2\pi(s+2k)-\ln\frac{s+2k}{s-2k}\Big]$$

Cix is the cosine integral. Graphs of $D_{0,cl}$ are shown in Fig. 5.

The band limitation causes crosstalk between the digits of adjacent characters. If the character l, represented by the time function $f_l(\theta)$, is transmitted during the time $-1/2\leqslant\theta\leqslant+1/2$, and the character $l+1$ is transmitted during the time $+1/2\leqslant\theta+\leqslant 3/2$, the crosstalk from character l to the digits of character $l+1$ becomes

$$C_0=\int_{-3/2}^{3/2} f_l(\theta)d\theta \tag{22}$$

$$C_{s,k}=\int_{-1/2}^{3/2} f_l(\theta)\sqrt{2}\sin 2k\pi\theta d\theta \tag{23}$$

$$C_{c,k}=\int_{-1/2}^{3/2} f_l(\theta)\sqrt{2}\cos 2k\pi\theta d\theta \tag{24}$$

In the foregoing and in subsequent equations the subscripts c and s stand for cosine and sine, the subscripts k, m denote the respective harmonic. For $f_l(\theta)$ a combination of $F_0(\theta)$, $F_{s,k}(\theta)$, and $F_{c,k}(\theta)$ given by equations 11, 12, 13 must be introduced, depending on which digits are 1 and which are 0. Consider the crosstalk from the constant term of character l to the constant term of character $l+1$.

$$C_{0,0}=\int_{-1/2}^{3/2} F_0(\theta)d\theta=\frac{1}{\pi}\Big[\frac{1}{2\pi s}+2(\mathrm{si}\,4\pi s-\mathrm{si}\,2\pi s)+2\frac{\cos 4\pi s}{4\pi s}-2\frac{\cos 2\pi s}{2\pi s}\Big] \tag{25}$$

Using the asymptotic expansion 18, one may write equation 25 in the following form

$$C_{0,0}\approx\frac{1}{2\pi^2 s}\Big[1+\frac{\sin 2\pi s}{2\pi s}-\frac{1}{2}\,\frac{\sin 4\pi s}{4\pi s}\Big] \tag{26}$$

$C_{0,0}$ is plotted versus s in Fig. 6. For $\alpha=0$ $(s=\alpha+1/2)$, which is the ideal limit of the bandwidth, one obtains a crosstalk of 10%.

The crosstalk between the constant term of character l and the term $\sqrt{2}\cos 2k\pi\theta$ of character $l+1$ is obtained from equations 11 and 24.

$$C_{0,kc}=\int_{1/2}^{3/2} F_0(\theta)\sqrt{2}\cos 2k\pi\theta d\theta$$

$$=\frac{(-1)^k\sqrt{2}}{4\pi^2 k}[\mathrm{Ci}\,4\pi(s+k)-\mathrm{Ci}\,4\pi(s-k)-2\mathrm{Ci}\,2\pi(s-k)] \tag{27}$$

$$\mathrm{Ci}\,x=-\int_x^\infty\frac{\cos y}{y}\,dy\approx 0!\frac{\sin x}{x}-1!\times\frac{\cos x}{x^2}-2!\,\frac{\sin x}{x^3}+3!\,\frac{\cos x}{x^4}\dots \tag{28}$$

Introduction of the asymptotic expansion 28 into 27 yields

$$C_{0,kc}\approx\frac{(-1)^k\sqrt{2}}{4\pi^2 k}\,\frac{\sin 2\pi(s-k)}{2\pi(s-k)}\times[2+\cos 2\pi(s-k)] \tag{29}$$

$C_{0,kc}(-1)^{k+1}k/\sqrt{2}$ is plotted versus $s-k$ in Fig. 7. The crosstalk for $k=1$, $\alpha\geqslant 1/2$ is 1% or less. One may deduce from this result that the crosstalk between adjacent characters is only important for the digits transmitted by the same trigonometric function, constant to constant, $\cos 2k\pi\theta$ to $\cos 2k\pi\theta$, etc.

The crosstalk between the constant in character l and the term $\sqrt{2}\sin 2k\pi\theta$

in character $l+1$ is obtained from equations 11 and 23.

$$C_{0,ks}=\frac{(-1)^k\sqrt{2}}{4\pi^2 k}[4\mathrm{Si}\,2\pi s-2\mathrm{Si}\,4\pi s+\mathrm{Si}\,4\pi(s+k)-2\mathrm{Si}\,2\pi(s+k)+\mathrm{Si}\,4\pi(s-k)-2\mathrm{Si}\,2\pi(s-k)] \quad (30)$$

Using the asymptotic expansion 18 for the sine integral, equation 30 may be expressed in the following form

$$C_{0,ks}\approx\frac{(-1)^k\sqrt{2}}{4\pi^2 k}\times\left[\frac{2\cos 2\pi(s-k)-\frac{1}{2}\cos 4\pi(s-k)}{2\pi(s-k)}-2\,\frac{2\cos 2\pi s-\frac{1}{2}\cos 4\pi s}{2\pi s}+\frac{2\cos 2\pi(s+k)-\frac{1}{2}\cos 4\pi(s+k)}{2\pi(s+k)}\right] \quad (31)$$

The average decline $\sqrt{2}(-1)^k/4\pi^2 k$ is the same as for the cosine terms; the oscillations however are more complicated.

The crosstalk between sine-sine, cosine-cosine, and sine-cosine terms may be computed in the same way, the only difference being that equations 12, 13 contain twice as many terms as equation 11. However, it has been shown by equations 21, 22 that these additional terms yield only small corrections, and equations 26, 29, 31 may thus be used as first approximations for the crosstalk between any orthogonal trigonometric functions of two adjacent characters

$$C_{kc,kc}\doteq C_{ks,ks}\doteq C_{0,0}$$

$$C_{kc,mc}\doteq C_{ks,ms}\doteq C_{0,kc}$$

$$C_{kc,ms}=C_{ks,mc}\doteq C_{0,ks}$$

$$m\neq k \quad (32)$$

The total crosstalk from all digits of character l to the digits of character $l+1$ may now be written from equations 22–24

$$C_0=C_{0,0}+C_{1c,0}+C_{1s,0}+C_{2c,0}+C_{2s,0}+\ldots$$

$$C_{s,k}=C_{0,2k}+C_{1s,sk}+C_{1c,sk}+\ldots C_{sk,sk}+C_{ck,sk}+\ldots$$

$$C_{c,k}=C_{0,ck}+C_{1s,ck}+C_{1c,cb}+\ldots+C_{sk,ck}+C_{ck,ck}+\ldots$$

$$k=1,2,\ldots \quad (33)$$

Since the crosstalk between two different trigonometric functions can be made very small by choosing $s-k=1/2, 1, 3/2, \ldots,$ as may be seen from Fig. 7, one may write as first approximations

$$C_0=C_{0,0}$$

$$C_{s,k}=C_{sk,sk}$$

$$C_{c,k}=C_{ck;ck} \quad (34)$$

The crosstalk from character l to character $l+2$ may be computed in the same way and turns out to be negligible compared with the crosstalk between adjacent characters. This result together with equation 34 justifies the assumption of α being independent of n.

Influence of Noise

Consider a balanced binary character which is represented by digits of value $+1$ and -1 rather than 1 and 0. A signal has the general form

$$f(\theta)=\pm\phi_1(\theta)\pm\phi_2(\theta)\ldots$$

instead of the form in equation 2.

Let the function $\phi_j(\theta)$ be represented by a Fourier series

$$\phi_j(\theta)=\sum_{k=-\infty}^{\infty}a_{jk}\epsilon^{2ik\pi t/\tau}$$

$$a_{jk}=\frac{1}{\tau}\int_{-\tau/3}^{\tau/2}\phi_j(\theta)\epsilon^{-2ik\pi t/\tau}$$

$$E_j=\int_{-\tau/2}^{\tau/2}\phi_j^2(\theta)dt=\tau\sum_{k=-\infty}^{\infty}a_{jk}a_{jk}^* \quad (35)$$

Consider white noise in the frequency domain. Let the frequency band be divided into intervals $\Delta f=f_l-f_{l-1}$. The probability that a sample of noise has a frequency component between f_l and f_{l-1} is independent of l. The amplitudes of the frequency components in any interval Δf have a normal distribution. A sample of noise can be represented by a Fourier series.[1]

$$g(t)=\sum_{l=-\infty}^{\infty}A_l\epsilon^{2il\pi\tau f t} \quad (36)$$

If the function $f(\theta)=\Sigma\pm\phi_j(\theta)$ is transmitted through a noisy channel the signal arriving at the receiver has the form $\Sigma\pm\phi_j(\theta)+g(t)$. The correlation of this signal with the functions $\phi_j(\theta)$ yields E_j or $-E_j$ plus the contribution of $g(t)$.

$$N_{j\tau}=\int_{-\tau/2}^{\tau/2}g(t)\phi_j(\theta)dt=\tau\sum_{k=-\infty}^{\infty}\sum_{l=-\infty}^{\infty}a_{jk}A_l\sin\pi(k+\mu)/\pi(k+\mu)$$

$$\mu=l\Delta f\tau \quad (37)$$

μ becomes a continuous variable for $\Delta f\to 0$ and the sum over l becomes an integral.

For computation of the error probability the distribution of $N_{j\tau}$ normalized by E_j is required. Since the A_l have a normal distribution with the average equal to zero the joint distribution of $N_{j\tau}/E_j$ has the form

$$W(N_{j\tau}/E_j)=(2\pi)^{-1/2}\sigma^{-1}\times\exp[-(N_{j\tau}/E_j)^2/2\sigma^2] \quad (38)$$

A component of $g(t)$ with amplitude A_λ and frequency $\mu=\lambda\Delta f\tau$ correlated with $\phi_j(\theta)$ produces the term $l=\lambda$ in equation 37, the square of this term divided by E_j is the square deviation $\sigma_{A\mu}^2$ from the average $\overline{N}_{j\tau}/E_j=0$.

$$\sigma_{A\mu}^2=\left(\frac{\tau}{E_j}\right)^2A_\lambda A^*\sum_{k=-\infty}^{\infty}a_{jk}\frac{\sin\pi(k+\mu)}{\pi(k+\mu)}\times\sum_{k=-\infty}^{\infty}a_{jk}^*\frac{\sin\pi(k+\mu)}{\pi(k+\mu)} \quad (39)$$

σ^2 is the average of R deviations $\sigma_{A\mu}^2$ for large values of R. The averaging may be performed first for the frequencies then for the amplitudes.

$$\sigma_A^2=\lim_{\Delta f\to 0,R\to\infty}\frac{1}{R}\sum_{r=0}^{R}(\sigma_{A\mu}^2)_r=\int_{-\infty}^{\infty}\sigma_{A\mu}^2d\mu=\left(\frac{\tau}{E_j}\right)^2A_\lambda A_\lambda^*\times\sum_{k=-\infty}^{\infty}a_{jk}a_{jk}^* \quad (40)$$

$$=\frac{\tau}{E_j}A_\lambda A_\mu^*$$

$A_\lambda A_\lambda^*$ is the power dissipated in a unit resistor by the noise components with an

amplitude in the interval $\Delta A_\lambda = |A_\lambda| - |A_{\lambda-1}|$. Hence it follows from equation 40 that the average power of all noise components with amplitudes $|A_\lambda|$ in the frequency interval $-\infty < \mu < +\infty$ equals after integration the average power of all noise components with amplitude $|A_\lambda|$ in the band $-1/2 \leqslant \mu \leqslant +1/2$ before integration. Averaging equation 40 over all amplitudes A_λ yields the average noise power N_n in the band $-1/2 \leqslant \mu \leqslant +1/2$ or $0 \leqslant f \leqslant 1/2\tau$ in real notation

$$\sigma^2 = \frac{\tau}{E_j} N_n = N_n/S_j = N/nS \tag{41}$$

S designates the average power of a signal containing n orthogonal functions of energy E_j each. N is the average noise power in the band $0 \leqslant f \leqslant n/2\tau$, which is the theoretical minimum of the bandwidth required for a transmission rate of n binary digits per time interval τ.

The probability p for $N_j\tau/E_j$ being larger than 1 is obtained from equations 38 and 41

$$p - 1 - \theta(\sqrt{S/2N})$$

$$\theta(x) - \frac{2}{\sqrt{\pi}} \int_0^x e^{-y^2} dy \tag{42}$$

The probability p_n of an error in an n-digit character caused by white, normal noise becomes in first approximation

$$p_n = \frac{1}{2} np \tag{32}$$

The factor 1/2 takes into account the fact that a distortion caused by noise must have the right "direction," that is, only a positive contribution to the digit -1 can cause it to be interpreted as $+1$. The error probability equation 43 is the same as that of a system using amplitude sampling, an ideal low-pass filter of bandwidth $w = 1/2T$, and pulses of the shape $\sin 2\pi wt/2\pi$ wt.[2]

Design Requirements for a Communication System Using Orthogonal Functions

The sine and cosine functions required for the transmitter and the receiver of Fig. 1 may be produced by L-C or R-C oscillators. The phase relationship between sine and cosine may be obtained by integration, use of phase bridges etc. For a Teletype system ($n=5$) transmitting 6 characters per second, the time available to transit one character is 166.6 ms (milliseconds) for synchronous transmission. The five time functions required have thus the following frequencies 0 (constant), 6 cps ($\sin 2\pi t/\tau$, $\cos 2\pi t/\tau$), and 12 cps ($\sin 4\pi t/\tau$, $\cos 4\pi t/\tau$). One has further $T = \tau/n = 33.3$ ms and obtains thus from equation 10 the bandwidth

$$w = (1+\alpha/2.5)/0.066 \text{ cps}$$

The required bandwidths for various values of α are given in Table I together with the reduction E of the received digits (from Fig. 4) and the maximum possible crosstalk $C_{0,0}$ from two adjacent characters (twice the values of Fig. 6). $w = 15$ cps is the theoretical limit of the bandwidth. Table II shows the absolute values of the crosstalk between the digits of a character for a bandwidth of 24 cps.

For a multichannel Teletype system the time functions would be allocated as shown in Table III. Crosstalk and digit reduction for a multichannel system are negligible for all channels except the highest one. The highest channel is also the one that is most affected by synchronization errors. A synchronization error of $\phi = \pm 1/4k$ will change $\sqrt{2} \sin 2k\pi(t/\tau+\phi)$ into $\pm\sqrt{2}\cos 2k\pi t/\tau$ and an output of 0 instead of ± 1 will result. The limit for the tolerable synchronization error in Table III is defined by $E_s = \pm 1/2\phi\tau = \pm\tau/8k$ and is given in milliseconds.

The dependence of the output of the receiver on the accuracy of the synchronization is obtained by evaluating the integrals

$$I_{sk} = 1 \int_{-1/2}^{1/2} \sin 2k\pi\theta \sin 2k\pi(\theta+\phi) d\theta = \cos 2k\pi\phi$$

and

Table III. Frequency Allocation in a Multichannel Teletype System

$$\overset{\text{Encoding Matrix}}{\frac{1}{\sqrt{8}}\begin{vmatrix}1&1&1&1&1&1&1&1\\1&1&1&1&-1&-1&-1&-1\\1&-1&1&-1&1&-1&1&-1\\1&1&-1&-1&1&1&-1&-1\end{vmatrix}}\times\overset{\text{Decoding Matrix}}{\frac{1}{\sqrt{8}}\begin{vmatrix}1&1&1&1\\1&1&-1&1\\1&1&1&-1\\1&1&-1&-1\\1&-1&1&1\\1&-1&-1&1\\1&-1&1&-1\\1&-1&-1&-1\end{vmatrix}}=\overset{\text{Transmission Matrix}}{\begin{vmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&1\end{vmatrix}}$$

$$I_{ck}=2\int_{-1/2}^{1/2}\cos 2k\pi\theta\cos 2k\pi(\theta+\phi)d\theta$$

$$=\cos 2k\pi\phi$$

For small values of ϕ desired the output is independent of the synchronization error, but the output caused by crosstalk increases linearly with ϕ.

The synchronization of a communication system may be accomplished by transmitting the function $\sqrt{2}\cos 2k\pi\theta$, multiplying it at the receiver with $\sqrt{2}\sin 2k\pi\theta$, and integrating. If receiver and transmitter are in phase the integral over the product will vanish. In the case of an synchronization error of $\pm\phi$ the output of the receiver will be

$$I=2\int_{-1/2}^{1/2}\cos 2k\pi\theta\sin 2k\pi(\theta+\phi)d\theta$$

$$=-\sin 2k\pi\phi$$

The output voltage of the integrator is proportional to the synchronization error ϕ if ϕ is small.

Fig. 1 shows transformers used for adding the various voltages. Resistors may be used as well.

Appendix. Matrix Notation for Encoding and Decoding

It is assumed that the information to be transmitted is represented by binary characters of amplitude 0 or 1. A set of such characters may be regarded as a high matrix. For instance, the 32 characters with 5 digits each used in Teletype transmission form a matrix of 32 rows and 5 columns. For the transmission the 32 characters may be transformed (encoded) into another form, e.g., the functions $f(\theta)$ composed of sine and cosine terms used in this paper. The most general linear transformation that can be performed in Hilbert space is the multiplication by a matrix of finite or infinite rank.

At the receiver the encoded message has to be transformed back into its decoded form. This transformation can again be performed by a matrix multiplication. We have then the "encoding matrix" for encoding the original set of characters and the "decoding matrix" for decoding the encoded characters back into their original form. Since the matrix multiplication is associative, the result of the multiplication of a set of characters by the encoding and then the decoding matrix may also be obtained by multiplying the set of characters by the product of the encoding and decoding matrices. The product of encoding and decoding matrix will be called "transmission matrix."

As an example consider the set of 16 characters with 4 binary digits each. This matrix of 4 columns and 16 rows is multiplied by a square matrix (encoding matrix) with 4 rows and columns; see Table IV. The result is the "encoded character matrix" which shows the sixteen characters in the form in which they are being transmitted. The decoding matrix is so chosen that its product with the encoded character matrix yields the original character matrix. The product of encoding matrix A and decoding matrix B yields the transmission matrix C, which turns out to be the unit matrix, $AB=C=1$. This is the necessary and sufficient condition for the decoded character matrix being equal to the original character matrix.

A case where encoding and decoding matrices are not square is shown in Table V. The encoding matrices of Table V are obtained from the encoding and decoding matrices of Table IV by eliminating the first row. It is noted that the transmission matrix is no longer a unit matrix, but is still a square matrix. Both properties are specializations of the two general rules: 1. The product of two matrices A_{mn} and B_{nm} is a matrix C_{mm}, if m is the number of rows and n is the number of columns. 2. The product of a high matrix and a long matrix cannot be the unit matrix (the product of a long matrix and a high matrix may be the unit matrix).

The practical advantage of using nonsquare matrices is the reduction of digits from 4 to 3 in the encoded character matrix, which means a reduction of time or frequency band for transmission. The price for the reduced bandwidth is evident from the form of the decoded character matrix; the first and the last character are identical and only 31 characters can thus be distinguished. Note that the difference in amplitude of the digits equals 1 for any one of the 30 "good" characters of the decoded character matrix, e.g., 1/4(3+1); 1/4(2+2); 1/4(1+3).

Table VI shows an example of encoding with a long matrix. The encoded characters here have more digits then the original characters. The transmission matrix is a unit matrix and the decoded character matrix is equal to the character matrix.

The transition to matrices of infinite rank can be made in the following way: The product of a matrix A with the terms a_{ik} and a matrix B with the terms b_{jm} yields a matrix C with terms c_{np}. According to the rule of multiplication for finite matrices one has

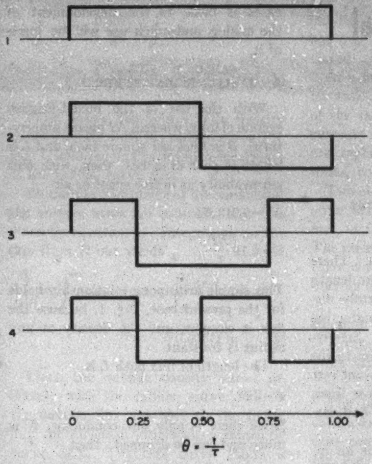

Fig. 8 (left). Set of four orthogonal step functions. Amplitudes are +1/2

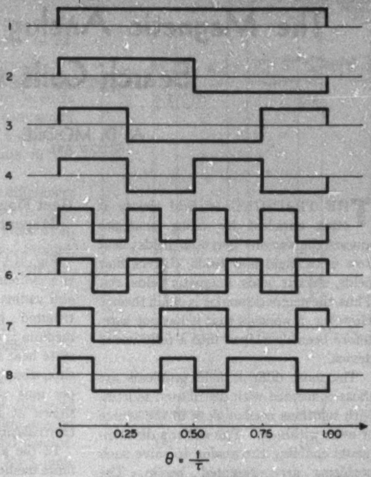

Fig. 9 (right). Set of orthogonal step functions. Amplitudes are $+1/\sqrt{8}$

$$c_{np} = \sum_{i=1}^{s} a_{ni} b_{ip}$$

$$\begin{vmatrix} a_{11} & \cdots\cdots & a_{1s} \\ \cdot & & \cdot \\ \cdot & & \cdot \\ a_{n1} & \cdots\cdots & a_{ns} \\ \cdot & & \cdot \\ \cdot & & \cdot \\ & & \cdot \\ a_{r1} & \cdots\cdots & a_{rs} \end{vmatrix} \begin{vmatrix} b_{11} & \cdots & b_{1p} & \cdot\cdot & b_{1q} \\ \cdot & & \cdot & & \cdot \\ \cdot & & \cdot & & \cdot \\ \cdot & & \cdot & & \cdot \\ \cdot & & \cdot & & \cdot \\ \cdot & & \cdot & & \cdot \\ & & & & \\ b_{s1} & \cdots & b_{sp} & \cdot\cdot & b_{sq} \end{vmatrix}$$

$$= \begin{vmatrix} c_{11} \cdots\cdots & c_{1p} & \cdot\ c_{1q} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ c_{n1} \cdots\cdots & c_{np} & \cdots\cdots c_{nq} \\ \cdot & \cdot & \cdot \\ & & \\ & & \\ c_{r1} \cdots\cdots & c_{rp} & c_{rq} \end{vmatrix}$$

Let the row $a_{11} \ldots a_{1s}$ become continuously infinite. Instead of the terms a_{1i} one then has continuously variable function $a_1(i)$. Let also the column $b_{11} \ldots\ldots b_{s1}$ become a continuous function $b_1(i)$. The matrix A will then have r rows but continuously infinite columns; matrix B will have q columns and continuously infinite rows; matrix C remains finite and contains terms

$$c_{np} = \int a_n(i) b_p(i) di$$

The integration has to be extended over the whole range of definition of $a_n(i)$ and $b_n(i)$.

As an example, consider the following functions (θ is written rather then i)

$$a_1(\theta) = b_1(\theta) = 1$$

$$a_2(\theta) = b_2(\theta) = \sqrt{2} \sin 2\pi\theta$$

$$a_3(\theta) = b_3(\theta) = \sqrt{2} \cos 2\pi\theta$$

$$a_4(\theta) = b_4(\theta) = \sqrt{2} \sin 4\pi\theta$$

$$a_5(\theta) = b_5(\theta) = \sqrt{2} \cos 4\pi\theta$$

The range of definition is $-1/2 < \theta < +1/2$. Hence it follows

$$c_{np} = \int_{-1/2}^{1/2} a_n(\theta) b_p(\theta) d\theta = 1 \text{ for } n = p$$
$$= 0 \text{ for } n \neq p$$

$$n, p = 1, 2, 3, 4, 5$$

The encoding and decoding matrices used in Table IV may be interpreted as a set of orthogonal step functions as shown in Fig. 8. Leaving out the first quarter of these functions leads to the matrices of Table V. The matrices of Table VI use a subset of the complete set of orthogonal functions shown in Fig. 9.

The encoding and decoding scheme of Fig. 1 has been shown to be described by matrix multiplications. The matrices used are of finite rank if the use time functions are step functions with a finite number of steps and are infinite in all other cases. It follows that the encoding-decoding scheme of Fig. 1 is the most general one that can be devised for linear transformations in Hilbert space.

The Magnetic Analog with Spiral Search Coils

A. D. MOORE
FELLOW AIEE

THE TEACHING of field theory is often enriched by citing analogies among the various potential fields: heat flow fields, fluid flow fields, current flow fields, electric fields, magnetic fields, etc. Thus, the magnetic analog is old in theory. However, it appears that it has not heretofore been developed into a fully useful device.

The most difficult field problems are those concerned with distributed sources, with solutions needed close to the source or even within it. The writer's developments enabling the analog to solve such problems are presented herein. The analog described applies to 2-dimensional fields in an infinite uniform medium. Some may feel that this seriously limits its scope. Even so, there such problems and they do need solution.

For example, it may not be widely known that, in the gas bubble method of underground gas storage, difficult fluid flow problems arise involving distributed-source phenomena together with an essentially infinite 2-dimensional medium. Large sums are involved, the art of using such storage is widely advanced, and it is rapidly expanding. The magnetic analog might apply to some of these situations.

In any case, policy must always be based on the need for all procurable analogs. There is simply no way of predicting their ultimate utility. A given analog may be useless in one worker's problem in his field; at the same time, it may offer the greatest convenience to the next worker on a different problem in a different kind of work.

The development of the magnetic analog called for the invention of a new form of search coil: the spiral search coil. It may well find applications outside of the analog itself.

Heat Flow Field and Analogous Magnetic Field

Fig. 1(A) presents both cases. There is a cylindrical volume of infinite length and radius R which is a uniformly distributed heat sink. The conducting medium is everywhere uniform. Steady-state heat flows from the medium to the sink, disappearing in it at a constant rate per unit volume. The heat flow lines, shown at the left, are radial, and isothermals are circular.

In the analogous case there is an infinite medium of unit permeability. The cylinder has become a long nonmagnetic conductor-carrying current uniformly distributed. An inward current sets up the magnetic field shown at the right. Flux lines are circular. The magnetic equipotentials outside of the conductor, and the lines-of-no-work inside it are radial. Either field is an inversion of the other. The flux lines of one are equipotentials of the other, and vice versa.

Heat flow has been adopted here for illustrative purposes; it is more familiar to most engineers than some other fields. The particular geometry of the above cases is basic to the development of the analog, and much use will be made of it.

ANALYSIS OF MAGNETIC FIELD

With the use of the mixed-English system of units wherein NI means ampere-turns, B is lines per square inch, and L is length of path in inches; then, with unit permeability as in free space or air

$$NI = 0.313\,BL \tag{1}$$

$$B = 3.19\,\frac{NI}{L} \tag{2}$$

This simple arithmetic relationship holds for the present case, Fig. 1, because the flux is circular, and the density at any radius is constant.

The length of flux path L is

$$L = 2\pi r \tag{3}$$

Since there is only one conductor, N is unity and can be dropped; then

$$B = 3.19\,\frac{I}{2\pi r} = 0.5077 I\,\frac{1}{r} \tag{4}$$

First, analyzing inside the conductor yields

$$\frac{i}{I} = \frac{\pi r^2}{\pi R^2} \tag{5}$$

$$i = I\left(\frac{r}{R}\right)^2 \tag{6}$$

$$B = 0.5077 I\left(\frac{r}{R}\right)^2 \frac{1}{r} = \frac{0.5077}{R^2}\,Ir \tag{7}$$

Next, integrate for the flux ϕ, for unit axial distance, one inch:

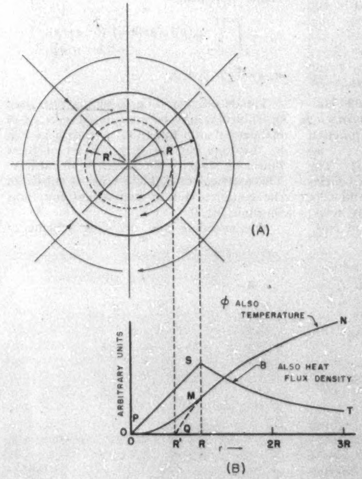

Fig. 1 (left). A—Solid conductor and replacement by smaller thin-wall tube conductor. B—Curve PNM, solid conductor's flux; curve PQMN, tube conductor's flux

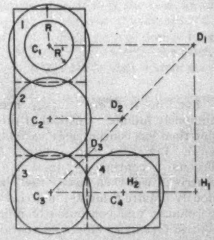

Fig. 2 (above). L-shaped section of distributed heat source; by analogy, section of distributed current

Paper 60-129, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, January 31–February 5, 1960. Manuscript submitted October 26, 1959; made available for printing December 10, 1959.

A. D. MOORE is with the University of Michigan, Ann Arbor, Mich.

The writer is grateful to Profs. L. N. Holland and M. B. Stout, and others of the electrical engineering staff, for assistance on instrumentation, and advice on the use of a power amplifier.

$$\phi = \int_0^r Bdr = \frac{0.5077}{R^2} I \int_0^r rdr$$

$$= \frac{0.5077}{R^2} I \frac{r^2}{2} = \frac{0.2539}{R^2} Ir^2 \quad (8)$$

Thus, inside the source, flux density varies directly with the radius, curve *PS*, Fig. 1; and the flux varies with the square of the radius, curve *PM*.

To analyze for outside of the conductor, the ampere turns are constant, and *B* is given by equation 4. Integrating for the flux from *R* out yields

$$\phi\Big]_R^r = \int_R^r Bdr = 0.5077\, I \int_R^r \frac{dr}{r}$$

$$= 0.5077 I \ln \frac{r}{R} \quad (9)$$

Thus, the outside density varies inversely with the radius, curve *ST*. If the outside flux is added to the inside flux, the variation with radius is shown by curve *MN*. The flux curve *PMN* is continuous; *PM* and *MN* have the same slopes where they meet at *M*.

CORRESPONDING HEAT FLOW FIELD VARIATIONS

It can be shown by similar analyses that the heat field has similar, but inverted, variations. The curve *PST* now displays heat flux density. The curve *PMN* shows the temperature difference between the axis and a point in the field at any radius.

THE ANALOG

It follows then, that if the magnetic case, set up to let the flux out to any radius, be measured, such measurements would stand for, and be in proportion to, the temperature differences between the axis and the same radii in the heat case. There would be no point in doing so for the above case, because it is easily solved analytically. The application appears in due course.

First Replacement: Squares Replaced by Circles

The *L*-shaped polygon of Fig. 2 is made up of four squares. It is the section of a uniformly distributed heat source or sink, infinitely long, and buried in an infinite medium having the same conductivity everywhere. The case could be solved in part by a magnetic analog in which the section becomes that of a solid conductor with uniformly distributed current. The outside field could be explored and mapped, and for some problems this would suffice; for others, requiring solution inside the current, the bus bar type of analog conductor would not do. The inside field cannot be explored.

As a first step toward inside solutions, let each square be replaced by a circle of the same area. The four component currents in the solid square conductors are replaced by equal currents in the round conductors.

Two objections arise. First, differences occur between the new field and the original, in the inside region and close to it. The errors will be treated later. Second, there is an impossibility; the round conductors overlap.

Second Replacement: Solid Round Conductors Replaced by Smaller Tubes

The problem of overlap of the solid conductors is overcome by using smaller tube conductors. Let the solid conductor, Fig. 1, have a radius of $R=1$ inch. The flux measured from the axis out to any radius is shown by the *PMN* curve. It is proposed to replace the solid conductor by a thin-wall tube of radius R' so that, for the same current, the flux from the axis out to any radius is the same as before, for any radius equal to or greater than *R*. One *R*-circle and its R' replacement tube are shown in the square 1, Fig. 2.

To simplify the derivation of R', let the current be such that, at radius *R*, flux density *B* is unity. Also, let the axial length taken be one inch.

The solid conductor's inside flux is found first:

$$B = r$$

$$\phi\Big]_R^r = \int_0^1 Bdr = \int_0^1 rdr = \frac{r^2}{2}\Big]_0^1 = 0.5 \text{ line} \quad (10)$$

The outside flux comes next:

$$B = \frac{1}{r}$$

$$\phi\Big]\frac{r}{R} = \int_1^r Bdr = \int_1^r \frac{dr}{r} = \ln r \text{ lines} \quad (11)$$

The total solid conductor flux beyond *R* is then

$$\phi = 0.5 + \ln r$$

To pass to the tube current, such a current can have no inside flux. The flux around it begins at its surface, at radius R'. It must be required of it that, at unit radius *R*, its flux will be 0.5 line, the same as produced by the solid conductor at that radius. Placing the tube's flux at *R* equal to 0.5 yields

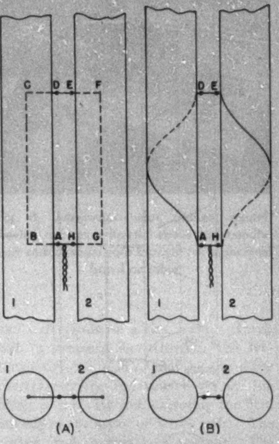

Fig. 3. A—Pair of tube currents with coaxial wire search coils. B—Spiral coils replace the coaxial wires

$$\ln \frac{R}{R'} = \ln \frac{1}{R'} 0.5 \quad (12)$$

$$\ln R' = -0.5$$

$$R' = \epsilon^{-0.5} = 0.606$$

or in general,

$$R' = 0.606R \quad (13)$$

TUBULAR CURRENT'S FLUX

As to the flux linking the axis, Fig. 1, the solid conductor's flux is given by curve *PMN*, whereas that of the tube current is curve *PQMN*. There is perfect agreement along *MN*, for anywhere outside of the solid conductor.

Inside (radii less than *R*) there is disagreement. But this is of no concern whatever, if, as is here done, the measurements are confined to the region outside of *R*.

To sum up, square conductors were replaced by round conductors, which overlapped; when they are replaced by smaller R' tubes, there is ample room for the tubes, and the tube current's field outside of *R* is identical with the round conductor current's field.

COAXIAL-WIRE SEARCH COILS

Fig. 3(A) shows a search coil arrangement to handle two tubes. Tube 1 has a coaxial wire *BC*, brought out radially to terminals *A* and *D* through holes in the tube wall. Tube 2, likewise equipped, has the *EFGH* wire. The wires are joined at *D* and *E*, with twisted leads

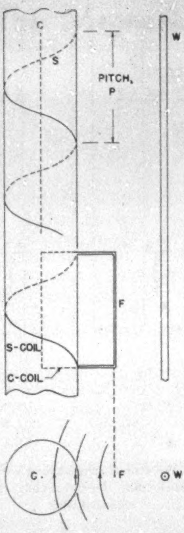

Fig. 4. Spiral search coil. Validity proof uses this figure

brought out from A and H. A rectangular search coil is thus formed, ready to measure flux by fluxmeter if direct currents are used; or by vacuum-tube voltmeter if alternating currents are used. The flux measured would be that which links with the coil.

Suppose tube 2 carries no current. It is interesting to note that the length BC in tube 1 need not then be coaxial: it could be anywhere inside tube 1, and give the same reading. Tube 1 can set up no flux inside itself. However, when two or more tubes are used, coaxial wire locations are necessary, so that net flux between centers may be measured, and ascribed to those locations.

The tube-and-coaxial-wire combination is feasible, but it presents handicaps. First, tubes of finite wall thickness would have to be used; the higher the currents used, the greater the thickness; some error might thus be introduced. In the second place the construction difficulties are formidable.

Third Replacement: Spiral Search Coil and Its Theory

The spiral search coil was invented to evade the construction difficulties mentioned above; in the third replacement, it does away with the coaxial wire coil; see Fig. 3(B). Instead of wires being put inside of tubes, they are simply wrapped around them spirally. The spiral search coil concept has been described to numerous workers familiar with flux measurements; it was new to all of them. It remains to prove that the replacement makes no change in the flux measured.

The theory of the spiral search coil is as follows:

Let the cylinder surface, Fig. 4, be wound uniformly full of spirals to the number of N strands, to make a hollow stranded cable. If each strand carries the current I_S, cable current is NI_S. The cable current sets up a circular flux, some of which links with wire W. Spiral pitch is P. Let ϕ_P be the flux linkage per pitch.

If the stranded cable should be replaced by an equal tube current flowing axially along the cylinder surface, the tube current would cause the same ϕ_p linkage with the wire. This is because axial components of spiral current are identical with elements of the tube current; and peripheral components of spiral current can cause no linkage with wire W.

Next, no change of linkage with W occurs if the NI_S tube current is replaced by an equal current flowing along axis C. Therefore, the axis current gives the same linkage as did the stranded cable current. Since all strands of the cable contribute equally to the linkage, it follows that one strand or spiral S, having current I_S, has the same linkage ϕ_{PS} per pitch with with W, as would be caused by I_S flowing along axis C.

Therefore, for one or more full pitches, the mutual inductance M_{SW} of spiral S with wire W is the same as the mutual inductance M_{CW} of axis wire C with W. Therefore the mutual inductance of wire W with axis wire C is the same as with spiral S. This is to say that when a current in wire is changed, its flux induces equal emf (electromotive forces) per pitch, in S as in C.

In Fig. 4, there are also two closed single-pitch search coils (the outer straight parts, meant to be superimposed, are drawn slightly apart that they may be seen). It is now obvious that current in wire W will cause the same linkage with both these coils, and that either may be used to measure the flux through the C-coil rectangle. This was amply verified by a drastic test made on a special large spiral built for the purpose.

It follows further that the straight parallel length of search wire at F may be replaced at will, by another spiral at any other tube. In Fig. 3, then, the spiral search coil will do the same job as the coaxial-wire coil, and with far greater ease of construction.

Table I. First Replacement Error*

Position	Per-Cent Error
H_1	0.66
H_2	0.67
D_1	0.57
D_2	0.91
D_3	3.5†

* Error in flux measured from center C_3 out to various positions, due to replacement of square by round conductor of equal area; see Fig. 2.
† Approximate.

Spirals must be one or more full pitches in length. Otherwise, it makes no difference whether they are wound to the right or left, or with long or short pitch. All spirals must have the same axial length; lead wires joining two spirals to make a search coil should be held in planes normal to the axis, out to where they can be twisted, so as to have no emf induced in them.

Ordinary search coils often have several, or many, turns. Spiral search coils as described are 1-turn coils, and this form will be retained here. Note, however, that more than one turn can be used. For example, each rod could be wound with two spirals, side by side. The two leads at one end of a rod would be brought out to a terminal board and joined to make a 2-turn search coil; jumpers would be used at each end to achieve the proper in-series connections.

Fourth Replacement: Tubes Replaced by Rods

In the second replacement, a solid round conductor was replaced with a thin tube of smaller radius. The validity de-

Table II. Return Loop Errors

	Return Loop Error, Per Cent		
	Single Loop		
Rs, Inches	Roving Coil Outside Loop	Roving Coil Inside Loop	Double Loop
0.26	−0.91	+0.91	
0.52	−0.91	+0.92	
1.05	−1.20	+1.23	
2.10	−1.78	+1.87	+0.040
4.20	−2.74	+3.05	+0.154
8.40	−4.45	+5.30	+0.425

pended in part on the tube's current having no inside flux. If the R' tube is now replaced by a solid rod of the same size, inside flux appears. If coaxial-wire search coils were used, the validity is destroyed. But it was a pleasant surprise to find that if the rod has the spiral coil, validity is restored. The spiral, being wound around circular inside flux, cannot link with it, and ignores it. This advantage was not anticipated when the spiral search coil was conceived.

The rod offers advantages: first, the need for using an extremely thin tube (or else accepting error) is eliminated; second, the rod has superior stiffness and higher current-carrying capacty.

ACCOMMODATING TO THICKNESS OF SPIRAL WIRE

It has been assumed that the spiral wire had no thickness. Real wire has an insulated thickness that is not negligible. Heretofore, rod diameter R' was made to be (0.606 R), but this does not hold for real wire. R' must now be taken as the mean radius of the spiral, with rod radius smaller than R'. If we take R'' as rod radius R'' will be R' minus the radius of the insulated wire section.

The use of the smaller rod entails no error. In fact, any still smaller rod may be used if the spiral is kept coaxial with it. Such a use is considered later.

Summary of Dimension Relationships

The basic dimension in the analog is the size of the original square, which is also the center-to-center distance (as C_1 to C_2); see Fig. 2. Taking this dimension as unity:

Size of square $= 1$
R, radius of circle of same area $= 0.564$
R', mean radius of spiral coil, $0.606 \times 0.564 = 0.366$
R'', rod radius $= R'$ minus wire radius

This order might imply that the design routine is to adopt square size, then fix other dimensions. Instead, rod and spiral wire sizes would be settled upon first, and other dimensions derived therefrom.

Replacement Error

Error appears with the first replacement. The round conductor replaces the square conductor, and their two fields are different, internally and in the nearby region.

Let square 3, in Fig. 2, carry current. It would set up a certain flux between its center C_3 and a position at some radius r. Its round replacement will in general set up a different flux. The writer carried out extensive error studies (not included), the results being given in Table I. It is seen that for nearby centers H_1, H_2, D_1, and D_2, the error is less than 1.0%. Further out, the error is less. The error at the square's corner D_3 is about 3.5%.

Thus the first replacement introduces error for fluxes between centers, but it is very small. These are positive errors; for the positions cited, replacement flux is in excess of flux due to square conductors. The other three replacements, ending in the rod-spiral combination, cause no further errors.

Additional Straight Search Wires

Measurements for additional positions inside the source and at its boundary would sometimes be desirable. These can be had by installing stretched straight search wires at corners of squares, as at D_3 in Fig. 2. Any such wire would act in series with any other, or with a spiral, to form a complete search coil. The flux of square 3 between C_3 and D_3 would be in error by about 3.5%, but this would be the largest error. When wire D_3 is used with rods further away, the error is less.

Layout for One Element of the Analog

A feasible layout for one element (one rod) is shown in Fig. 5. The rod GH is 30.5 inches long, its spiral being wound on for 30 inches. Flux measurements thus are made between the planes GI and HJ. Flexible connectors AG and HB extend the straight part of the current to a distance AB of 10 feet. The current returns by a single loop $BCDA$; or divides equally and returns by double loops $BCDA$ and $BFEA$, whichever design is adopted.

The 1/4-inch rod has an R'' of 0.125 inches. The no. *30* Belden enamelled copper wire for spirals has a diameter of 0.0106 inch. R' is found to be 0.1303 inch.

IJ is another rod, with spiral. The IJ and GH spirals, in series, form a search coil to measure flux through the rectangle $GHJI$. Rod IJ may be one of the current-carrying rods which set up the field; or a roving rod, exploring the field outside of the array of active rods. The roving rod carries no current. The pioneer model is built to the above specifications; see Fig. 6.

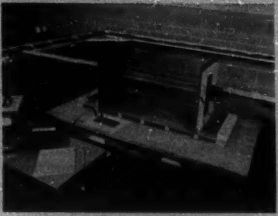

Fig. 6. Magnetic analog pioneer model. Roving rod seen directly above rod bundle. Left ends of spiral coils brought out to terminal board on table

Return Loop Errors

Heretofore, flux computation was simple, the currents being taken as straight and infinitely long. Now, the conductor has the finite length AB, and the current returns nearby. A return loop error will ensue. The error study is much too long to be included, but results are given in Table II. For the case when the roving spiral is in the loop plane, these are the largest errors. For example, when the distance R_s between centers, Fig. 5 becomes 8.4 inches, a single return loop gives errors of −4.45% and +5.30%, depending on whether the roving spiral is outside or inside the loop. The two loops largely cancel their effects when the double loop is used, dropping the error to +0.425%. The double loop also reduces spurious emf due to fields of extraneous currents.

The low error with double return predicts that a single rod would produce a highly circular field out to 8 inches or more. A test on the pioneer model at a 7.5-inch radius, made with eight roving rod positions 45 degrees apart, gave verification: the greatest departure from average flux measured was 0.6%.

Modifying Relative Loop Size. If the rod-and-spiral design as described is retained but return loops are made smaller, loop error will rise. However, a new error study might well show that a double-loop frame size as small as 8 by 8 feet, or even 7 by 7 feet, could give all of the accuracy needed for handling many problems.

Source and Sink Cases. Consider a case in which there is a source, represented by a bundle of rods with current to the right; and a nearby sink of the same total strength, represented by the same number of rods, in a bundle with current to the left. There would be no return loops. All rods would be in series, the connector junctions being made at the terminal block locations.

Principal Design Considerations

The analog inherently has low flux values, measured by 1-turn search coils. These considerations justify the use of long spirals, such as 30 inches. They also indicate the use of alternating current in the rods, with the vacuum-tube voltmeter as the instrument.

The power supply can be 60 cycles if the analog is large enough to carry the currents needed. A large analog makes it easier to get a given degree of construction accuracy.

Rod stiffness is a factor, to get minimum sag and avoid lack of parallelism for horizontal rods supported only at the ends. In a standing-on-end design, with rods vertical, sag would be eliminated.

Bending of rods by electromagnetic forces should be considered. In the illustrative case worked on the pioneer model, and described later, the maximum total lateral force on a rod, at a high momentary current of 100 amperes, was computed to be equal to about one-fifth of the weight of the rod. Spacers can be provided at rod centers, if needed.

Main Features of the Pioneer Model

The pioneer analog was built as indicated in Fig. 5, with double loops laid on a 10- by 10-foot wooden frame. The frame tilts to let the far side rest on the floor. One can walk under the near side. Fig. 6 shows the frame when horizontal.

The rod frame has a base with two head panels rigidly mounted on it. The 1/4-inch Masonite panels, 17 inches wide and 18 inches high, have the smooth sides facing in. The inner faces are $30\frac{5}{8}$ inches apart.

The rods are of 1/4-inch round full-hard brass, $30\frac{1}{2}$ inches long, each with a spiral of no. *30* enamelled copper wire. The spiral was hand-wound by holding the rod at an angle to the oncoming wire and turning the rod. The pitch is 1/2 inch. The 30-inch spiral stops 1/4 inch from each end and is tied down at the ends by wraps of thread. An insulation test at 115 volts eliminated spirals with weak spots in the enamel.

The panels have an array of matched holes in the central areas, and any one rod is positioned and held by a mated pair of holes. The square size (distance between adjacent rod centers) works out to be 0.382 inch. Each panel has 169 holes in a square array of 13×13 holes, spaced 0.382 inch on centers.

Each rod is extended one inch at each end by 1/4-inch brass studs which go through the panel holes. The inner end of a stud screws into the end of the rod. The stud's outer end is drilled to receive the connector wire, which is soldered into it. A connector such as *HB*, Fig. 5, is braided no. *12* copper, rubber-covered. The outer end terminates in a spade lug, for attachment to terminal blocks mounted at *A* and *B*. The double loops are pairs of no. *16* braided copper, rubber-covered, the pairs ending in spade lugs permanently attached to the terminal blocks.

To mount a rod, it is held to hole positions. A loose stud-connector is picked up, the stud is slipped through its hole, and is screwed into the rod end; this is repeated for the other end. Connections are then made to the terminal blocks.

This model is designed for 60 cycles. Normal currents of 10 to 20 amperes are easily carried. When unusually low fluxes are measured, currents can go to 50-ampere levels (or more) for long enough to get readings.

Screw connections were adopted to make sure of handling such currents. Use of higher frequency and lower current levels would permit use of a slip fit of stud into rod, and banana-plug endings for the connectors. This would make it much faster, in changing from one setup to another.

The inner panel faces have horizontal and vertical lines scratched on the smooth surfaces to form a grid with 0.382-inch spacings. The grid locates the roving spiral when exploring the outside field. The holes in an array are centered on intersections.

When the roving spiral comes within the hole array, it is located by special studs going through holes; a stud extension fits smoothly with a hole drilled in the end of the dummy rod which carries the spiral.

A spiral and its leads are all one piece of wire. When rods are being inserted during a setup, their longer leads at one end are brought out and connected to a small terminal board that duplicates the setup. The shorter leads at the other end are all connected together. The pioneer model is large, but the design permits disassembly. The loop frame stacks against the wall when not in use.

Voltage Equation

The voltage equation for a magnetic analog is given below. It applies when one rod carries current, and its spiral, together with a roving spiral, forms a search coil. With the use of a sine wave:

I = amperes (effective)
f = frequency
L_S = axial length of spirals, inches
R' = mean radius of spiral on rod, inches
r = radius to center of roving spiral, inches
E = volts induced

$$E=3.19IfL_S(10)^{-8}\ln\frac{r}{R'} \qquad (14)$$

In the pioneer model, let one rod be in use, with the roving rod one hole away from it. R' is 0.1303, and r is 0.382. With 60 cycles, and the high momentary current of 100 amperes

$$E=3.19\times100\times60\times30(10)^{-8}\ln\frac{0.382}{0.1303}=0.00618 \text{ volt}$$

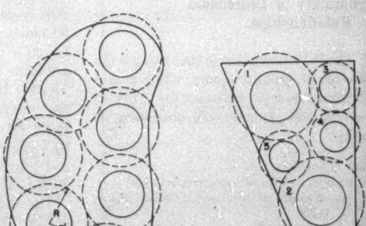

Fig. 7. A—Irregular source section replaced by equal rod elements. B—Another section, replaced by two sizes of rod elements

Adaptation of Analog to Irregular Sections

When the distributed source section divides into squares with regular spacings, the construction described suffices. The handling of iregular sections is indicated in Fig. 7. In Fig. 7(A), the seven R-circles, whose totalized area equals that of the original section, could be drawn to parcel out the section very well indeed. This amounts to the first replacement. Each circle now replaces a polygon rather than a square. Next, the R'-circles (rod-and-spiral combinations) replace the R-circles. This is a case when the section may well be carved into equal sized elements.

Other cases occur, Fig. 7(B), where a limited number of elements gives a better fit by using two, or more, sizes. Here, the larger areas 1 and 2 are equal, and the smaller areas 3 through 6 are all equal. With uniform distribution in the source, rod currents are made proportional to the areas they represent.

If rods (or tubes) of the larger size are available, they can be used, with the spirals wound directly on them. Or smaller rods all of the same size can be used throughout: a rod having to carry a large spiral can be built up by slipping a thin-wall brass tube concentrically over it, the tube to carry the spiral. Commercial tube and wire sizes can be found that will combine to bring R' very close to a required value.

If additional measurements are made with straight search wires, they should be placed where R-circles do not overlap. The 3.5% replacement error found for D_3 at the square's corner, Fig. 2, will now, with polygons instead of squares, be greater for some positions, and less for others.

Construction for Irregular Spacings. The regular hole arrays described could not locate rods with irregular spacings. Flexibility of hole positions is needed. The central areas of both panels would be cut out, making, say, square openings were rod bundles are located. Masonite hole-pieces would be cut to fit the openings as inserts. The inserts would be drilled for the studs at the positions required.

Nonuniform Distributions

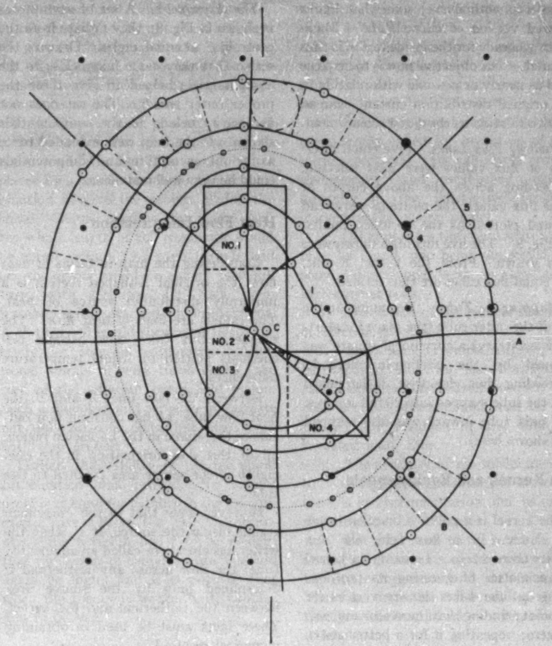

Fig. 8. Computed field map for L-section case; analog should produce same field. Analog flux dashed line in tube 3-4 agrees with computed field

Potential field problems occur in which the source has a nonuniform distribution. For example, heat production with the section, Fig. 7(A), might not be uniform. The rate of heat production assignable to each polygon would be known, and individual rod currents made proportionate to these values.

Numerical Solution of a Case

Before building the pioneer model, the case of Fig. 2 was worked out on paper, to see how much information the proposed analog could yield and how useful it would be in solving the field. The original section, Fig. 8, was given the coarsest breakdown possible, being treated as only four square current components. It was assumed the replacements had been made, with the rod-spiral combinations in use. The total flux per axial inch of no. 1, for example, from center out to any radius was then given by only one equation, equation 9, with R in the denominator changed to R'.

The steps leading to the computed map, Fig. 8, will be outlined. They have much to do with the use of the analog itself. Also, the map will be used to indicate in a brief way some routines involved in putting the map to use, to obtain desired answers from it.

No. 2 was chosen as the reference rod, it being foreseen that the current centroid C and the kernal K would fall within it. The positions taken were also kept on the coarse, limited basis, being confined to the 42 black dots; see Fig. 8. The routine was to compute the flux from no. 2 center out to any position, due to the 4-rod currents.

Two families of curves (not included) were then plotted. An H-family of seven curves came from flux-versus-horizontal position, going across the horizontal rows. A V-family of six curves were of flux-versus-vertical position, along the vertical rows. Curves from diagonal plots can be had for additional points, and one such was used.

These curves are much alike, broadly speaking, being upswept either way from where they go through lows within the source. It is most important to give the correct trend to the low part of such a curve. Here, the rod-spiral treatment is not used in sweeping in the low part, for this would give a sort of skewed version of the broken curve $PQMN$. Instead, for this particular purpose, the first replacement is reverted to, and the sweep is in a smooth curve, somewhat like a skewed version of curve PMN. Maximum accuracy for the inside region is thus secured. The objective now is to map the field as nearly as possible with relation to the original distribution current, instead of with relation to the 4-rod replacement.

Plotting Flux Lines. Five equal intervals of flux values were next selected. Proceeding across the above curves at these flux values, the positions were read off and plotted as the encircled points; see Fig. 8. The five flux lines shown were then drawn. From the kernel K out, five equal-flux tubes are thus formed.

Mapping the Tubes. Beginning at the top of the outer tube (the place for starting is arbitrary) a curvilinear square was mapped by the circling-in method.[1] Proceeding thus clockwise, it happened that the tube mapped into 26 full squares. The next tube inward was also mapped (not shown here).

The Kernel, and Equipotentials

The kernel is a point of inaction inside the source. In a flux field, the flux density there is zero. Locating the kernel was a matter of guessing its position; laying out the 4-flux density vectors for the point; finding that the vector sum was not zero; repeating it for a better guess, etc. Actually, the trial-and-error work quickly ended in a very good location at K.

The eight lines radiating from the kernel came next. Inside the source they are lines of no work; outside, they are equipotentials. The lines were to be at equal potential differences. If 3.25 is obtained by dividing the 26 squares of the outer tube by 8, it follows that these lines should cross the tube at intervals of 3.25 curvilinear squares. An arbitrary beginning is made somewhere, and the lines thus located. Since graphical work is subject to some error, the next tube inward, also mapped, was likewise treated, and both tubes were allowed to compromise in deciding the locations.

The lines were then prolonged inward to K, with two criteria in mind: first, that the map must be orthogonal; second, that the lines should divide the source area into eight equal areas. Some trial-and-error work was required to do this sufficiently well.

Be it specifically noted that the lines do not arrive at K with equal angles. The belief is often met that they should do so; instead, the several angles can be fantastically unequal, as this case illustrates.

The Asymptotes. A set of asymptotes is shown in Fig. 8; they radiate from the centroid C, at equal angles. Drawing the set so that they came fairly close to the equipotentials helped to give these the proper outer trends. The set does not necessarily belong to the equipotentials shown. If the map were extended twice as far out, asymptotes and equipotentials could be very well matched.

Heat Flow Interpretation

Considering the map in terms of heat flow, the original L-shaped section is a uniformly distributed source of heat. The radials are lines of heat flow. The magnetic flux lines now become isothermals plotted for equal temperature differences.

Between the flow lines A and B, the heat flow tube AB has constant flow outside of the source in the Laplacian region, all of this flow originating in the one-eighth of the source area devoted to this tube.

However, note that in the Poissonian region inside the source, it is what the writer has elsewhere called an augmented tube; the flow across any isothermal is determined only by the source area between the isothermal and the kernel. These facts must be used in obtaining numerical results.[2]

Use of Heat Flow Map. Let k be the medium's heat conductivity, in these terms: If one degree centigrade difference exists between the faces of a 1-inch cube, then k watts of (parallel) heat flow occurs through the cube. Passing to the map, consider any curvilinear square volume of 1-inch axial depth (into the paper) and faced by any curvilinear square. The conductance of this volume is the same as that of the 1-inch cube.[1] Curvilinear square volumes can be combined in series, or parallel, or both, in terms of Ohm's law. Thus, if temperature differences are known, heat flows can be computed, or vice versa.

The inner part of tube AB is partly mapped into squares. One of these squares is subdivided into four curvilinear squares. The temperature drop across this square, for example, can be taken as due to the heat originating in the area between the subdivider isothermal, and the kernel.[2]

Case Solved on Analog

The case of Fig. 2, already solved on paper on a coarse basis and giving the map shown in Fig. 8, was set up on the analog, Fig. 6. However, the analog was set up in terms of the next finer degree of subdivision: 16 rods were used, or four for each of the original four squares. The rod bundle occupied the central area of the hole array. The sixteen rods were in series. The roving rod is shown directly above the rod bundle.

The current was 50 amperes, used momentarily, at 60 cycles. The highest search coil voltages were obtained when the roving rod went to the corners of the hole array, these then being around 60 to 80 millivolts.

Plots of the data in terms of H- and V-families gave highly consistent curves. One of the experimental flux lines is shown dashed about midway of the tube defined by computed lines 3 and 4. The analog-produced line is highly consistent with the computer lines. Other parts of the two maps likewise agree. The experimental points are enclosed in the smaller circles close to or on the dashed line.

Use of Higher Frequencies

Rod current would vary inversely with frequency, for the same search coil voltage output. Therefore, speaking of the pioneer model, a high momentary current of 50 amperes at 60 cycles could be replaced by a steady current of 5 amperes, 600 cycles. Since the model can carry 20 amperes, this current at 600 cycles would give four times as many millivolts to measure on the vacuum-tube voltmeter.

Readings were taken of the case described above, at 10 amperes, 680 cycles, by the use of a rotating generator as the source. A very good check was obtained with readings from the 60-cycle measurements.

Another test was made at 2 amperes, 4,600 cycles, with a power amplifier as the power supply. The check was poor, the fluxes within the rod bundle close to the kernal being below expectation. This suggests that proximity effect was causing a redistribution of rod currents within the rod sections. Approximate calculations of proximity effect bore this out. It is concluded that the design of the pioneer model permits frequencies up to about 700 cycles, without need to worry about proximity effect.

Using hard brass for the rods not only gives stiffness; it also gives desirably high resistivity, helpful in minimizing proximity effect at higher frequencies. At 680 cycles, the ohms reactance for the analog as set up was found to be 4.9 ohms. This converts to 0.43 ohm at 60 cycles.

Types of Use for Analog

At least two kinds of uses for the analog can be envisaged, here to be called types 1 and 2. Type 1, the "map" type, is illustrated by Fig. 8 and the discussion of it. The problem requires a complete, or rather complete, analysis. The operation of the analog leads to a flux map. Any convenient rod current value can be used, as long as the map is obtained. Once the map exists, its magnetic flux origin is forgotten, and it becomes a thermal (or other) map, standing on its own merits, and ready to be used in terms of heat data put into it in order to get answers from it, i.e., in type 1 uses, the analog current chosen need have no relation whatever to the ultimate use of the map.

In type 2, the "direct" type, the analog would be set up and used on a specific case, to give immediate answers. For example, for a given rate of heat production, it is required to know the temperatures at a few particular locations. Appropriate conversions would then be made, so that when analog current is fixed at the right value to represent heat produced, emf measured could at once be converted to degrees of difference.

In the foregoing, the word "current" applies when all rods have the same current. The word becomes plural, when a case requires rod currents to be individually set.

Other Uses of Spiral Search Coil

The spiral search coil may find applications outside of the analog. For example, large current-limiting reactor coils continue to be studied and improved. They are 3-dimensional and axisymmetric. Forces tending to disrupt them are high and may go higher as generator capacities rise. It is important to know the flux densities within the reactor, so that force computations can be made.

A small-scale model of a proposed coil could be built. The conductor radius, to scale, would be R. This would be replaced by a smaller conductor-spiral combination to give the proper R' for the spiral. Before winding the model coil, the whole length of the conductor would be spiral wound. As each turn is laid on, the spiral would be cut at each full turn, with terminals for each turn-length of spiral attached and brought out. A 48-turn coil would then have 48 spirals, ready for internal exploration. Additional spirals or wire turns could take care of the adjacent outer field region. Such a model should serve to investigate not only air-core coils, but also those with iron present.

Earlier, the validity of the rod-spiral combination was proved. No similar proof is at hand for validity in the axisymmetric case. From the practical standpoint, the writer holds it to be evident that the center-to-center accuracy would again be high; and it is possible that when the theory is worked out, validity may be proved.

Conclusions

1. The magnetic analog has been changed from a theoretical concept to a workable reality. Two-dimensional potential fields of heat flow, fluid flow, current flow, etc., in an infinite uniform medium, can be solved by setting up the analogous magnetic field.
2. The analog described achieves solutions inside of distributed sources, as well as outside of them.
3. Uniformly distributed sources of regular or irregular boundaries can be handled, and for nonuniform distributions.
4. The development of a usable magnetic analog called for invention of the spiral search coil. Its validity is proved theoretically, and established experimentally in the illustrative problem worked on the pioneer model.
5. Other uses for the spiral search coil may be found, one being suggested for some 3-dimensional work on very large, high-current coils.
6. The design of the pioneer model is completely described.
7. The analog is simple, rugged, can be kept to moderate size limits, and can be operated on 60-cycle power. The cost is low. Measurements can be suspended and resumed at any time, or repeated at any time.
8. The accuracy of the model appears to be so high that the principal source of error is in instrumentation, due to using the vacuum-tube voltmeter.
9. For watt-hour meter research, the analog's rod currents could replace driving flux components and their images.[3] The flux map from the analog would then give the map of eddy currents in the disk.

Discussion

Walter E. Rogers (University of Washington, Seattle, Wash.): I should like to submit an alternative mathematical proof of Professor Moore's somewhat surprising conclusions regarding the spiral search coils. I shall show that the net flux contributed to the coil by the spiral *surrounding* a current of circular symmetry is independent of the way in which the spiral is wound. On the other hand, I shall show that a spiral *with a uniform pitch*, wound on a supporting cylinder external to the currents producing the field, is effectively located on the axis of that cylinder.

Referring to Fig. 4, let us compute the flux through search coil S assuming that the cylinder which supports the spiral carries a current which is distributed with circular symmetry. While the common procedure of evaluating the flux through any convenient surface bounded by the search coil produces the same result, the use of Stokes' theorem and the equivalent line integral of the vector potential is simpler and more illuminating.

As is customary, let us define the vector potential **A** by

$$\mathbf{B}=\text{curl }\mathbf{A} \tag{15}$$

Reference to equation 7 will demonstrate that a suitable vector potential for points outside the current-carrying region has only an axial component and is given by

$$A_z=c\log r \tag{16}$$

where r is the distance from the axis of the current and c is a constant depending on the total current, its direction on the axis and on the system of units.

The flux through the search coil is given by the line integral of A around the perimeter of the search coil.

$$\phi=\oint \mathbf{A}\cdot d\mathbf{S} \tag{17}$$

with

$$d\mathbf{S}=\mathbf{i}\,dx+\mathbf{j}\,dy+\mathbf{k}\,dz \tag{18}$$

The first segment of the integral is path AD in Fig. 3(B). Since this segment is at constant distance from the axis, the vector potential is a constant. Where R is the radius of the supporting cylinder

$$A_z=c\log R \tag{19}$$

and the differential is exact.

$$\int_A^D \mathbf{A}\cdot d\mathbf{S}=\int_A^D A_z dz=c\log R(D-A) \tag{20}$$

This contribution to the flux is therefore independent of the shape of the spiral, and depends only on its axial length. Indeed, this leg of the search coil need only lie on the surface.

Referring again to Figs. 3(B) and 4, the horizontally drawn segments of the search coil are perpendicular to the vector potential and contribute nothing to the line integral. The remaining portion is the straight segment F of Fig. 4. Here A_z is also a constant, since r is a constant, and

$$\int_D^A \mathbf{A}\cdot d\mathbf{S} = c \log r(A-D) \tag{21}$$

Combining equations 20 and 21 into equation 17, yields

$$\phi = c(A-D)\log \frac{r}{R} \tag{22}$$

which is equivalent to equation 9.

We turn now to the case in which the spiral segment is external to the sources of the field. This is illustrated by Fig. 4 if the current sources are confined to wire W. To draw a conclusion, we need only to compute the line integral along the spiral path of the S coil. Let r again be the radial distance to the axis of the currents, now in wire W, and let g be the vector distance between axes. Let the parametric equations of the spiral be

$$|\mathbf{r}-\mathbf{g}| = \rho \tag{23}$$

where ρ is the radius of the supporting cylinder, and

$$\theta = \frac{2\pi}{P} z \tag{24}$$

We find here that the line integral

$$\int_A^D A_z dz = \int_A^D c \log r dz \tag{25}$$

depends on the path, since r is a variable. Using the law of cosines and the path of equation 24, we transform the variable to obtain

$$\int_A^D A_z dz = \int_0^{2\pi} \frac{cP \log g}{2\pi} d\theta + \int_0^{2\pi} \frac{cP}{2\pi} \log\left[1+\frac{\rho^2}{g^2}-\frac{2\rho}{g}\cos\theta\right] d\theta \tag{26}$$

The second definite integral on the right is zero when the bracketed quantity is always positive, as it is in this case. Therefore

$$\int_A^D A_z dz = cP \log g \tag{27}$$

We interpret this result in the following way: The contribution of the uniform spiral segment is the same as though it were a straight wire of length equal to its pitch and located at the center of its supporting cylinder. This interpretation arises because in the result, $c \log g$ is the vector potential on the axis.

While a result equivalent to the spiral could be achieved by a straight segment lying on the surface of the cylinder at distance g from one wire W, the circular symmetry will be destroyed if other wires are present.

Circular symmetry products results which would not be expected from intuition alone. Another example is the fact that the mutual inductance of circuits of long, parallel round wires depends only on their spacing and not on their size.[1] Neither does it depend on the distribution of the current, as long as circular symmetry is preserved.

Reference

1. Introduction to Electric Fields (book), W. E. Rogers. McGraw-Hill Book Company, Inc., New York, N. Y., 1954, pp. 314–17.

A. D. Moore: As Prof. Rogers says of the spiral search coil, circular symmetry produces results which would not be expected from intuition alone. This is confirmed by the way it came into existence. The constructional difficulties presented by the coaxial search wire arrangement, Fig. 3(A), were so distasteful that the writer was driven to grasp at any other idea that might show promise. This may explain why the spiral search coil has come along so belatedly, in spite of the wide use of spiral wire forms in many examples of electrical engineering.

One is grateful to Prof. Rogers for his analyses, and especially for the alternative proof of validity of the spiral search coil. He lends emphasis to the fact that the search coil spiral should be uniform. However, this should not lead to the conclusion that extreme accuracy is required. In the magnetic analog, for example, due care should insure that hand-wound spirals will suffice, if several to many pitches are used. One may repeat the hope that the spiral search coil will find uses other than that covered in the paper.

Shall an Electron Tube or a Semiconductor Device Be Used?

E. E. SCHENEMAN
MEMBER AIEE

S. K. WALDORF
MEMBER AIEE

A WIDE variety of electron tubes is now available to satisfy the needs of almost every application, but new types are still appearing as the field of electronics continues to enlarge. Also available are many kinds of semiconductor devices, although they are not as numerous as the types of electron tubes. With such a large range of operating characteristics available in both classes of electron devices, a designer of electronic equipment often is obliged to consider both types and make a choice of either an electron tube or a semiconductor device. The proper selection may not be immediately apparent, although each kind of electron device has a number of distinctive characteristics which can serve as aids in arriving at a reasonable decision.

It is the objective of this paper to present in convenient form a summary and comparison of numerical data in order of magnitude, not in exact figures, on both electron tubes and semiconductor devices which will serve as a general guide for those areas where both types of devices might be considered as being worthy of consideration.

General Considerations

In any one application, the designer necessarily must make the choice between an electron tube and a semiconductor device after making his own evaluation of relative costs, marketability, fabrication and maintenance conditions, and the factors enumerated in the accompanying tables. It is important to note that semiconductor devices have the following distinctive characteristics:

1. Require no cathode heater power.
2. Certain types perform well at very low voltage.
3. Generally they have low mass, as little as 0.1 gm (gram) for diodes and 0.3 gm for transistors, and small volume, 0.4 cc (cubic centimeters) minimum, with consequent excellent capability of resisting vibration and mechanical shock.

On the other hand, electron tubes also have several distinctive characteristics:

1. Very high electric resistance between tube elements is available for isolation of circuits.

Paper 60-74, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted March 18, 1959; made available for printing December 8, 1959.

E. E. Scheneman is with the Westinghouse Electric Corporation, Baltimore, Md. S. K. Waldorf (deceased) was with the Westinghouse Electric Corporation, Baltimore, Md.

The authors wish to acknowledge the information supplied by the Baltimore Divisions, the Electronic Tube Division, and the Semiconductor Department of the Westinghouse Electric Corporation.

Table I. Satisfactory Environmental Conditions for Semiconductor Devices and Electron Tubes

			Electron Tubes		
	Semiconductor Devices*		Thermionic		
Environmental Condition	Germanium	Silicon	Vacuum	Gas Filled	Cold Cathode
Junction or envelope temperature	−65 C to 85 C	−65 C to 175 C	−65 C to 500 C (Ceramic)	−55 C to 90 C	−55 C to 90 C
Altitude	No limit		Sea level to 80,000 ft; heating and flashover may reduce rating		
Relative humidity	0 to 100%		0 to 100%		
Maximum vibration	30 g at 20 to 2,000 cycles per second†				
Maximum mechanical shock	40 g at 10 milliseconds; 500 g at 1 millisecond				
Method of mounting	Usually soldered; some plug-in		Soldered or plug-in		
Thermal shock	0 C to 100 C		0 C to 100 C		
Failure method	Sudden or gradual		Sudden or gradual		
Nuclear radiation	See reference 1		See reference 2		

* See Figs. 1 and 2.

† See explanation of tables in text.

2. Operating temperature can exceed about 175 C (degrees centigrade), the upper limit for most semiconductor devices.

3. Very high voltages can be rectified, converted, or utilized.

Electron tubes also are now made in small sizes with volumes as low as 0.58 cc and masses of 1.6 grams.

There are often considerable differences in the criteria of acceptability used by designers of equipment for use by the Department of Defense, by industry, or by the general public. Equipment used by the first of these groups usually has the most stringent conditions to satisfy, with some reduction of requirements for industrial equipment and least severe conditions for consumer products. Correspondingly, tubes and semiconductor devices are made with varying degrees of reliability and sturdiness and at different levels of cost. Thus, each designer must rely upon his own judgment and experience, but it is hoped that the tables presented here will serve as check lists to expedite the preliminaries of design procedure.

Explanation of Tables

The data given in the accompanying tables and graphs were compiled from manufacturers' data, published literature, and specifications of the United States Department of Defense. The numerical data in the tables are based on characteristics of units generally available commercially at the end of 1958. It must be kept in mind that the limiting values of operating conditions are being extended almost continually by new developments in both electron tubes and semiconductor devices.

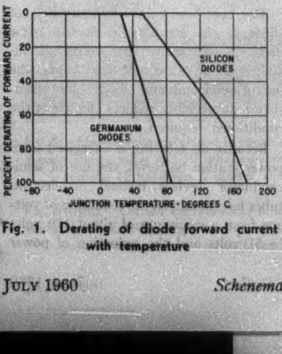

Fig. 1. Derating of diode forward current with temperature

It is believed that the information in the tables in general is self-explanatory; however, a few comments follow for clarification.

Table I. Environmental

Temperature. Operating temperature has a marked effect upon the performance of semiconductor devices. For example, although the nominal upper temperature limit for silicon units is 175 C, at this temperature both the current and power ratings drop to zero, as shown in Figs. 1 and 2. Thus, for practical purposes, the permissible maximum temperatures for semiconductor devices are appreciably under the nominal values given in Table I. However, certain units are now being manufactured where the zero rating point is at about 200 C.

Generally, it is not recommended that electron tubes with soft glass envelopes or seals be operated above about 175 C for maximum life and reliability. Some tubes with ceramic insulation are rated for 500 C operation, with certain developmental types rated for 750 C.

Altitude. The voltages applied to, and the heat dissipation in, most semiconductor devices usually are so low that there are no altitude limitations on the operation of these devices.

However, the appreciable voltage and heat dissipation associated with many electron tubes places limitations on the altitude or atmospheric pressure at which they can operate. Reduced ambient gas density may require reduced voltages to prevent external flashovers and reduced rating and losses to limit tube temperature to a practical level. The cooling effect of the ambient gas is reduced with reduction of gas density at increasing altitudes.

Relative Humidity. Humidity may reduce insulation resistance and affect both types of electron devices in much the same way, although the greater heat dissipation in electron tubes is sometimes helpful in drying insulation. Semiconductor devices must be hermetically sealed to prevent rapid deterioration.

Maximum Vibration and Mechanical Shock. Although Table I shows the same limits for both types of electron devices, semiconductor devices are inherently better able to withstand physical stresses, and manufacturers and users report that semiconductor devices in general are appreciably more resistant to vibration and mechanical shock than are electron tubes. The values in the table are those often specified for tests, although some transistors are now being vibration tested at 100 *g* (gravitational acceleration).

Method of Mounting. The high temperature of molten solder may change the characteristics of, or even damage, semiconductor devices. When mounting them in circuits by soldering, it is advisable to provide temporarily some form of heat sink on the lead being soldered, between the device and the soldered joint. This usually will limit the temperatures in the device to tolerable values.

Thermal Shock. In R-C (resistance-capacitance) type oscillators using transistors, thermal shock has been noted to have a marked effect on the frequency stability. It has been found that a change in temperature of about 20 C over a period of a few minutes causes the fre-

Regulated voltage		1 to 6×10^2		60 to 2×10^4

* See Figs. 1 and 2.

quency to drift excessively, whereas the same temperature variation over a few hours has only a minute effect. In electron tubes this effect is not present, probably because of the heat liberated by the cathode heaters.

Failure Method. Both types of electron devices may fail suddenly or gradually. The life and reliability of a device vary with the usage and class, whether the device be a tube or a semiconductor device. In a number of applications, experience has shown that semiconductor devices have much longer service lives than tubes under comparable conditions. An example is cited in the section on industrial applications.

Nuclear Radiation. The effects of nuclear radiation on electron devices is still being studied by several groups and only limited and general information is available. Two references to such studies are given.[1,2] In general, semiconductors suffer deleterious effects at lower levels of radiation than do tubes.

TABLE II. ELECTRICAL: VACUUM TUBES AND TRANSISTORS

Input Resistance. The input resistance rather than the input impedance is listed in the table because the former is relatively fixed for any one electron device, whereas the latter varies with the operating frequency

Voltage Gain. Does not apply to transistors which are essentially current amplifiers.

Current Gain. Does not apply to vacuum tubes which are essentially voltage amplifiers.

Amplifier Operating Frequency. The zero lower limit in the table signifies that direct currents and voltages can be amplified.

Ability to Withstand Surges. Semiconductor devices are quite susceptible to surge voltages and are not suitable in circuits where component failures, or maintenance or operating procedures can introduce high-voltage transients. A recent experimental study indicates that the ability of transistors to withstand surges can be improved by some changes in construction details.

Table III compares the characteristics of tubes and semiconductor devices used as switches, regulators, or rectifiers.

Examples of Choices for Equipment

CONSUMER PRODUCTS

The use of transistor hearing aids has become prevalent because of the remarkably small size and light weight of these devices. The prolonged battery life makes this type of hearing aid additionally attractive because users do not feel compelled to carry a spare battery. The long life and resistance to mechanical shock of transistors also has greatly improved reliability. For these reasons, transistors have the outstanding advantage in this field.

In television receivers, the electron tube predominates because of the high frequencies involved, the closer tolerances maintained in the manufacture of tubes, the high voltages required for the picture tube, and the higher cost of semiconductor devices for the relatively large number of units needed.

INDUSTRIAL APPLICATIONS

A typical industrial application in which semiconductors are used throughout is in a carrier-current transmitter-receiver for electric power system relaying. The use of semiconductors and miniature components reduced the size so that it can be mounted in a standard relay case instead of requiring a 72-inch-high cabinet, as can be seen in Fig. 3. This permitted it to be mounted on the same switchboard with the associated relays, which facilitates over-all relay testing.

The heat losses are less than 10% of those in the comparable electron tube unit. Where many such units are installed in an air-conditioned room, the use of semiconductor diodes and transistors appreciably reduces the size of the conditioner required.

Because all relaying is energized from power station batteries, the use of semiconductor devices instead of electron tubes has permitted the reduction of voltage from a minimum of about 129 volts to 51 volts and the reduction of power

Vol.

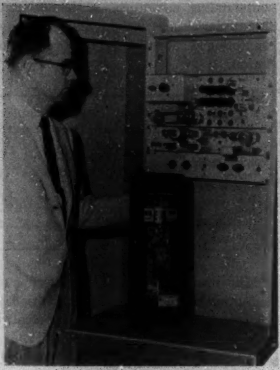

Fig. 3 (left). Transistorized carrier transmitter-receiver in black case is approximately 1/20th the size of the equivalent tube assembly including cabinet

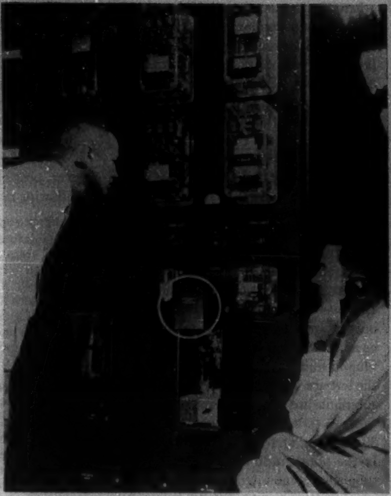

Fig. 4 (right). Unit circled is a voice adapter unit for voice communication over the relaying carrier channel. It is small and sturdy enough to be carried in a technician's tool kit

requirements by 90%. This has permitted the use of appreciably smaller batteries and battery chargers.

Semiconductor devices have made possible an entirely new feature in this carrier-current equipment: a small, compact 3-transistor voice adapter unit for use with the relaying transmitter-receiver. This unit, shown circled in the center of Fig. 4, permits voice communication over the relaying channel for installation, test, and maintenance purposes when it is plugged into an octal socket on the relaying unit. Its small size, 6 by 4 by $3^1/_2$ inches, and the sturdiness of the transistors make it practicable for a technician to include the unit in his kit of tools and have it available for use at any location. A feature of the equipment is the priority given to the relaying functions, which automatically and instantaneously take precedence over voice communication when necessary. That is, if a conversation is in progress when a relay operation occurs, the speech signal is blocked and full transmitter output produced for relaying purposes. The low-impedance input of transistors has made it possible to block the modulator with a small change in base current. This greatly simplifies circuit requirements. The low impedance of transistors also has made it possible to make a single transistor perform two functions in the transmitter-receiver. The output transistor is used as a modulator when transmitting and as an audio amplifier when receiving. Relay contacts effectively switch the transistor from transmitting to receiving, and vice versa, utilizing the low-impedance characteristic of the transistor.

The anticipated increased reliability of the semiconductor devices as compared to electron tubes has been realized in field installations of the relaying equipment, resulting in less maintenance. On one power system the transistor equipment has operated more than 3,200,000 transistor hours with only one failure, in contrast to average tube life of 15,000 hours, which would have required 130 tubes for the same length of time. These figures take into account that there are less tubes required for the equivalent tube equipment.

Although the foregoing example is an outstanding one for which semiconductor devices are particularly appropriate, there are numerous other industrial applications for which electron tubes are especially suited, such as microwave equipment

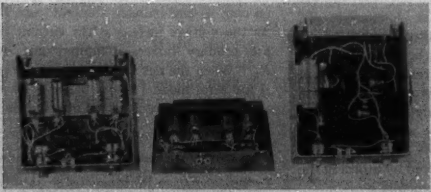

Fig. 5. Plug-in units on left and in center are the same, each containing 4 subminiature tubes and 10 other components. Plug-in unit on right contains 12 transistors, 2 diodes, and 33 other components

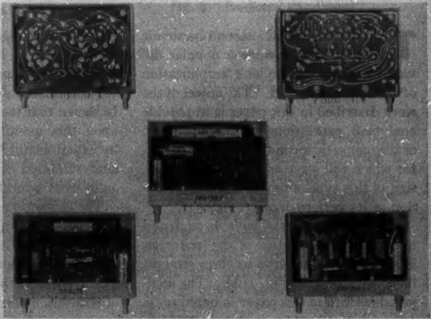

Fig. 6 (right). On left are two views of a d-c amplifier; on right, two views of a stabilizing amplifier; in center, a transistorized monostable multivibrator where the frequencies are higher than the limits for semiconductor devices; welders, where the currents to be controlled are large and the time intervals are short; and induction heating, where the power requirements are large and high voltages are needed for the output tubes.

MILITARY APPLICATIONS

To attain the design objectives in military aircraft equipment of minimum size and weight with capability for withstanding vibration and mechanical shock, subminiature electron tubes and semiconductors are used, each type of device selected for its distinctive electrical characteristics. In general, electron tubes are used as output amplifiers, semiconductor devices as amplifiers and switches. In Fig. 5, the plug-in unit in the center and the one on the left are identical, each containing four subminiature tubes, the tubes chosen because output signal voltages greater than 30 volts and up to 200 volts were required. In the photograph can be seen the metal tube shields mounted on a metal support which in turn is welded to the frame of the plug-in unit. The frame of the unit fits snugly in its mounting in the assembled equipment, all of these intimate metal-to-metal contacts being necessary to dissipate the approximately 5 watts of cathode heater power in the four tubes. It will be noticed that no components other than tubes are mounted on the metal heat-conducting strip, or "heat sink."

The transistor unit shown on the right in Fig. 5 is $4^1/_2$ by $5^1/_8$ by 7/8 inches, only about 15% larger in volume than the electron tube unit shown in the photograph, yet it contains several times as many circuit components as are in the tube unit. The airborne equipment housing these two types of plug-in units is not mounted on shock isolators.

Semiconductor devices were used wherever possible in the equipment for the following reasons:

1. The typical power supply voltage for subminiature tubes is 150 volts as compared to 30 volts for transistors. Assuming the same current drain, the power consumption is reduced 80% by the use of transistors, in addition to the elimination of cathode heater power of approximately $1^1/_4$ watts per tube. Thus, the heat to be dissipated by the equipment is minimized when transistors are used.
2. The small mass and volume of semiconductor devices.
3. Transistors permit superior timing circuit accuracy when they are used as switches because their collector saturation potential, on the order of 100 millivolts or less, yields greater uniformity in the performance of transistors of the same type. However, allowances must be made in the design for the effect of temperature changes on the performance of semiconductors.

Fig. 6 shows three computer plug-in units for military equipment which is not airborne, yet is made as compact as possible by the use of silicon semiconductor devices. The two amplifiers shown in the photograph, together with a chopper unit not shown, replace a tube amplifier. The outstanding advantages of the new units are savings in size, weight, and power consumption as shown in the following tabulation:

	Tube	Semiconductor
Weight, gm	359	197
Volume, cubic inches	14.3	13.8
Power, watts		
B+	2.38	1.46
B−	3.25	1.47
Cathode heaters	8.45	None
Totals	14.08	2.93

The marked reduction in power consumption has permitted the elimination of blowers for cooling, and the use of smaller circuit components.

The new unit has proved more reliable, will operate over a wider temperature range, has better zero and drift characteristics, and can be manufactured with better and more uniform quality than the former tube units. The use of printed circuits has contributed to better quality control by eliminating some wiring errors during assembly.

An Analysis of the Operation of the Magnetic Second-Harmonic Modulator

B. W. JALBERT
ASSOCIATE MEMBER AIEE

THE MAGNETIC second-harmonic modulator has become a popular device for the detection and amplification of low-level d-c signals. The object of the work described in this paper is to provide analytical expressions of the operation of the magnetic second-harmonic modulator which will serve as a basis for the design of this type of device and the prediction of its performance.

Previous analyses[1,2] have been based upon the representation of the hysteresis loop of the core material by three straight lines, as shown in Fig. 1(A). The analysis described in this paper is based upon the rectangular hysteresis loop as shown in Fig. 1(B). It is believed that this assumption is more realistic in view of the core materials now available. It will be shown that the analytical results based upon this assumption are corroborated by experimental results. The method of analysis is that employed by Storm in the analysis of saturable reactors.[3]

The magnetic second-harmonic modulator circuit upon which this analysis is based is shown in Fig. 2. It is assumed that the cores have a hysteresis loop as in Fig. 1(B), that they have the same value of saturation flux density, and that the sinusoidal supply voltage is greater than twice the voltage required to saturate one core.

To understand the operation, first assume that the supply voltage is at its maximum negative value. Core A will be at negative saturation while core B is at positive saturation. A positive control current will decrease the net ampere turns on core A, and increase those on core B. As the voltage increases, the current in the primary increases, limited only by R_p. When the net ampere turns on core A are zero, mode 1 starts. The voltage across core A is transformed into the load

---

and control windings. When the net ampere turns on core B become zero, that core comes out of saturation and mode 2 is initiated. During this mode, the load current is constant and proportional to control current. When core A reaches saturation, the voltage across that core becomes zero and mode 3 commences. During this mode, the voltage across core B is transformed into the load. Since this voltage is opposite in polarity to that across core A, the load current reverses. Mode 4 starts when core B gets into negative saturation. In mode 4, the load current is zero. The waveshapes of voltage, current and flux are shown in Fig. 3. As the supply voltage decreases, core B comes out of saturation first. Since the voltage is going negatively and since the polarity of core B is opposite to that of core A, the voltage across the load winding of core B will be the same as that across the load winding of core A in the previous half-cycle. Thus, the output waveshape repeats itself each half-cycle. Since it contains both positive and negative portions, the output contains only even harmonics, the largest of these being the second harmonic. A reversal in control current will cause a reversal in phase of the load current.

The voltage across core A during interval I is

$$e_A=\frac{1}{1+\alpha}\left(\frac{\pi}{2}\,E_p\sin\,\omega t+\frac{N_C}{N_P}I_CR_P\right) \tag{8}$$

where α is the ratio of the primary circuit resistance to the parallel combination of reflected control circuit resistance and load resistance. This may be expressed as

$$\alpha=\frac{R_P}{N_P{}^2}\left(\frac{N_L{}^2}{R_L}+\frac{N_C{}^2}{R_C}\right) \tag{5}$$

Interval 1 commences when positive volt-seconds are applied to core A to effect a flux change in that core. Interval 1 then starts when the voltage across core A, equation 8, is zero and increasing positively. This occurs at the angle θ_1, which is determined from

$$\sin\,\theta_1=-\frac{N_CI_C}{N_P\frac{\pi}{2}E_P/R_P} \tag{9}$$

The voltage across the primary of core B during interval 2 is

$$e_B=-\frac{1}{2}\left(\frac{\pi}{2}E_P\sin\,\omega t-\frac{1}{\alpha}\frac{N_C}{N_P}I_CR_P\right) \tag{17}$$

Likewise, this interval starts when the quantity is zero and increasing negatively.

The phase angle at which this occurs is θ_2, and is determined from

$$\sin\,\theta_2=\frac{1}{\alpha}\,\frac{N_CI_C}{N_P\frac{\pi}{2}\frac{E_P}{R_P}} \tag{18}$$

The phase angle at which core A goes into positive saturation is θ_3; that at which core B goes into negative saturation is θ_4. The determination of these angles will be discussed later.

The voltage across core A during interval 2 is

$$e_A=\frac{1}{2}\left(\frac{\pi}{2}\,E_P\sin\,\omega t+\frac{1}{\alpha}\,\frac{N_C}{N_P}I_CR_P\right) \tag{16}$$

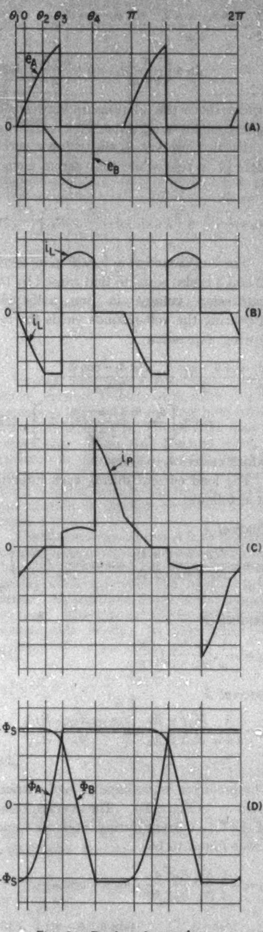

Fig. 3. Predicted waveshapes

A—Gate voltages
B—Load current
C—Primary current
D—Core fluxes

The flux excursion in core A from negative saturation to positive saturation is caused by the volt-seconds applied to that core in intervals 1 and 2. This excursion is equal to that which occurs when the saturation voltage, $\pi/2E_s\sin\omega t$, is applied for one half-cycle. Equating these volt-seconds and introducing the excitation factor $\bar{x}$ yields the following relationship:

$$\frac{2}{\bar{x}}=\frac{\cos\theta_1-\cos\theta_2}{1+\alpha}+\frac{\cos\theta_2-\cos\theta_3}{2}+$$
$$\sin\theta_2\left(\frac{a}{1+\alpha}(\theta_2-\theta_1)+\frac{\theta_3-\theta_2}{2}\right) \quad (27)$$

which shows the relationship between the phase angles θ_1, θ_2, and θ_3.

During interval 3, the voltage across core *A* is zero while that across core *B* is

$$e_B=-\frac{1}{1+\alpha}\left(\frac{\pi}{2}E_P\sin\omega t-\frac{N_C}{N_P}I_CR_P\right) \quad (25)$$

The flux excursion in core *B* in intervals 2 and 3 is also equal to that caused by the saturation voltage in one half-cycle. Equating the volt-seconds yields the following expression:

$$\frac{2}{\bar{x}}=\frac{\cos\theta_2-\cos\theta_3}{2}+\frac{\cos\theta_3-\cos\theta_4}{1+\alpha}-$$
$$\sin\theta_2\left[\frac{\theta_3-\theta_2}{2}+\frac{\alpha}{1+\alpha}(\theta_4-\theta_3)\right] \quad (28)$$

which relates θ_4 to θ_2 and θ_3.

The load current during each interval is as follows:

Interval 1

$$i_L=-\frac{N_L}{N_P}\frac{1}{1+\alpha}\left(\frac{\pi}{2}\frac{E_P}{R_L}\sin\omega t+\frac{N_C}{N_P}I_C\frac{R_P}{R_L}\right) \quad (7)$$

Interval 2

$$i_L=-\frac{1}{\alpha}\frac{N_C}{N_P}\frac{N_L}{N_P}I_C\frac{R_P}{R_L} \quad (15)$$

Interval 3

$$i_L=\frac{1}{1+\alpha}\frac{N_L}{N_P}\left(\frac{\pi}{2}\frac{E_P}{R_L}\sin\omega t-\frac{N_C}{N_P}I_C\frac{R_P}{R_L}\right) \quad (24)$$

The predicted waveshape of load current is shown in Fig. 3(B). The average value of the load current during intervals 1 and 2 was found to be

$$I_L=-\frac{1}{4}\frac{N_L}{N_P}\frac{E_P}{R_L}\left[\frac{4}{\bar{x}}-(\cos\theta_2-\cos\theta_3)+\right.$$
$$\left.(\sin\theta_2)(\theta_3-\theta_2)\right] \quad (30)$$

The average load current during interval 3 was found to be

$$I_L=\frac{1}{4}\frac{N_L}{N_P}\frac{E_P}{R_L}\left[\frac{4}{\bar{x}}-(\cos\theta_2-\cos\theta_3)+\right.$$
$$\left.(\sin\theta_2)(\theta_3-\theta_2)\right] \quad (32)$$

These equations show that the total average load current each half-cycle is zero; hence no d-c component of current appears in the load circuit. Since the positive and negative portions of load current appear in each half-cycle of the supply frequency, the output contains only even harmonics.

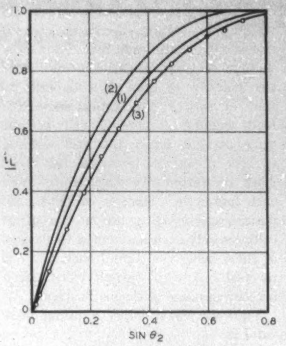

Fig. 4. Per-unit load currents as function of sin θ_1 with $\alpha=0.1$

Curve 1—$\bar{x}=4$
Curve 2—$\bar{x}=6$
Curve 3—Experimental data at $\bar{x}=4$

When the signal current is such that $\theta_2=\theta_3$ (and for larger values of signal current), core *A* will experience its total flux change before core *B* comes out of saturation. For this condition, the average voltage which is transformed into the load circuit for the flux excursion of each core is the saturation voltage. The maximum average value of each positive and negative portion of load current is

$$I_{L,max}=\frac{N_L}{N_P}\frac{E_S}{R_L} \quad (37)$$

That the derived equations may be expressed on a dimensionless basis, the following per-unit quantities are defined.

Per-unit load current (ratio of actual load current to maximum value of load current):

$$\bar{i}_L=\frac{I_L}{\dfrac{N_L}{N_P}\dfrac{E_S}{R_L}} \quad (33)$$

Per-unit control ampere turns (ratio of control ampere turns to maximum load ampere turns):

$$\bar{a}=\frac{N_CI_C}{N_L\dfrac{N_L}{N_P}\dfrac{E_S}{R_L}} \quad (34)$$

From equation 32, the per-unit load current is

$$\bar{i}_L=+\frac{\bar{x}}{4}\left[\frac{4}{\bar{x}}-(\cos\theta_2-\cos\theta_3)+\right.$$
$$\left.(\theta_3-\theta_2)\sin\theta_2\right] \quad (36)$$

From equations 18 and 5, the per-unit control ampere turns is

$$\bar{a}=\frac{\pi}{2}\bar{x}\left(1+\frac{N_C^2}{N_L^2}\frac{R_L}{R_C}\right)\sin\theta_2 \quad (35)$$

From a graphical solution of equation 27, the relationship between θ_1, θ_2, and θ_3 can be determined for various values of α and $\bar{x}$. When these are substituted into equation 36, curves of $2\bar{i}_L$ versus $\sin\theta_2$ are obtained, as shown in Fig. 4. The value of $2\bar{i}_L$ is used because this is the full-wave rectified output current.

Experimental test data were taken on the circuit shown in Fig. 2. The toroidal cores are those of Magnetic Metals, Inc., square-mu *80* consisting of 0.004-inch punched rings having an inside diameter of 0.633 inch, and an outside diameter of 0.844 inch and stacked 0.375 inch high. The cores were matched by a comparison of hysteresis loops with a sinusoidal excitation voltage applied. Fig. 5 shows the hysteresis loop. There is no noticeable difference between the loops of the two cores used. The circuit parameters are as follows: $N_P=N_L=2{,}000$ turns, $N_C=600$ turns, $R_P=500$ ohms, $R_c=2{,}000$ ohms, $R_1=6{,}500$ ohms, $\alpha=0.1$. The experimental data are plotted in Fig. 4 for comparison with the analytical results. The close correlation bears out the validity of the analysis.

Fig. 6 shows the waveshapes. A comparison of this with Fig. 3 shows that the waveshape is as predicted.

Conclusions

The magnetic second-harmonic modulator is an extremely useful device for the detection and amplification of signals where zero output at zero signal is desired and where a phase reversal of the output occurs when the signal is reversed in polarity. For zero output current at zero signal current, it is important that the hysteresis loops of the cores be very closely matched and that the corresponding windings on each core be turns-matched.

The current gain of the modulator is nonlinear and lower in value than that of a series saturable reactor. However, for low values of signal current, the gain is nearly linear.

Appendix

The circuit under analysis is shown in Fig. 2. Consider core *A* originally at negative saturation and core *B* at positive saturation. The first interval of operation occurs from the time core *A* comes out of saturation until core *B* comes out of saturation.

The net mmf (magnetomotive force) on core *A* during this time is zero. The circuit equations during this period are

$$e_B=0 \quad (1)$$

$$\frac{\pi}{2}E_p\sin\omega t=e_A+i_PR_P \quad (2)$$

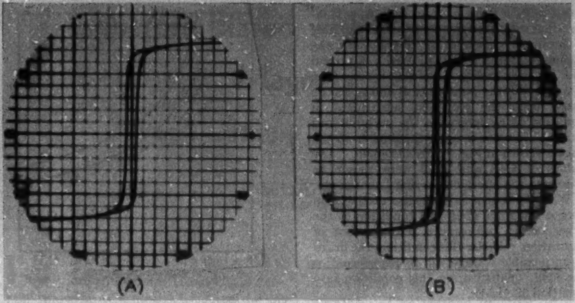

Fig. 5. Dynamic hysteresis loops of cores used. A—Core A: calibration 510 gausses per vertical division. B—Core B: calibration 0.007 oersted per horizontal division

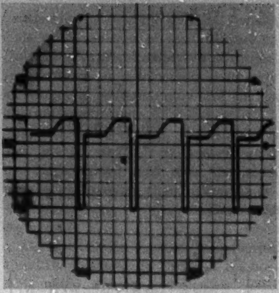

Fig. 6. Load current with excitation factor of $\bar{x}=4$

$$e_A=-\frac{N_P}{N_L}i_LR_L=-\frac{N_P}{N_C}i_CR_C \tag{3}$$

$$\Sigma mmf_A=0=N_Pi_P+N_CI_C+N_Ci_C+N_Li_L \tag{4}$$

These equations can be solved simultaneously for i_p, i_L and e_A. In the solution, a dimensionless quantity appears, which is designated α and is defined as

$$\alpha=\frac{R_P}{N_P{}^2}\left(\frac{N_L{}^2}{R_L}+\frac{N_C{}^2}{R_C}\right) \tag{5}$$

This quantity is the ratio of primary resistance to the parallel combination of reflected control circuit resistance and reflected load resistance. Utilizing equation 5, the simultaneous solution of equations 1 through 4 yields the following:

$$i_P=\frac{1}{1+\alpha}\left(\frac{\pi}{2}\frac{E_P}{R_P}\sin\omega t-\frac{N_C}{N_P}I_C\right) \tag{6}$$

$$i_L=-\frac{N_L}{N_P}\frac{1}{1+\alpha}\left(\frac{\pi}{2}\frac{E_P}{R_L}\sin\omega t+\frac{N_C}{N_P}I_C\frac{R_P}{R_L}\right) \tag{7}$$

$$e_A=\frac{1}{1+\alpha}\left(\frac{\pi}{2}E_p\sin\omega t+\frac{N_C}{N_P}I_CR_P\right) \tag{8}$$

Interval 1 commences when positive volt-seconds are applied to core A. It can be seen that this occurs when equation 8 is equal to zero. This is at the angle θ_1 which is determined from

$$\sin\theta_1=-\frac{N_CI_C}{N_P\frac{\pi}{2}\frac{E_P}{R_P}} \tag{9}$$

Interval 2 occurs from the time core B comes out of saturation until core A goes into saturation.

During this period, the circuit equations are

$$\frac{\pi}{2}E_p\sin\omega t=e_A-e_B+i_PR_P \tag{10}$$

$$e_A+e_B=-\frac{N_P}{N_L}i_LR_L=-\frac{N_P}{N_C}i_CR_C \tag{11}$$

$$\Sigma mmf_A=0=N_Pi_P+N_CI_C+N_Ci_C+N_Li_L \tag{12}$$

$$\Sigma mmf_B=0=-N_Pi_P+N_CI_C+N_Ci_C+N_Li_L \tag{13}$$

From these equations the following are derived:

$$i_P=0 \tag{14}$$

$$i_L=-\frac{1}{\alpha}\frac{N_C}{N_P}\frac{N_L}{N_P}I_C\frac{R_P}{R_L} \tag{15}$$

$$e_A=\frac{1}{2}\left(\frac{\pi}{2}E_p\sin\omega t+\frac{1}{\alpha}\frac{N_C}{N_P}I_CR_P\right) \tag{16}$$

$$e_B=-\frac{1}{2}\left(\frac{\pi}{2}E_P\sin\omega t-\frac{1}{\alpha}\frac{N_C}{N_P}I_CR_P\right) \tag{17}$$

Interval 2 commences when negative volt-seconds are first applied to core B, i.e., when equation 17 is equal to zero. The angle at which this interval starts is θ_2 and is determined from

$$\sin\theta_2=\frac{1}{\alpha}\frac{N_CI_C}{N_P\frac{\pi}{2}\frac{E_P}{R_P}} \tag{18}$$

During interval 3, which is the time from which core A goes into saturation until core B goes into saturation, the circuit equations are

$$e_A=0 \tag{19}$$

$$\frac{\pi}{2}E_P\sin\omega t=-e_B+i_PR_P \tag{20}$$

$$\Sigma mmf_B=0=-N_Pi_P+N_CI_C+N_Ci_C+N_Li_L \tag{21}$$

$$e_B=-\frac{N_P}{N_L}i_LR_L=-\frac{N_P}{N_C}i_CR_C \tag{22}$$

These equations will yield the following:

$$i_P=\frac{1}{1+\alpha}\left(\frac{\pi}{2}\frac{E_P}{R_P}\sin\omega t-\frac{N_C}{N_P}I_C\right) \tag{23}$$

$$i_L=\frac{1}{1+\alpha}\frac{N_L}{N_P}\left(\frac{\pi}{2}\frac{E_P}{R_L}\sin\omega t-\frac{N_C}{N_P}I_C\frac{R_P}{R_L}\right) \tag{24}$$

$$e_B=-\frac{1}{1+\alpha}\left(\frac{\pi}{2}E_P\sin\omega t-\frac{N_C}{N_P}I_CR_P\right) \tag{25}$$

Interval 3 starts at θ_3 when core A saturates: interval 4 starts at θ_4 when core B saturates; interval 4 is the time from which both curves are in saturation until core B comes out. When this happens, core B performs in the same way as did core A in interval 1. The process is thus repeated. Both θ_3 and θ_4 must be determined from an examination of the flux excursions in the cores.

The flux excursion of core A from negative to positive saturation occurs during intervals 1 and 2. The volt-seconds applied to core A during these intervals can be found by integrating equations 8 and 16 with respect to time. This integral will be equal to the volt-seconds applied by the saturation voltage for one half-cycle.

$$\pi E_S=\frac{\pi}{2}E_P\left(\frac{\cos\theta_1-\cos\theta_2}{1+\alpha}+\frac{\cos\theta_2-\cos\theta_3}{2}\right)+\frac{N_C}{N_P}I_CR_P\times\left(\frac{\theta_2-\theta_1}{1+\alpha}+\frac{\theta_3-\theta_2}{2\alpha}\right) \tag{26}$$

With the use of the excitation factor $\bar{x}$ and equation 18, expression 26 can be simplified to become

$$\frac{2}{\bar{x}}=\frac{\cos\theta_1-\cos\theta_2}{1+\alpha}+\frac{\cos\theta_2-\cos\theta_3}{2}+\sin\theta_2\left(\frac{\alpha}{1+\alpha}(\theta_2-\theta_1)+\frac{\theta_3-\theta_2}{2}\right) \tag{27}$$

The flux excursion of core B from negative to positive saturation takes place during intervals 2 and 3. Integrating equations 17 and 25 and equating to the saturation volt-second integral yields the following relationship:

$$\frac{2}{\bar{x}}=\frac{\cos\theta_2-\cos\theta_3}{2}+\frac{\cos\theta_3-\cos\theta_4}{1+\alpha}-\sin\theta_2\left[\frac{\theta_3-\theta_2}{2}+\frac{\alpha}{1+\alpha}(\theta_4-\theta_3)\right] \tag{28}$$

The average value of the negative half of the load current is found by integrating equations 7 and 15 over a half-cycle. This integration yields

$$I_L = -\frac{1}{2}\frac{N_L}{N_P}\frac{E_P}{R_L}\times \left[\frac{\cos\theta_1-\cos\theta_2}{1+\alpha}+\frac{N_CI_C}{N_P\frac{\pi}{2}\frac{E_P}{R_P}}\times \left(\frac{\theta_2-\theta_1}{1+\alpha}+\frac{\theta_3-\theta_2}{\alpha}\right)\right] \tag{29}$$

Substitution of equations 18 and 27 into equation 29 will yield

$$I_L = -\frac{1}{4}\frac{N_L}{N_P}\frac{E_P}{R_L}\times \left[\frac{4}{\bar{x}}-(\cos\theta_2-\cos\theta_3)+(\sin\ \theta_2)(\theta_3-\theta_2)\right] \tag{30}$$

The average value of the positive half of the load current is found by integrating equation 24:

$$I_L = \frac{1}{2}\frac{1}{1+\alpha}\frac{N_L}{N_P}\frac{E_P}{R_L}\times \left[\cos\theta_3-\cos\theta_4-\frac{N_CI_C}{N_P\frac{\pi}{2}\frac{E_P}{R_P}}(\theta_4-\theta_3)\right] \tag{31}$$

Substituting equations 18 and 28 into equation 31 shows that this current is

$$I_L = \frac{1}{4}\frac{N_L}{N_P}\frac{E_P}{R_L}\times \left[\frac{4}{\bar{x}}-(\cos\theta_2-\cos\theta_3)+(\sin\ \theta_2)(\theta_3-\vartheta_2)\right] \tag{32}$$

The average value of the positive half is equal to that of the negative half. This means that the average load current over each half-cycle is zero, i.e., there is no d-c component present.

The following per-unit quantities are defined:

$$\bar{i}_L = \frac{I_L}{\frac{N_L}{N_P}\frac{E_S}{R_L}} \tag{33}$$

$$\bar{a} = \frac{N_CI_C}{N_L\frac{N_L}{N_P}\frac{E_S}{R_L}} \tag{34}$$

$$\bar{a} = \frac{\pi}{2}\bar{x}\left(1+\frac{N_C^2}{N_L^2}\frac{R_L}{R_C}\right)\sin\theta_2 \tag{35}$$

The per-unit average value of each half of the load current as defined by equations 32 and 33 is

$$\bar{i}_L = \frac{\bar{x}}{4}\left[\frac{4}{\bar{x}}-(\cos\theta_2-\cos\theta_3)+(\theta_3-\theta_2)\sin\theta_2\right] \tag{36}$$

Equation 27 was solved by a graphical method. The relationship between θ_1 and θ_2 is known from equation 9 and 18. Various values of θ_2 were assumed. Then, by assuming different values of θ_3, for each value of θ_2, a value of $\bar{x}$ for each θ_2, θ_3 combination was determined. From these data, a family of curves of θ_3 versus $\bar{x}$ for the various values of θ_2 were plotted. A typical plot is shown in Fig. 7. Then, by choosing a value of $\bar{x}$, the parameter θ_2 and θ_3 can be taken from the plot and substituted in equation 18 to determine the per-unit load current. In this manner the data from the curves shown in Fig. 4 were obtained. The values of $\bar{x}=4$ and $\bar{x}=6$ were chosen to illustrate the effect of varying line voltage.

When θ_2 is equal to θ_3, the flux excursion in core *A* from one saturated condition to the other occurs before core *B* comes out of saturation. Under this condition, the maximum possible voltage will be transferred to the load. Substituting this condition into equation 32 yields

$$I_{L,\max} = \frac{N_L}{N_P}\frac{E_S}{R_L} \tag{37}$$

The power output of the modulator will be:

$$P_0 = I_LR_L^2 = \left(\frac{N_L}{N_P}\right)^2\frac{E_S^2}{R_L}\left(\frac{\bar{x}}{4}\right)^2\times \left[\frac{4}{\bar{x}}-(\cos\theta_2-\cos\theta_3)+(\theta_3-\theta_2)\sin\theta_2\right]^2 \tag{38}$$

The maximum power output will be

$$P_{0,M} = \left(\frac{N_L}{N_P}\right)^2\frac{E_S^2}{R_L} \tag{39}$$

For extremely low-level signals, as in

$$I_C \ll \frac{\pi}{2}\frac{N_P}{N_C}\frac{E_P}{R_P} \tag{40}$$

and

$$I_C \ll \frac{1}{\alpha}\frac{\pi}{2}\frac{N_P}{N_C}\frac{E_P}{R_P} \tag{41}$$

θ_1 and θ_2 are essentially zero, and equations 27 and 36 reduce to

$$\frac{\bar{a}}{\bar{x}}\left(\frac{1}{1+\left(\frac{N_C}{N_L}\right)^2\frac{R_L}{R_L}}\right) = \frac{\frac{4}{\bar{x}}-1+\cos\theta_3}{\frac{2\theta_3}{\pi}} \tag{42}$$

$$\bar{i}_L = \frac{x}{2}\left(\frac{4}{\bar{x}}-1+\cos\theta_3\right) \tag{43}$$

For this case, the per-unit load current can be expressed as

$$\bar{i}_L = \bar{a}\left(\frac{1}{1+\left(\frac{N_C}{N_L}\right)^2\frac{R_L}{R_C}}\frac{\theta_3}{\pi}\right) \tag{44}$$

Both cores are driven from one value of saturation to the other during each half-cycle of supply frequency. Thus, if a step change in current is applied to the control winding, it will cause a transient change in the load current in the half-cycle in which it is applied. On the subsequent half-cycle, the cores will start from a saturated condition. The output current will be at its new quiescent value. Thus, this circuit can be said to have half-cycle response.

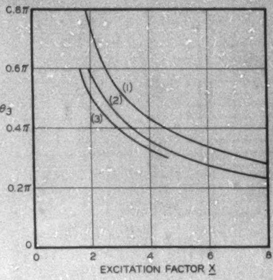

Fig. 7. Phase angle θ_3 versus excitation factor for $\alpha=0.1$

Curve 1—$\theta_2=0.05\ \pi$
Curve 2—$\theta_2=0.15\ \pi$
Curve 3—$\theta_2=0.25\ \pi$

Nomenclature

$\bar{a}$ = per-unit control ampere turns
$e_{A,B}$ = instantaneous voltage across primary winding of cores *A* and *B*, volts
E_P = average value of supply voltage, volts
i_L = instantaneous current in load, circuit, amp (amperes)
i_P = instantaneous current in primary circuit, amp
i_C = a-c component of control current, amp
I_C = d-c component of control current, amp
I_L = average value of each half-cycle of load current, amp
$\bar{i}_L$ = per-unit load current
N_L, N_P, N_C = number of turns on each core of the load, primary and control windings respectively
R_L = total load circuit resistance, ohms
R_C = total control circuit resistance, ohms
R_p = total primary circuit resistances, ohms
$\bar{x}$ = per-unit excitation factor, E_p/E_s
α = reflected resistance ratio
θ_1 = phase angle at which first core comes out of saturation, radians
θ_2 = phase angle at which second core come out of saturation, radians
θ_3 = phase angle at which first core goes into saturation at opposite polarity, radians
θ_4 = phase angle at which second core goes into saturation at opposite polarity, radians

Inductors Biased with Permanent Magnets

Part I—Theory and Analysis

J. T. LUDWIG
ASSOCIATE MEMBER AIEE

IT HAS LONG been known that when a highly unsymmetrical ($I_{\min} \neq I_{\max}$) current magnetizes a closed iron core in an inductor or transformer, the optimum design includes an air gap in the core to reduce saturation. The presence of the air gap has two opposing effects: 1. it increases the reluctance of the core to both the biasing d-c magnetization and the incremental a-c magnetization; 2. the shift of magnetic operating point due to effect 1 reduces the reluctance of the iron to the incremental magnetization. The result of these two opposing effects is that as an air gap is increased from zero length in an iron core with unsymmetrical magnetization, the inductance of a coil linking the core first increases as the second effect is dominant and then a maximum is reached, after which the inductance decreases as the first effect is dominant.

If a permanent-magnet slab is used as a counterbiasing means instead of an air gap, the magnetic operating point may be shifted toward the maximum incremental permeability point with a gap much shorter than the optimum air gap. The direct increase in reluctance is then much smaller than in the air gap case, and the inductance is much larger. A given core size can supply a larger inductance or, conversely, a smaller permanent-magnet-gapped core can supply the same inductance as a larger air-gapped core.

Because of the thin gaps involved, it is not practical to laminate metal permanent magnets to form the gaps. If they were not laminated, eddy currents would nullify the advantages. The advent of barium ferrite,[1,2] a high resistivity permanent magnet, has made such counterbiasing gaps practical.[3–7] Such material can be inserted as thin slabs in gaps in ceramic or laminated metallic cores, or it can be formed directly as thin layers within ceramic cores.

Methods of air core inductor analysis have been discussed by several writers[8–22] with various degrees of approximation and trial-and-error procedure. The analysis method given by Karapetoff[8] in 1911 for finding the induction in a series magnetic circuit when a known d-c magnetomotive force is applied is of particular significance. This method involves an air gap line superposed on the iron normal induction curve. It requires no trial-and-error procedures, in contrast the usual method which requires the assumption of an induction and the calculation of the resulting magnetomotive force for comparison with the given magnetomotive force. Ludwig[3,22] has shown how the Karapetoff method may be extended, by the use of various induction curves, for the analysis of air-gapped inductors with superposed a-c and d-c (unsymmetrical) magnetization. The same general principle has had its application further extended to the analysis of biased inductors. A method was developed for analysis of an inductor with either specified current or specified voltage.

A synthesis method for biased inductors is presented in Part II of this report.[23]

The Basic Equations

An "ideal" magnetic circuit will be considered in the mathematical analysis. The magnetic induction is constant around the circuit, and there is no fringing of flux lines at points where the permeability changes. Because of the linear nature of the gap materials considered here, the corrections for fringing (spatial variation of induction) may be made almost independent of the main problem.

The fundamental equations relating the electrical conditions in the coil to the magnetic conditions in the core will be considered.

The core comprises a magnetically soft iron circuit interrupted by a magnetically hard gap. Both these ferromagnetic materials have inductions not proportional to their magnetizing forces. The appropriate *bh* relationships are introduced into the analysis by the following means. It should be noted that a mixed system of units is used. All the magnetic and spatial units are in the cgs (centimeter-gram-second) electromagnetic system, while the electrical units are in the mks (meter-kilogram-second) practical system. This mixed system is used because in United States practice nearly all electrical specifications are in mks units and nearly all magnetic material data are in cgs electromagnetic units.

In the iron, the *bh* relationship is very complicated. It is neither linear nor single-valued, and it is this complicated relationship that makes the design of magnetic circuits a difficult and esoteric art.

The first relation between the induction b and the magnetizing force h is the normal induction curve and the associated normal permeability. The normal induction curve is the locus of the tips of all symmetrical hysteresis loops. The coordinates of any point on the normal induction curve are then the maximum values, B_m and H_{mi}, for some symmetrical loop. The normal permeability μ_i for any point on the normal induction curve is defined by

$$\mu_i \overset{\Delta}{=} \frac{B_m}{H_{Mi}} \tag{1}$$

Since μ_i is a function of either B_m or H_{mi}, the choice of the independent variable is arbitrary. In the method of analysis, it is more convenient to use the direct relation between B_m and H_{mi} (the normal induction curve), but in the synthesis method it is more convenient to use the normal permeability.

A second relation between b and h is necessary to describe unsymmetrical (minor) hysteresis loops in which the maximum and minimum values are not the equal negatives of each other. The maximum point of a minor loop lies on the normal induction curve within engineering accuracy.[25–28]

An incremental permeability is associated with each unsymmetrical or minor loop. It is usually defined as

$$\mu_{\Delta i} = \frac{B_\Delta}{H_{\Delta i}} \tag{2}$$

where

B_Δ = half the total change of induction in gausses and is called the incremental induction

$H_{\Delta i}$ = half the total change of magnetizing force in oersteds and is called the incremental magnetizing force

The incremental permeability represents the slope of the minor loop and is a

Paper 60-198, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted November 24, 1958; made available for printing December 11, 1959.

J. T. LUDWIG is with Electronic Communications, Inc., St. Petersburg, Fla.

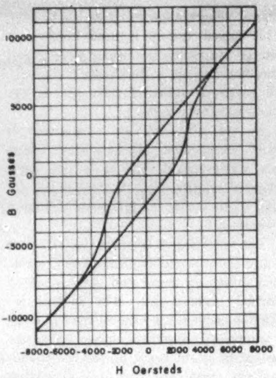

Fig. 1. Hysteresis loop of barium ferrite

function of any two variables which specify the tips of the minor loop.

The relative location of the minor loop is determined by the upper tip which falls on the normal induction curve so the ratio of B_m to H_{mi} is the normal permeability. Another method of specifying the location of the minor loop is by means of the center point whose co-ordinates are B_b and H_{bi}, the biased induction and the biasing magnetizing force, respectively. The relationship between B_b and H_{bi} depends on B_Δ or $H_{\Delta i}$ as well as B_b or H_{bi}. Thus, the use of this method of locating the minor loop involves one more variable and is, therefore, not used in this development except where data are already presented in terms of B_b or H_{bi}.

Since the magnetic induction is uniform around the circuit, the B's are not doubly subscripted, and the development will make use of the permeabilities as functions of the inductions rather than functions of magnetizing forces. In this manner, μ_i will represent $\mu_i(B_m)$ where B_m is the peak induction of a major (symmetrical) or minor (unsymmetrical) loop, and $\mu_{\Delta i}$ will represent $\mu_{\Delta i}(B_m, B_\Delta)$.

In the ferrite gap material, the bh relationship, like that of iron, is neither linear nor single-valued, but the scale is quite different. Fig. 1 shows the saturation hysteresis loop of unoriented barium ferrite. The portions of the loop utilized in this type of magnetic circuitry are substantially linear.

In a magnetic circuit containing no magnetomotive force sources, a permanent magnet operates in the second or fourth quadrant of its hysteresis loop. Where a magnet is being used to depolarize a magnetic circuit containing magnetomotive force sources, the operating point may move slightly counterclockwise around the loop to fall in the third or first quadrants.

If polarities are chosen so that the premagnetization of the permanent-magnet gap material is negative induction and magnetizing force (third quadrant), then the equation of the loop in and near the fourth quadrant is

$$H_g = H_c + (H_c B/B_r) \qquad (3)$$

where

H_g = the magnetizing force in the gap in oersteds
H_c = the absolute value of the coercive force in oersteds (H axis intercept)
B_r = the absolute value of the residual induction in gausses (negative B axis intercept)

For the case of peak positive magnetization, equation 3 becomes

$$H_{mg} = H_c + (H_c/B_r)B_m \qquad (4)$$

To effect a better match of characteristics between the core and gap materials, the gap material may be placed at an angle other than 90 degrees with the main flux path. If the gap material is sufficiently thin, the flux will cross the gap perpendicular to it, and the induction (flux density) in the gap material will be reduced by the factor sin θ. Since the actual gap material characteristics enter the equations by means of H_c and B_r, an equation for the effective residual induction may be written as

$$B_r = (B_{ra}/\sin\theta) \qquad (5)$$

where

B_r = the effective residual induction in gausses
B_{ra} = the actual residual induction in the gap material in gausses

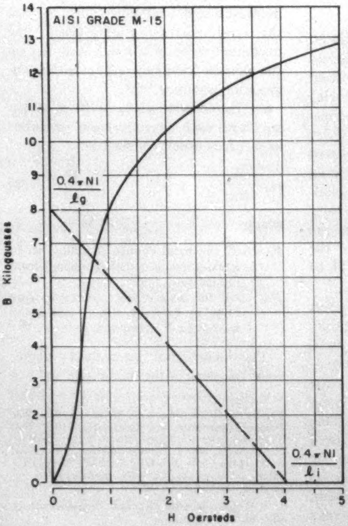

Fig. 2 (left). The normal induction curve with Karapetoff's air gap line to find d-c induction in absence of a-c induction

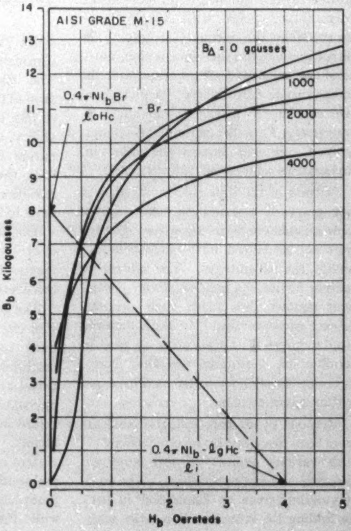

Fig. 3 (right). The biased (anhysteretic) induction curves with gap line to find the center of the minor loop

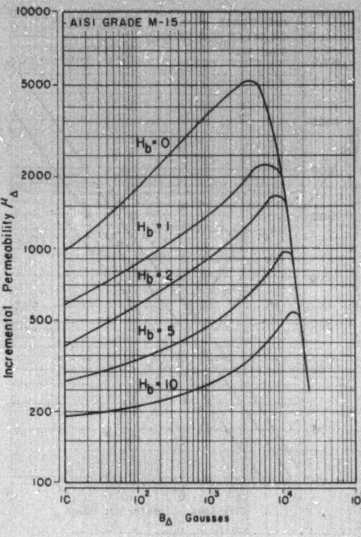

Fig. 4 (left). Incremental permeability curves

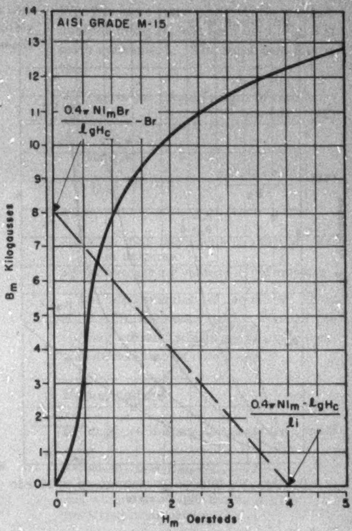

Fig. 5 (right). The normal induction curve with gap line to find the upper tip of the minor loop

The numbers for coercive force H_c and gap length ℓ_g do not need correction for angular gaps. Equation 5 for B_r in terms of B_{ra} will not be introduced directly into the synthesis method since it can be treated separately.

From the basic magnetomotive force equation, the following equations may be derived:

$$B_m = \frac{0.4\pi NI_m - \ell_i \beta H_c}{\ell_i[(1/\mu_i) + (\beta H_c/B_r)]} \qquad (6)$$

$$B = \frac{0.4\pi NI_\Delta}{\ell_i[(1/\mu_{\Delta i}) + (\beta/\mu_{\Delta g})]} \qquad (7)$$

which are basic equations for the design method.

Equations for the inductance of a coil linking this magnetic circuit may be derived from the definition of inductance:

$$L = \frac{NB_\Delta a_i}{I_\Delta 10^8} \qquad (8)$$

and

$$L = \frac{0.4\pi N^2 a_i 10^{-8}}{\ell_i[(1/\mu_{\Delta i}) + (\beta/\mu_{\Delta g})]} \qquad (9)$$

These are the basic inductance equations to be used in the analysis and in the synthesis method of the companion paper.[23]

The Analysis of Inductors

A method of analysis, determining the electrical characteristics from the physical configuration, is helpful to the design procedure in providing a check on designs and in evaluating the effect of changes of the various physical dimensions.

Because of the nonlinearity of the iron characteristics, the inductance of any iron-core inductor is not a constant but depends upon the electrical conditions under which it is operated. Methods of analysis will be developed for two types of electrical conditions:

1. The biasing current, I_b, and a time-varying component of voltage $e'(t)$, which produces a symmetrical time-varying current component, are specified.
2. The current $i(t)$ is specified.

ANALYSIS WITH THE SPECIFIED ALTERNATING VOLTAGE COMPONENT

When the time-varying component of voltage is given, the voltage drop across the resistance R_c is assumed to be small compared to the back electromotive force of the inductance.

By the usual methods,

$$B = \frac{\int_{t_1}^{t_2} e'dt 10^8}{2Na_i} \qquad (10)$$

where t_1 and t_2 are points of minimum and maximum $\int e'dt$, respectively.

When e' is a sinusoidal wave with frequency f and effective value E_{ac},

$$B_\Delta = \frac{E_{ac} \times 10^8}{\sqrt{2}\pi f N a_i} \qquad (11)$$

or

$$B_\Delta = \frac{E_{ac} \times 10^8}{4.44 f N a_i} \qquad (12)$$

which is the customary transformer equation.

Karapetoff[8] describes a method for finding the induction in a uniform magnetic circuit with air gaps when a known d-c magnetomotive force is applied. First it is assumed that the relation between B and H in the iron is known and plotted as in Fig. 2. If the circuit is magnetized by a magnetomotive force $0.4\pi NI$, the magnetomotive force equation is

$$0.4\pi NI = H\ell_i + B\ell_g \qquad (13)$$

or, alternatively,

$$\frac{0.4\pi NI}{\ell_i} = H + B\frac{\ell_g}{\ell_i} \qquad (14)$$

This is the equation of a straight line on the BH plane having intercepts

$$H = \frac{0.4\pi NI}{\ell_i} \qquad (15)$$

and

$$B = \frac{0.4\pi NI}{\ell_g} \qquad (16)$$

This straight line may be plotted by means of these intercepts or any two points which satisfy equation 14. Such a line is shown in Fig. 2. The intersection of this line with the iron BH curve then gives the induction and magnetizing force in the iron. The B value of this point is

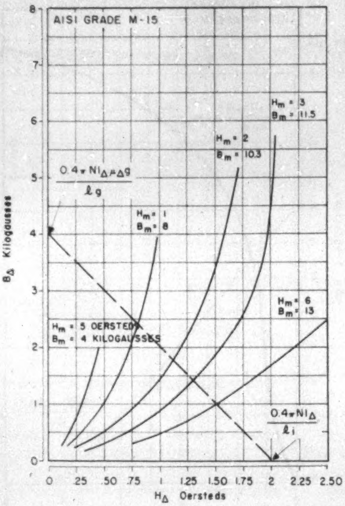

Fig. 6 (left). The incremental induction curves with gap line to find the incremental induction

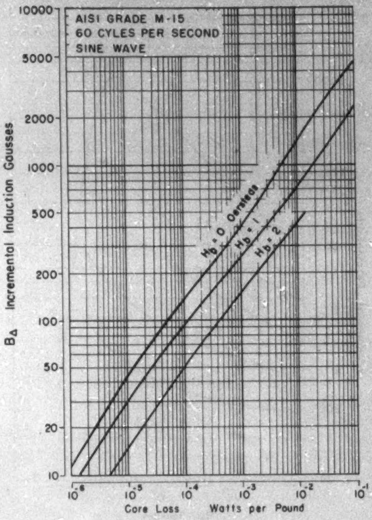

Fig. 7 (right). Core loss with biasing magnetizing force as a parameter

the induction and magnetizing force in the air gap.

This method can be extended to the problem of magnetic circuits with "hard" gaps. In such a circuit the magnetomotive force equation is

$$0.4\pi NI = H\ell_i + \ell_g[(BH_c/B_r)+H_c] \tag{17}$$

Dividing by ℓ_i and rearranging gives

$$\frac{0.4\pi NI}{\ell_i} - H_c\frac{\ell_g}{\ell_i} = H + \frac{\ell_g}{\ell_i}\frac{H_c}{B_r}B \tag{18}$$

This is the equation of a straight line with intercepts

$$H = \frac{0.4\pi NI}{\ell_i} - H_c\frac{\ell_g}{\ell_i} \tag{19}$$

$$B = \frac{0.4\pi NI}{\ell_g}\frac{B_r}{H_c} - B_r \tag{20}$$

When this line is plotted together with the appropriate BH curve, their intersection is the solution.

A comparison of these hard gap lines with the air gap lines shows that for the case of the hard gap, both intercepts are closer to the origin than in the case of the air gap. Both of these effects tend to move the operating point (intersection) toward the origin with a subsequent increase in incremental permeability and inductance for a given structure.

In the analysis of the inductor with specified I_b and $e'(t)$, the extended method can be applied to find the B_b, H_b point.[29] A set of plots of B_b versus H_b for various B_Δ values is shown in Fig. 3. The equation of the Karapetoff line is

$$\frac{0.4\pi NI_b}{\ell_i} - H_c\frac{\ell_g}{\ell_i} = H_b + \frac{\ell_g}{\ell_i}\frac{H_c}{B_r}B_b \tag{21}$$

and its intercepts are

$$H_b = \frac{0.4\pi NI_b - \ell_g H_c}{\ell_i} \tag{22}$$

and

$$B_b = \frac{0.4\pi NI_b}{\ell_g}\frac{B_r}{H_c} - B_r \tag{23}$$

The values of B_b and H_b in the iron may be found at the intersection of this line with the B_b H_b curve for the particular value of B_Δ, already found by equation 10 or 12.

One method of presenting incremental permeability data is shown in Fig. 4. Several curves show μ_Δ as a function of B_Δ, each for a different value of H_b. The values of B_Δ and H_b already found are used to find $\mu_{\Delta i}$ directly from this graph.

The inductance L may be calculated by equation 9:

$$L = \frac{0.4\pi N^2 a_i 10^{-8}}{\ell_i[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]}$$

Thus, when an alternating voltage and a direct current are specified, the analysis steps are:

1. Calculate B_Δ from equation 10 or 12.
2. Construct Karapetoff line on the biased induction curves (B_b vs H_b). For the value of B_Δ found above, read B_b and H_b of equations 21, 22, and 23.
3. For B_Δ and H_b found above, find $\mu_{\Delta i}$ from curve, Fig. 4.
4. Calculate the inductance from equation 9.

Analysis with Specified Current

When the current, $i(t)$, is specified, a different analysis method is used. First, the minimum and maximum values of $i(t)$ are determined and I_Δ is calculated by

$$I_\Delta = \frac{I_m - I_{\min}}{2} \tag{24}$$

The extended Karapetoff-type method is applied to the normal induction curve such as Fig. 5. The equation of the straight line is

$$\frac{0.4\pi NI_m}{\ell_i} - \frac{\ell_g H_c}{\ell_i} = H_m + \frac{\ell_g}{\ell_i}\frac{H_c}{B_r}B \tag{25}$$

and its intercepts are

$$H_m = \frac{0.4\pi NI_m - \ell_g H_c}{\ell_i} \tag{26}$$

and

$$B_m = \frac{0.4\pi NI_m}{\ell_g}\frac{B_r}{H_c} - B_r \tag{27}$$

The intersection of the normal induction curve and the straight line is the H_m, B_m point of the minor loop, because the right hand (H_m, B_m) tips of all the minor loops lie on the normal induction curve independently of B_Δ or H_Δ.

Instead of considering the incremental permeability curves as before, the incremental induction (B_Δ vs H_Δ) curves

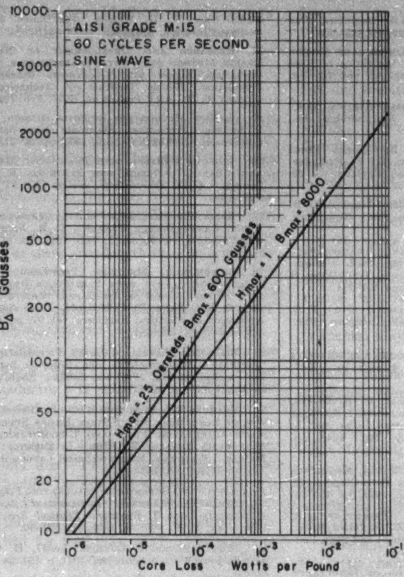

Fig. 8. Core loss with maximum magnetizing force as a parameter

shown in Fig. 6 will be used with a Karapetoff line construction. Each incremental induction curve is associated with one (H_m, B_m) point on the normal induction curve, and the appropriate curve (or interpolated curve) is used for the (H_m, B_m) value found by the extended Karapetoff-type line construction on the normal induction curve. The line on this incremental induction graph is drawn to fit the equation

$$\frac{0.4\pi NI_\Delta}{\ell_i}=H_\Delta+\frac{\ell_g}{\ell_i}\frac{B_\Delta}{\mu_{\Delta g}} \qquad (28)$$

which may be derived from Ampere's law equations for I_m and I_Δ points. The intercepts are

$$H_\Delta=\frac{0.4\pi NI_\Delta}{\ell_i} \qquad (29)$$

and

$$B_\Delta=\frac{0.4\pi NI_\Delta\mu_{\Delta g}}{\ell_i} \qquad (30)$$

The intersection of this line with the proper incremental induction curve gives H_Δ and B_Δ in the iron, and the B_Δ value is also the incremental induction and incremental magnetizing force in the air gap. The inductance, L, can now be found from equation 8:

$$L=\frac{NB_\Delta a_i}{I_\Delta}10^{-8}$$

Thus, when the current is specified, the analysis steps are:

1. Construct hard gap line on normal induction curve by equations 25, 26, and 27. Read B_m and H_m.
2. Construct a Karapetoff-type line on incremental induction curves by equations 28, 29, and 30. For the value of B_m found above, read B and H.
3. Calculate the inductance from equation 8.

ANALYSIS OF RESISTANCE

In either case, specified voltage or specified current, the copper resistance R_c is calculated by the usual methods. The general resistance equation is

$$R_c=(\rho N\ell_c/a_w) \qquad (31)$$

where

ρ = the resistivity in ohm-centimeters
N = the number of turns
ℓ_c = the mean length of turn in centimeters
a_w = the cross-sectional area of the wire in square centimeters

A more convenient method for the resistance calculation is the use of a wire table for the value of ρ/a_w and the appropriate $N\ell_c$ in the units consistent with the wire table units.

The core loss component of resistance is calculated by use of incremental core loss data as in Fig. 7 or Fig. 8. If the voltage analysis using H_b has been used, Fig. 7 is more convenient; if the current analysis using H_m has been used, Fig. 8 is more convenient. The total core loss is then

W_i = watts per pound (weight of core in pounds) (32)

and

$$R_i=\frac{W_i}{I_{rms}^2-I^2} \qquad (33)$$

where

I_{rms} = the root-mean-square value of $i(t)$ in amperes
I = the average d-c value of $i(t)$ in amperes

The denominator of equation 33 is ($I_{rms}^2-I^2$), the mean square value of the varying current which is the only component resulting in core losses.

Nomenclature

Subscripts on time variable quantities (period P)

b = biased, $Z_b=(Z_{max}+Z_{min})/2$
m = maximum value during a cycle
min = minimum value during a cycle
rms = root-mean-square, $Z_{rms}=\sqrt{(1/P)\int_0^P z^2dt}$
Δ = incremental, $Z=(Z_{max}-Z_{min})/2$
no subscript = time average, $Z=(1/P)\int_0^P zdt$

General Subscripts

g = value within the gap
i = value within the iron

Letter Symbols

a_i = net iron cross-section area in cm^2
a_w = net wire cross-sectional area in cm^2
b = time variable induction in gausses
B_r = gap material effective residual induction in gausses
B_{ra} = gap material actual residual induction in gausses
e' = a time variable voltage in volts which produces a symmetrical time varying current
E_{ac} = sine wave effective (rms) voltage in volts
f = frequency in cycles per second
h = time variable magnetizing force in oersteds
H_c = gap material coercive force in oersteds
i = time variable current in amperes
ℓ = generalized length in centimeters
ℓ_c = mean length of turn in centimeters
ℓ_g = effective length of gap in centimeters
ℓ_i = mean iron length in centimeters
L = inductance in henrys
N = number of turns
R_c = copper resistance in ohms
R_i = core loss component of resistance in ohms
t = time in seconds
W_i = iron core loss in watts

Greek Symbols

β = ratio of effective gap length to iron length, ℓ_g/ℓ_i
θ = angle between the flux lines and the plane of the gap
μ = normal permeability in gausses
μ_Δ = incremental permeability in gausses per oersted

μ_t = normal permeability of the iron (distinguished from the gap)

ρ = coil resistivity in ohm-centimeters

Inductors Biased with Permanent Magnets

Part II—Design and Synthesis

J. T. LUDWIG
ASSOCIATE MEMBER AIEE

INDUCTORS biased with permanent magnet slabs and their analysis have been discussed in Part I of this report.[1] The design of such devices is discussed here. It is desirable that a method of design proceed from the specified electrical characteristics directly to the physical dimensions of the inductor without the use of trial-and-error methods.

The literature of air-gapped inductor synthesis includes papers by Hanna,[2] Crowhurst,[3] Carter and Richards,[4] Legg,[5] and Ludwig.[6,7] Hanna's method,[2] which has widespread usage, will determine the best air gap to use for an inductor when the core size is known or assumed. Carter and Richards[4] present an algebraic method of synthesis and Crowhurst[3] presents a graphical method based on a similar derivation, but both of these assume that the maximum incremental permeability is a simple exponential function of the polarizing magnetizing force. This is not an entirely satisfactory approximation over the range normally encountered. Legg[5] has attacked the problem by solving the system of governing equations so a design chart may be prepared from the magnetic characteristics of the core material. This chart specifies all the physical dimensions when the electrical requirements are known.

The synthesis methods of Carter and Richards, Crowhurst, and Legg are all applied to the case of small a-c inductions and the use of specified copper resistance as the only size-limiting factor. The method of Ludwig[6,7] removed these limitations; it included the effects of both copper and iron losses in terms of both specified circuit resistance and thermal heating (specified surface power density). The basic attack on the problem was the simultaneous solution of the pertinent equations relating the electrical, magnetic, and physical factors in terms of the iron characteristics. With the electrical specifications known, the physical dimensions and magnetic factors may be found from charts obtained from the iron characteristics.

The present theory treats the permanent-magnet-biased inductor in an analogous manner. It also shows that the writer's previous theory and method for air-gapped inductors are a special limiting case of the present general theory and method for permanent-magnet-gapped inductors.

Paper 60-199, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted June 29, 1959; made available for printing December 23, 1959.

The Design Method for Inductors Limited by Copper Resistance

SHAPE NUMBERS AND GENERAL EQUATIONS

In the mathematical formulation of the problem, it is convenient to separate size and shape. The spatial quantities of principal importance are: the mean iron length, the mean copper turn length, the net cross-sectional area of copper, and the net cross-sectional area of iron. The mean iron length may be arbitrarily chosen as a measure of size, and the other three quantities may be related to it by means of dimensionless multiplying factors u, v, and w respectively.

These numbers then describe the shape, while ℓ_t describes the size of the inductor. It should be noted that the v and w are defined in terms of the net cross-sectional area, which includes the respective space factors for the copper and iron. In the optimization process, finding the smallest size design, the u, v, and w are treated as constants to simplify the solution. This simplification is justified for two reasons: 1. It is relatively simple to make several designs with this constant-shape method to compare the advantage of different shapes for the particular specifications to be met. 2. The economic factors are strongly in favor of the "scrapless" *EI* lamination. A method of considering various stack heights will be described later.

By eliminating N between the general inductance equation 9 in the companion paper[1] and the resistance equation

$$R_c=u\rho L[(1/\mu_{\Delta t})+(\beta/\mu_{\Delta g})]10^8/[0.4\pi vw\ell_t^2] \tag{1}$$

Examination of equation 1 shows that the copper resistance varies directly with u, ρ, and $[(1/\mu_{\Delta t})+(\beta/\mu_{\Delta g})]$ and inversely with v, w, and ℓ_t^2 for a given inductance. The copper resistance is a dissipative factor which usually must be held under some limit. To make R_c small, the values of u, ρ, and $[(1/\mu_{\Delta t})+(\beta/\mu_{\Delta g})]$ should be as small as possible and the values of v and w should be as large as possible. Winding the conductor around the core with minimum insulation space will minimize u while the conductor material determines ρ. Minimum internal coil insulation and space-saving winding methods will maximize the copper space factor, F_c, and shape factor, v. Likewise, in the core, a high space factor, F_t, will maximize w.

The effective incremental reluctivity factor $(1/\mu_{\Delta t})+(\beta/\mu_{\Delta g})$ requires detailed consideration, because $\mu_{\Delta t}$ is a nonlinear function of the operating inductions. When an unsymmetrical magnetomotive force is applied to an air-gapped ferromagnetic core, a minimum value of effective incremental reluctivity may occur for a positive, nonzero value of air gap length. This occurs because of two conflicting factors. As the air gap length is increased from zero, it introduces incremental reluctance into the circuit, increasing the effective incremental reluctivity. It also, however, introduces normal reluctance which shifts the operating point closer to the origin. This shift of operating point decreases the iron incremental reluctivity more than enough to compensate for the direct increase in incremental reluctance due to the air gap. At some gap length, the two rates of change become equal; and there is a minimum value of effective incremental reluctivity.

In the case of a hard gapped core, the shift of operating point toward the origin is even greater for a given increase in direct gap incremental reluctance. This results in a deeper minimum value for the effective incremental reluctivity.

Since $\mu_{\Delta t}$ is a function of both B_m and B_Δ, two more fundamental equations are required.

$$B_m=[0.4\pi NI_m-\ell_t\beta H_c]/\{\ell_t[(1/\mu_t)+(\beta H_c/B_r)]\} \tag{2}$$

$$B_\Delta=[0.4\pi NI_\Delta]/\{\ell_t[(1/\mu_{\Delta t}+(\beta/\mu_{\Delta g})]\} \tag{3}$$

Equations 1, 2, and 3 are a system of 3 equations in 4 unknowns (β, B_m, B_Δ, ℓ_t) since μ_t and $\mu_{\Delta t}$ are functions of B_m and B_Δ. One more condition will generally be required to determine a single solution.

MINIMUM SIZE DESIGN

The first additional condition is that of minimizing $[(1/\mu_{\Delta t})+(\beta/\mu_{\Delta g})]$. The iron incremental permeability, $\mu_{\Delta t}$, is a function of two variables, B_m and B_Δ, but it is convenient to consider it as a function of B_m alone by fixing the ratio B_Δ/B_m. It is then necessary to consider various values of the B_Δ/B_m ratio. The incremental permeability treated in this way, as a function of B_m, will be symbolized by $\mu_{\Delta t}'$. It can be shown by appropriate algebra and calculus that the solution of equations 1, 2, and 3 with the minimum size condition is

$$\left\{(B_m+B_r)\left[B_mD_n-\mu_{\Delta g}\left(H_c+\frac{H_cB_m}{B_r}\right)D_\Delta\right]-\frac{B_r}{\mu}\right\}\times\sqrt[4]{\frac{1}{\mu_{\Delta t}'}+\frac{B_r}{H_c\mu_{\Delta g}}\left[B_mD_n-\mu_{\Delta g}\left(H_c+\frac{H_cB_m}{B_r}\right)D_\Delta-\frac{1}{\mu_t}\right]}=\sqrt[4]{n_1} \tag{4}$$

where

$$n_1=[(0.4\pi)^5v^3wI_m^4R_c^2 10^{-8}]/[u^3\rho^3L] \tag{5}$$

$$D_n=[d\mu_t/dB_m]/\mu_t^2 \tag{6}$$

and

$$D_\Delta=[d\mu_{\Delta t}'/dB_m]/\mu'_{\Delta t}{}^2 \tag{7}$$

Equation 4 relates B_m and the known factors of n_1, since D_N, D_Δ, μ_t, and $\mu_{\Delta t}$ are functions of B_m alone. Given an n_1, this equation specifies the optimum B_m, but it is an implicit relationship which cannot be solved directly. It can be solved in the opposite manner by assuming various values of B_m and tabulating the values of n_1. These points may then be plotted in a chart with B_m ordinates and n_1 abscissas. In practice the chart will be used the other way around; the quantity n_1 is an index function which may be calculated from the specifications to obtain the optimum magnetic operating point B_m.

Generally there is an upper limit beyond which no minimum of $[(1/\mu_{\Delta t}')+(\beta/\mu_{\Delta g})]$ exists. The curves will terminate at this limit. It is also necessary to obtain β, ℓ_t, and N to complete the design, and "application" function curves may be added to the chart for this purpose. The equation for β can be shown to be

$$\beta=\frac{B_r}{H_c}\left[D_nB_m-D_\Delta\mu_{\Delta g}\left(H_c+\frac{H_cB_m}{B_r}\right)-\frac{1}{\mu_t}\right]. \tag{8}$$

This quantity may be calculated and plotted on the chart against a second set of ordinates and the corresponding values of the abscissa n_1.

It can also be shown that

$$\ell_t=\sqrt{[(1/\mu_{\Delta t}')+(\beta/\mu_{\Delta g})]u\rho L10^8/[0.4\pi vwR_c]} \tag{9}$$

For computing ℓ_t, it is convenient to plot an application function g_1 which is defined as

$$g_1\triangleq\sqrt{[(1/\mu_{\Delta t}')+(\beta/\mu_{\Delta g})]} \tag{10}$$

so that

$$\ell_t=g_1\sqrt{u\rho10^8/(0.4\pi vw)}\sqrt{L/R_c} \tag{11}$$

The value of equation 11 may be found for each equation 8 β value and plotted against a third set of ordinates on the chart. From these points, ℓ_t may be calculated by equation 11.

The equation for N is

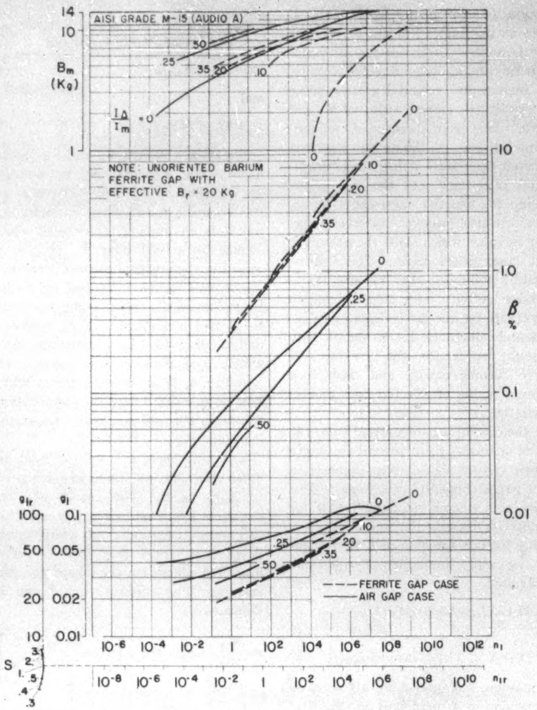

Fig. 1. Chart 1A: copper resistance limited designs, audio A

$$N=\sqrt{g_1\sqrt{v10^8/(0.4\pi u w \rho)}\sqrt{LR_c}} \qquad (12)$$

It should be recalled that the foregoing derivation was based on an additional restriction of a constant B_Δ/B_m ratio. Now the B_Δ/B_m ratio is not directly specified by the electrical requirements of the inductor so the method and chart developed above will not allow direct design from the electrical specifications. Several sets of calculations, each for a different value of B_Δ/B_m ratio, will be considered. The corresponding I_Δ/I_m ratio may be calculated from equations 2 and 3 for each point; from this information, design curves may be constructed in terms of the I_Δ/I_m ratio instead of the B_Δ/B_m ratio. These curves, each labeled with its respective I_Δ/I_m value, can then be used for direct design since the I_Δ/I_m ratio may be obtained from the electrical requirements.

Such a set of curves is presented in Chart 1A, Fig. 1. The dashed curves are for gaps of unoriented barium ferrite angled or arranged to have inductions one tenth those of the iron. The solid curves are for nonmagnetic gaps. Note that these curves, with index n_1 as abscissa and application functions B_m, β, and g_1 as ordinates, are determined solely by the magnetic characteristics of the core material, independent of the inductor geometry and the resistivity of the coil conductor.

To use the curves, the designer must calculate index n_1 by equation 5, and having found g_1 from the chart, he must calculate ℓ_i by equation 11 and N by equation 12.

AUXILIARY AXFS AND VARIABLE STACK HEIGHTS

If many designs are to be made with fixed constant values of u, v, w, and ρ, the design process may be simplified by adding two new axes to the chart. First consider the index function, n_{1r}, given by

$$n_{1r} \triangleq R_c^3 I_m^4/L = n_1 u^3 \rho^3 10^8/[(0.4\pi)^5 v^3 w] \qquad (13)$$

Since the n_1 axis is logarithmic, a logarithmic n_{1r} axis may be plotted parallel to it to perform the multiplication indicated in equation 13. The designer then need only calculate the middle term of equation 13 to find n_1 and enter the chart at this point on the n_{1r} axis. Unlike the n_1 axis, the n_{1r} axis depends on the shape numbers, u, v, and w and on the resistivity, ρ.

In a similar fashion, the calculations of ℓ_i from equation 11 can be simplified. Consider the application functions g_{1r} where

$$g_{1r} \triangleq \ell_i\sqrt{R_c/L} = g_1\sqrt{u\rho 10^8/[0.4\pi v w]} \qquad (14)$$

Having this value to insert in equation 11 simplifies the calculation. A logarithmic g_{1r} axis can be plotted parallel to the logarithmic g_1 axis to provide g_{1r} directly. The g_{1r} axis depends on u, v, w, and ρ.

From the g_1 or g_{1r} value obtained from the chart, the designer can calculate ℓ_i, the length of the core. This ℓ_i may have any value, while laminations are available only in discrete sizes, each with a discrete value of ℓ_i. One of the most convenient modifications of the standard shape is the variation of the height of the stack of laminations. In a qualitative manner, a lamination with an ℓ_i too small may be stacked higher to compensate; or, conversely, a lower stack of larger laminations may be used.

A variation in stack height will result in a change in u and w, since both the mean turn length and the net iron cross-section area are affected. If s is the ratio of the variable stack height to the standard stack height, the values of u and w will be symbolized generally by $u(s)$ and $w(s)$; and then $u(1)$ and $w(1)$ will be the standard values. The n_{1r} for the standard stack height axis is related to the n_1 axis by the factor $[u^3(1)\rho^3 10^8]/[(0.4\pi)^5 v^3 w(1)]$ and for variable stack heights the factor should be $[u^3(s)\rho^3 10^8]/[(0.4\pi)^5 v^3 w(s)]$. The n_{1r} axis for these variable stack heights should be shifted a distance of $\log\{[u^3(s)w(1)]/[u^3(1)w(s)]\}$.

By similar arguments, the g_{1r} axis for variable stack heights should be shifted a distance of $\log\{[u(s)w(1)]/[u(1)w(s)]\}^{1/2}$ from the position of the g_{1r} axis for standard stack height.

A convenient geometrical device for shifting the n_{1r} and g_{1r} axes is a transparent overlay with the n_{1r} and g_{1r} axes ruled on it. The main chart then may have an

Vol.
Pt. 1
196

auxiliary axis, s, to guide the location of some arbitrary reference point on the transparency. A convenient reference point is the intersection of the n_{1r} and g_{1r} axes. This auxiliary axis is the locus of points whose absicssas are $-\log\{[u^3(s)w(1)]/[u^3(1)w(s)]\}$ and whose ordinates are $-\log\{[u(s)w(1)]/[u(1)w(s)]\}$.

This curve can then be graduated with values of s. The transparency is placed over the chart with the corresponding axes parallel and with the intersection of the transparency axes lying on the s axis of the main chart. The n_{1r} and g_{1r} axes on the transparency will then be in correct relationship to the n_1 and g_1 axes and the curves on the chart for the particular value of s indicated on the s axis by the intersection of the n_{1r} and g_{1r} axes on the transparency. It should be noted that the application functions, B_m and β, are independent of the inductor geometry and are measured on the chart B_m and β axes directly. The abscissa (n_{1r}) for these curves must be the one on the transparency for stack heights other than standard.

The designer may use the transparency in either of two ways. If a design is wanted for a stack height other than standard, the transparency is located at the proper point on the s axis and the chart is read opposite the n_{1r} point on the transparency n_{1r} axis. The B_m and β values are read on the chart B_m and β axes, while the g_{1r} value is read on the transparency g_{1r} axis. If a design results in a value of ℓ_t intermediate between standard lamination sizes, the designer may determine the B_m, β, and s for the design using standard laminations having ℓ_t smaller or larger than that called for by the particular specifications.

He first calculates g_{1r} by equation 14 from the ℓ_t of the standard lamination and marks the n_{1r}, g_{1r} point on the transparency. He then moves the transparency, keeping the axes parallel to those on the main chart and keeping the intersection of the axes on the s axis of the main chart. When the n_{1r}, g_{1r} point on the transparency falls on the g_1 curve of the main chart, he can read s from the s axis at the intersection of the transparency n_{1r} and g_{1r} axes. The values of B_m and β are found from their respective curves and axes of the main chart, opposite the n_{1r} axis of the transparency.

This method of considering variation in stack height will be derived specifically for the case of "scrapless" *EI* laminations. For a stack of laminations s times as high as the center leg width

$$u(s)=\frac{2+s}{3} \qquad (15)$$

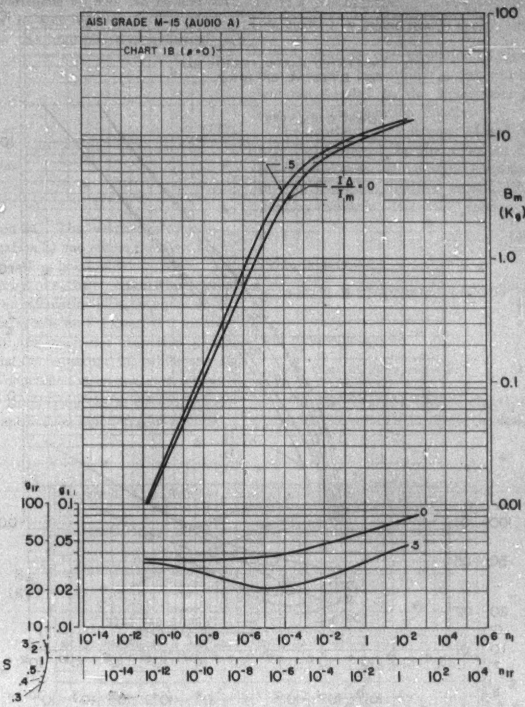

Fig. 2. Chart 1B: copper resistance limited designs with zero gap; audio A

$$v=0.00625 \text{ (for 30\% space factor)} \qquad (16)$$

and, for a 90% stacking factor,[8]

$$w(s)=(s/40)=0.025s \qquad (17)$$

The constant in equation 13 may now be evaluated for these values of u, v, w, and a copper resistivity of 1.724 microohm-centimeters:

$$n_{1r}/n_1=u^3\rho^3 10^8/(0.4\pi)^4 v^3 w=1/40 \qquad (18)$$

The constant in equation 14 is

$$g_{1r}/g_1=\sqrt{u\rho 10^8/0.4\pi v w}=1{,}000 \qquad (19)$$

The negative logarithmic co-ordinates of the points on the s axis are then $(2+s)^3/(27s)$ and $[(2+s)/(3s)]^{1/2}$. Such an axis is shown in Chart 1A, Fig. 1.

DESIGNS WITH ZERO AIR GAP

The method developed thus far provides a direct means of design when I_m, I_Δ, L, and R_c are specified. One limitation of this method is that there is no restriction on the sign of β; and for low values of n_1, the indicated gap length does become negative. For these specifications, the optimum design is the one with zero gap since a negative gap cannot be physically realized.

Previously the system of equations 1, 2, and 3 was solved in such a way that $(1/\mu_{\Delta t})+(\beta/\mu_{\Delta g})$ was a minimum. Now, for the zero gap case, the system of equations 1, 2, and 3 will be solved together with

$$\beta=0 \qquad (20)$$

The solution is

$$B_m{}^4/[\mu_t{}^4\mu_{\Delta t}{}']=n_1 \qquad (21)$$

Equation 21 gives the relation between B_m and the known requirements contained in n_1 since the μ's are functions of B_m. This equation is analogous to equation 4, and a design chart relating n_1 and B_m can be set up in the same way as Chart 1A was constructed. From equations 10 and 20

$$g_1=\sqrt{1/\mu_{\Delta t}{}'} \qquad (22)$$

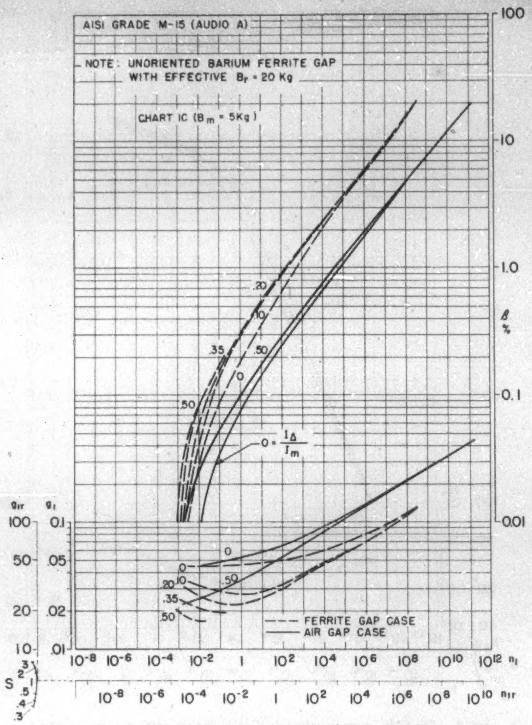

Fig. 3. Chart 1C: copper resistance limited designs with five kilogauss maximum induction; audio A

Equation 11 still applies for calculating ℓ_t, and equation 12 still applies for N.

This design chart has curves of application functions B_m and g_1 versus index n_1 for various I_Δ/I_m ratios. Axes for n_{1r}, g_{1r}, and s are identical to those of Chart 1A. This chart, for $\beta=0$, is shown as Chart 1B, Fig. 2.

Normally the designer would first calculate n_1 or n_{1r} and consult Chart 1A. If the value of n_1 or n_{1r} was too small to be found on Chart 1A, he would consult Chart 1B for the $\beta=0$ design which is the optimum design when the "minimum size" design gap is negative.

DESIGN WITH INDUCTION LIMITATION

Another limitation of the minimum size method of Chart 1A is that the B_m may be too large for the linearity or core loss requirements of the inductor. The specification and mensuration of linearity and nonlinearity is a very complicated question, especially when the waveforms of current and voltage are of unlimited shapes. The maximum induction B_m is a guide. If it is above the "knee" of the core material induction curve, minor loops with a large B_Δ will generally bend around the knee. If the peak induction B_m is great enough to drive the gap biasing material over the third quadrant corner, it will recoil with lower demagnetizing effect. It is then useful to have the design curves for various limiting values of B_m. If the limiting value of B_m is below the optimum value found in Chart 1A, the "B_m-limited" design will generally be larger. If the limiting value of B_m is above the optimum value found in Chart 1A, the optimum design of Chart 1A should be used.

For this B_m-limited method, consider the simultaneous solution of equations 1, 2, 3 and

$$B_m = (\text{constant}) \tag{23}$$

The solution is

$$\beta = \mu_{\Delta g}[g_1{}^2 - (1/\mu_{\Delta l}')] \tag{24}$$

and

$$\sqrt[4]{n_1} = \frac{B_m\sqrt{g_1}}{\mu_l} + \left(\frac{H_cB_m}{B_r} + H_c\right)\left(g_1{}^2 - \frac{1}{\mu_{\Delta l}'}\right)$$

$$\mu_{\Delta g}\sqrt{g_1} \tag{25}$$

For a constant B_m, this equation can be tabulated in a reverse manner similar to equation 4 or equation 21. First a value of B_m is assumed for the particular chart under construction. Then for various B_Δ/B_m ratios, various values of g_1 are assumed and the resulting n_1 values calculated by equation 25. Equation 24 can be used to calculate β for every point. For each point, the I_Δ/I_m ratio can be found by equations 2 and 3 and curves of g_1 and β versus n_1 can be drawn for the various I_Δ/I_m ratios. This is Chart 1C. The n_{1r}, g_{1r}, and s axes are identical to those on Charts 1A and 1B. Fig. 3 is Chart 1C for a B_m value of 5 kilogausses.

If the B_m from Chart 1A for a given set of specifications is too large, the designer would use Chart 1C. Equation 11 still applies for calculating ℓ_t and equation 12 still applies to N.

The Design Method for Inductors Limited by Copper Loss Heating-Power Density

MINIMUM SIZE DESIGN

In some cases the circuit requirements limiting the resistance are so loose that the only factor limiting the resistance of the inductor is the heating of the inductor by the current through its copper resistance. For these cases it is convenient to prepare charts for the design of inductors subject only to the limitation of their own heating.

The average rate of heat generation in the copper resistance is $I^2_{\text{rms}}R_c$. The deterioration or destruction of the inductor is a function of the temperature which, in turn, is a function of the density of thermal power passing through the surface of the unit. For units of the same shape, the surface area may be expressed by dimensionless constant, p.

When N has been eliminated from the inductance and thermal power density equations

$$K_c = \frac{u\rho LI^2_{\text{rms}}[(1/\mu_{\Delta 1}) + (\beta/\mu_{\Delta g})]10^8}{0.4\pi pvw\ell_t{}^4} \tag{26}$$

This equation is similar to equation 1 in the location of the various factors in numerator and denominator. The optimum design is again that for which $[(1/\mu_{\Delta l}') + (\beta/\mu_{\Delta g})]$ is minimum. The system of equations 2, 3, and 26 may be solved for minimum $[(1/\mu'_{\Delta i})+(\beta/\mu_{\Delta g})]$ in a manner analogous to that of the resistance-limited method. The solution is

$$\sqrt[8]{n_2}=\frac{(B_m+B_r)\left[B_mD_n-\mu_{\Delta g}\left(H_c+\frac{H_cB_m}{B_r}\right)D_\Delta\right]-\frac{B_r}{\mu_i}}{\sqrt[8]{\frac{B_r}{H_c\mu_{\Delta g}}\left[B_mD_n-\mu_{\Delta g}\left(H_c+\frac{H_cB_m}{B_r}\right)D_\Delta-\frac{1}{\mu_i}\right]+\frac{1}{\mu_{\Delta i}}}} \qquad (27)$$

where

$$n_2=(0.4\pi)^7p^3v^3LI_m^8K_c10^8/[u^3w\rho^3I_{rms}^6] \qquad (28)$$

Equation 27 is analogous to equation 4 for setting up a design chart. For various B_m values, n_2 can be calculated; and a plot of B_m versus n_2 can be made in a manner similar to that of Chart 1A.

A curve for β can be also added to the chart by use of equation 8.

The magnetic length

$$\ell_i=\sqrt[4]{[(1/\mu_{\Delta i}')+(\beta/\mu_{\Delta g})]u\rho LI_{rms}^2 10^8/[0.4\pi pvwK_c]} \qquad (29)$$

so that it is convenient to plot an application function g_2 defined by

$$g_2\triangleq\sqrt[4]{(1/\mu_{\Delta i}')+(\beta/\mu_{\Delta g})} \qquad (30)$$

With this definition,

$$\ell_i=g_2\sqrt[4]{u\rho10^8/[0.4\pi pvw]}\,\sqrt[4]{LI_{rms}^2/K_c} \qquad (31)$$

The value of g_2 may be calculated by inserting each β value of equation 8 into equation 30. These values can be added to the chart, and equation 31 can be used to compute ℓ_i. The formula for N is

$$N=g_2^{3/2}\sqrt[8]{\frac{pvL^3K_c10^{24}}{(0.4\pi)^3uw^3\rho I_{rms}^2}} \qquad (32)$$

The copper resistance may be calculated as

$$R_c=g_2^2\sqrt{\frac{pu\rho10^8}{0.4\pi vw}}\sqrt{\frac{LK_c}{I_{rms}^2}}. \qquad (33)$$

This equation may be used for calculating the winding resistance of a power-density-limited inductor without completing the other design calculations.

The design chart for power-density-limited inductors can be set up in terms of the I_Δ/I_m ratios in a manner similar to Chart 1A. The result is shown in Chart 2A, Fig. 4.

Auxiliary Axes and Variable Stack Heights

For designing with particular values of u, v, w, and ρ, it is convenient to set up additional axes similar to the n_{1r} and g_{1r} axes used in the resistance-limited design charts. First consider

$$n_{2r}\triangleq LI_m^8K_c^3/I_{rms}^6=\{u^3w\rho^310^{-8}/[(0.4\pi)^7p^3v^3]\}n_2 \qquad (34)$$

A logarithmic n_{2r} axis can be laid out parallel to the logarithmic n_2 axis to perform the multiplication indicated in equation 34. The designer calculates n_{2r} by equation 34 and enters the chart at the corresponding point of the n_{2r} axis. The calculation of n_{2r} by equation 34 is simpler than the calculation of n_2 by equation 28; but the n_2 axis on the chart is a function only of the magnetic properties of the material, in equation 27, while the n_{2r} axis is dependent upon u, v, ρ, w, and p.

For simplifying the ℓ_i calculation, another application function g_{2r} is defined.

$$g_{2r}\triangleq\ell_i\sqrt[4]{K_c/(LI_{rms}^2)}=g_2\sqrt[4]{(u\rho10^8)/(0.4pvw)} \qquad (35)$$

This simplifies the calculation of equation 31, and a logarithmic g_{2r} axis can be laid out parallel to the logarithmic g_2 axis to do this operation directly.

The constants in equations 34 and 35 may be evaluated for the scrapless *EI* low-voltage case, as were the constants in the resistance-limited design. For military standard (*MIL-T-27*) cases,

$$p=1.3 \qquad (36)$$

From equation 34

$$n_{2r}/n_2=u^3w\rho^310^{-8}/[(0.4\pi)^7p^3v^3]=5\times10^{-22} \qquad (37)$$

and from equation 35

$$g_{2r}/g_2=\sqrt[4]{u\rho10^8/[0.4\pi pvw]}=30 \qquad (38)$$

As in the resistance-limited charts, an s axis may be set up to facilitate the design

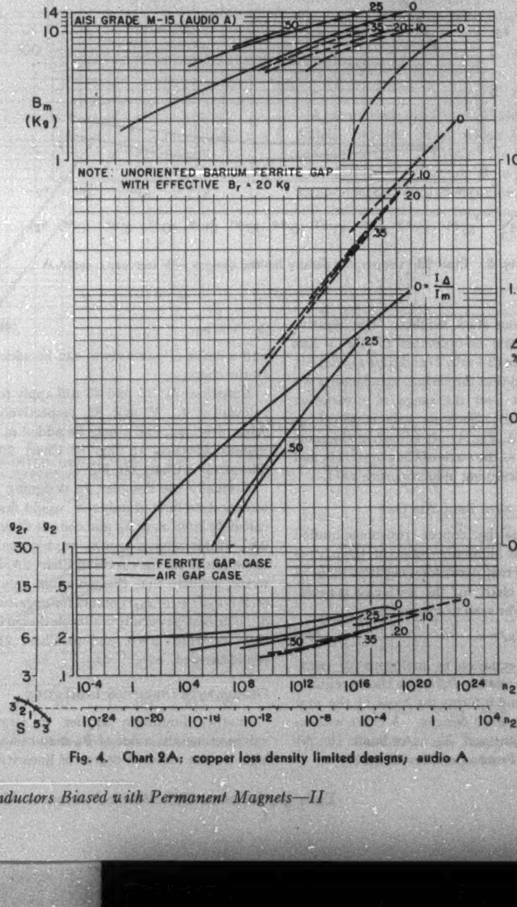

Fig. 4. Chart 2A: copper loss density limited designs; audio A

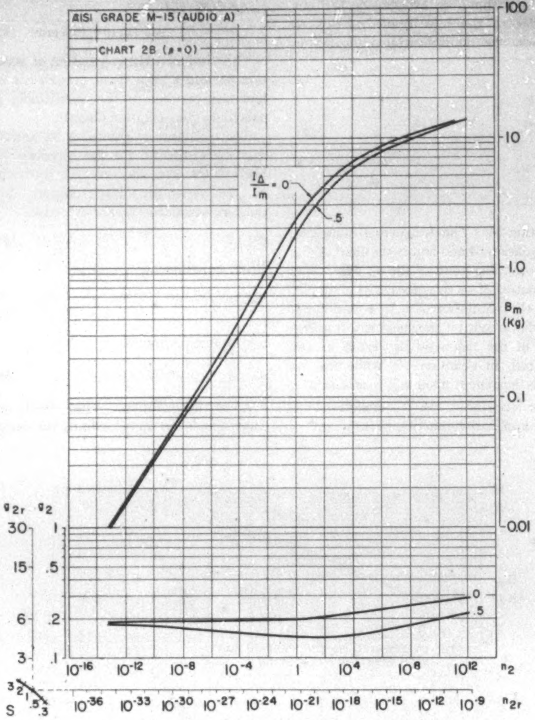

Fig. 5. Chart 2B: copper loss density limited designs with zero gap; audio A

for various stack heights. The negative logarithmic co-ordinates of the s axis points are $(2+s)^3s/27$ and $[(2+s)/(3s)]^{1/4}$, provided that the surface area factor p is a constant over the range of s variation considered. Such an axis is shown in Chart 2A, Fig. 4. It is used in the same manner as the s axis of Charts 1A, 1B, and 1C for designing inductors with $s \neq 1$.

Design with Zero Air Gap

As in the copper resistance-limited case, the minimum value of $[(1/\mu_{\Delta i}')+(\beta/\mu_{\Delta g})]$ may occur for a negative value of β, so a chart for the $\beta=0$ case is necessary. The system solution is

$$B_m{}^8\mu_{\Delta i}'/\mu_i{}^8=n_2 \tag{39}$$

This equation is analogous to equation 4 in relating B_m to the known requirements, and it forms the basis of the new chart for $\beta=0$ designs. A chart with n_2 as abscissa and B_m as ordinate can be made. From equations 20 and 30,

$$g_2=\sqrt[4]{1/\mu_{\Delta i}'} \tag{40}$$

and a curve of g_2 versus n_2 can be added to the chart.

Equations 31, 32, and 33 still apply for calculating l_i, N, and R_c, respectively. Axes of n_{2r}, g_{2r}, and s may be added in a manner identical to that of Chart 2A. The result is Chart 2B, Fig. 5.

Normally the designer, in designing a temperature-limited inductor, would first calculate index n_2 or n_{2r} and consult Chart 2A. If this value of n_2 or n_{2r} was too small to be found on the curves of Chart 2A, it would indicate that the minimum value of $[(1/\mu_{\Delta i}')+(\beta/\mu_{\Delta g})]$ occurs for negative β. The best physically realizable design is that for which $\beta=0$, and so Chart 2B would be used.

Design with Induction Limitation

Another limitation applies to large values of n_2; the value of B_m may be too high for the required degree of linearity, or $[(1/\mu_{\Delta i}')+(\beta/\mu_{\Delta g})]$ may not have a minimum. For such cases, charts for the optimum designs with fixed B_m values are useful.

The solution of the equations 2, 3, and 26 with $\beta=0$ is

$$\beta=\mu_{\Delta g}[g_2{}^4-(1/\mu_{\Delta i}')] \tag{41}$$

and

$$\sqrt[8]{n_2}=\frac{B_m\left[\frac{1}{\mu_i}+\mu_{\Delta g}\left(\frac{H_c}{B_r}+\frac{H_c}{B_m}\right)\left(g_2{}^4-\frac{1}{\mu_{\Delta i}'}\right)\right]}{\sqrt{g_2}} \tag{42}$$

This equation is tabulated by assuming a constant B_m value for the particular chart under construction. Then, for various B_Δ/B_m ratios, various values of g_2 are assumed, and the resulting n_2 values calculated by equation 42. Curves with n_2 as abscissas and g_2 as ordinates can then be plotted with I_Δ/I_m as a constant by the method used for previous charts. By means of equation 41, curves of β versus n_2 can be constructed. Such a chart is called Chart 2C. This also has the n_{2r}, g_{2r}, and s axes identical to those of Charts 2A and 2B. Fig. 6 is Chart 2C for a B_m value of 5 kilogausses. Chart 2C would normally be used after the designer has used Chart 2A and found the optimum B_m value to be too high. Equations 31, 32, and 33 would be used to calculate l_i, N, and R_c, respectively.

The Design Method for Inductors Limited by Total Resistance

General Equations

The first synthesis section considered the problem of synthesis of inductors where only the copper resistance was specified. In any iron core inductor, there is core loss when the induction or magnetizing force is varying with time. This core loss is generally a function of the iron, the induction wave (including frequency, waveform, and amplitude), and the volume of the iron having this waveform. For the type of core materials considered here, the core loss is expressed approximately by

$$W_i=\gamma B_\Delta{}^2wl_i{}^3 \tag{43}$$

where γ is a constant for a given material, frequency, and waveform.

The loss is supplied by the time-varying components of current and voltage, so that in computing the resistance which this loss presents in the circuit, the mean square current used must not include the d-c component.

The effective iron loss resistance is

$$R_i=0.4\pi\gamma I_\Delta{}^2L10^8/\\ \{(I_{\text{rms}}{}^2-I^2)[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]\} \tag{44}$$

The total resistance to the time-varying component of current is

$$R_{ac}=\frac{u\rho L10^8\left(\dfrac{1}{\mu_{\Delta i}}+\dfrac{\beta}{\mu_{\Delta g}}\right)}{0.4\pi vw\ell_i^2}+\frac{0.4\pi\gamma I_\Delta^2L10^8}{(I_{rms}^2-I^2)\left(\dfrac{1}{\mu_{\Delta i}}+\dfrac{\beta}{\mu_{\Delta g}}\right)}\quad(45)$$

The equation has a minimum when the two terms, copper resistance and iron loss resistance, are equal.

To have equal resistances

$$(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})=\sqrt{(0.4\pi)^2vw\gamma\ell_i^2I_\Delta^2/[u\rho(I_{rms}^2-I^2)]}\quad(46)$$

It has previously been shown that $[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]$ has a minimum value which is a function of the magnetic core material and the electrical specifications, L, I_m, I_Δ, and R_c. This minimum value of $[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]$ may be less than, equal to, or greater than the value given by equation 46 for minimum R_{ac}. If the minimum value of $[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]$ is greater than the value given by equation 46, the minimum R_{ac} condition cannot be realized, and from equations 44 and 45 it is apparent that

$$R_i<(R_{ac}/2)<R_c<R_{ac}\quad(47)$$

More than half the effective resistance is due to the winding loss. On the other hand, if the minimum value of $[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]$ is less than, or equal to, the value given by equation 46, the minimum R_{ac} condition can be realized. The components of resistance due to the winding loss and core loss are equal. In no case where R_{ac} is a controlling factor is it advantageous to design for a core loss component of resistance greater than the winding loss component of resistance.

Consider the case in which the optimum value of $[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]$ can be realized.

Then

$$\ell_i=[2L10^8/R_{ac}]\sqrt{[u\rho\gamma I_\Delta^2]/[vw(I_{rms}^2-I^2)]}\quad(48)$$

Inserting this value of ℓ_i into equation 46 gives

$$(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})=0.4\pi\gamma I_\Delta^2L10^8/[(I_{rms}^2-I^2)(R_{ac}/2)]\quad(49)$$

This equation may be used with Chart 1A, or with Charts 1B or 1C where their respective conditions apply, to determine in which case a given set of specifications lie. The value of index n_1 (or n_{1r}) may be calculated from the known specifications and an assumed value of winding resistance.

$$R_c=(R_{ac}/2)\quad(50)$$

From the chart the value of g_1 is read from the appropriate curve.

Equation 49 can be used to calculate the value of $[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]$ for minimum R_{ac}. This value will be symbolized by G_1^2 so that

$$G_1^2=\frac{0.4\pi\gamma I_\Delta^2L10^8}{(I_{rms}^2-I^2)(R_{ac}/2)}\quad(51)$$

A comparison of g_1^2 and G_1^2 will immediately indicate under which case the design will fall. If $G_1^2<g_1^2$ the value of $[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]$ for minimum R_{ac} cannot be reached and the optimum design will be one of the copper-resistance-

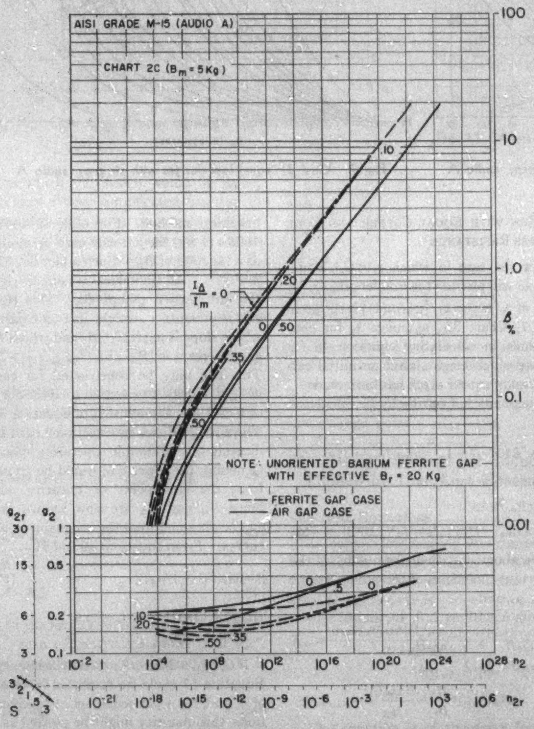

Fig. 6. Chart 2C: copper loss density limited designs with five kilogauss maximum induction, audio A

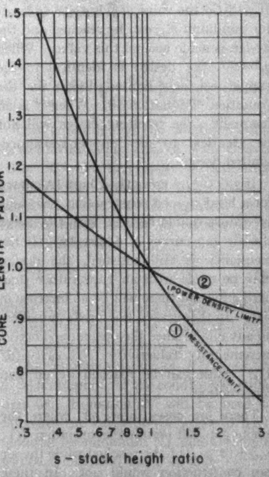

Fig. 7. Chart 3A: core length factors for scrapless EI laminations

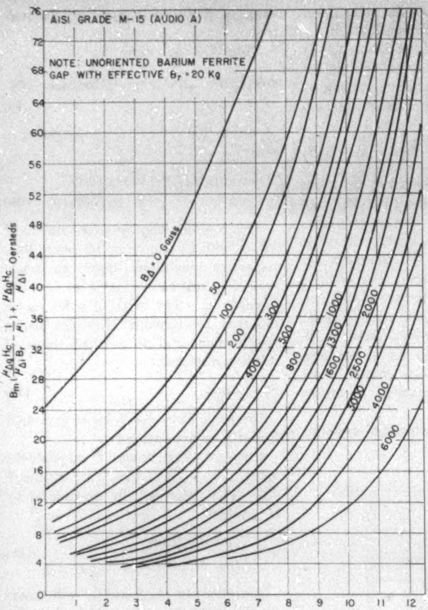

Fig. 8. Chart 3: equal loss designs with ferrite gap; audio A

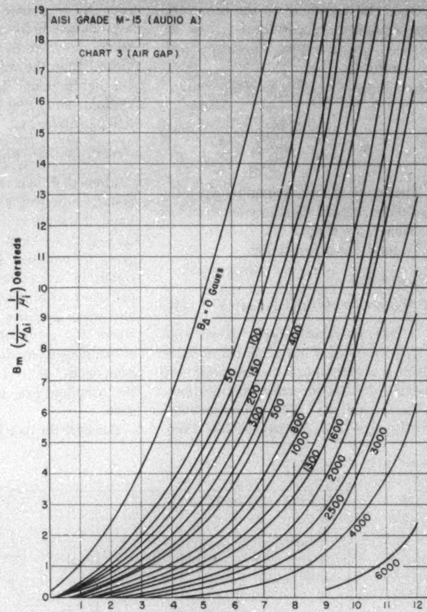

Fig. 9. Chart 3: equal loss designs with air gap; audio A

Vol.
Pt. 1
196

limited designs given by Chart 1A, 1B, or 1C, the specific details to be given later. If $g_1^2 \leqq G_1^2$ the value of $[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]$ for minimum R_{ac} can be reached and the design is made around this value. When $g_1^2=G_1^2$, the design is identical to the copper-resistance-limited design for the condition of equation 50. When it is an inequality, the resulting design will not be identical to any copper-resistance-limited design.

If $g_1^2<G_1^2$ by using the Chart 1A curves for a hard-gapped construction, the same procedure should be tried with the use of the air gap curves of Chart 1A. If the inequality is still satisfied, the design may be made with air gaps rather than hard gaps and there will be no increase in size. In these cases, the ferrite gap offers no advantage since the optimum effective incremental reluctivity $[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]$ value can be reached by air gap construction.

There are cases, however, where the ferrite gap will permit the optimum $[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]$ to be reached while the air gap construction would not. In these cases the ferrite-gapped construction will be smaller.

Design with Equal Copper and Core Loss Resistance

For the case in which $g_1^2<G_1^2$, equation 48 will provide the iron length, ℓ_i. A plot of $\sqrt{u(s)w(1)/[w(s)u(1)]}$ is shown in Fig. 7, Chart 3A, as curve 1, for convenience in calculating equation 48 for various stack heights after an initial calculation of square stack has been made.

The number of turns may be calculated from

$$N=\sqrt{L10^8}\ \sqrt[4]{v\gamma I_\Delta^2/[uw\rho(I_{\mathrm{rms}}^2-I^2)]} \qquad (52)$$

The equation for B_Δ is

$$B_\Delta=(R_{ac}/2)^2\times \sqrt[4]{v^3w(I_{\mathrm{rms}}^2-I^2)^5/[u^3\rho^3\gamma^5 I_\Delta^6(L10^8)^6]} \qquad (53)$$

The above equations formulate all the important quantities of the design except β, B_m, μ_i, and $\mu_{\Delta i}$.

From equations 2, 3, 49, and 51

$$B_m\left(\frac{\mu_{\Delta g}H_c}{\mu_{\Delta i}B_r}-\frac{1}{\mu_i}\right)+\frac{\mu_{\Delta g}H_c}{\mu_{\Delta i}} = B_m\mu_{\Delta g}G_1^2\frac{H_c}{B_r}-\frac{B_\Delta I_m G_1^2}{I_\Delta}+\mu_{\Delta g}G_1^2H_c \qquad (54)$$

This equation may be solved by a graphical method. For each of several values of B_Δ, the left side may be plotted as a function of B_m. Such a plot is Chart 3, Fig. 8. All the quantities on the right side are known except B_m. This right side represents a straight line on Chart 3 whose slope is $\mu_{\Delta g}H_cG_1^2/B_r$ and whose B_m axis intercept is $[B_\Delta I_m B_r/(I_\Delta \mu_{\Delta g} H_c)]-B_r$. This line may be constructed for each design, and its intersection with the curve of Chart 3 is the solution of equation 54. There may be two intersections, each indicating an allowable operating point. Generally the lower one would be chosen from the standpoint of linearity, etc. Since B_m and B_Δ are now known, $\mu_{\Delta i}$ can be obtained from the original iron $\mu_{\Delta i}$ curves. From equations 49 and 51

$$\beta=\mu_{\Delta g}[G_1^2-(1/\mu_{\Delta i})] \qquad (55)$$

Design Limited by Copper Resistance

If $G_1<g_1$, a different attack is necessary. Equation 51 could be rewritten in terms of n_1 and, for a particular set of specifications, this quantity might be plotted as a curve on Chart 1A. Its intersection with the g_1 curve would be the design point

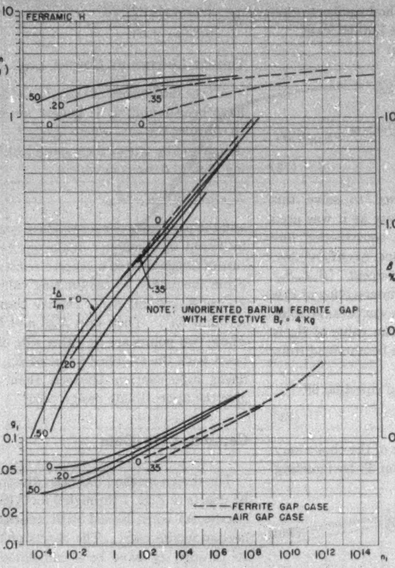

Fig. 10. Chart 1A: copper resistance limited designs, Ferramic H

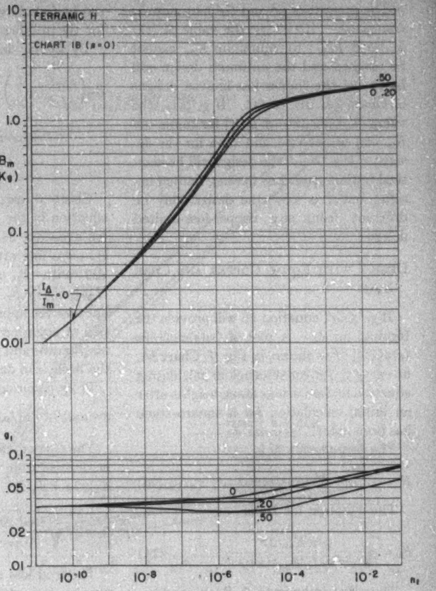

Fig. 11. Chart 1B: copper resistance limited designs with zero gap, Ferramic H

from which the design would be made, but it is a very complicated function to compute, and an approximate method will be satisfactory in most cases. From inequality 47 the limiting values that R_c can have are $R_{ac}/2$ and R_{ac}. Calculations can be made for these two points as follows:

Let

$$R_c'=(R_{ac}/2) \tag{56}$$

Calculate index n_1' corresponding to R_c' by equation 5. Read g_1' corresponding to n_1'. Calculate, from equation 44 and 10,

$$R_i'=0.4\pi\gamma I_\Delta^2 L10^8/[(I_{\mathrm{rms}}^2-I^2)(g_1')^2] \tag{57}$$

and

$$R_{ac}'=R_c'+R_i' \tag{58}$$

Let

$$R_c''=R_{ac} \tag{59}$$

In the same manner as before calculate n_1'', read g_1'', and calculate R_i'' and R_{ac}''. By consideration of equation 45, it is seen that

$$R_{ac}'<R_{ac} \tag{60}$$

As long as

$$I_\Delta\neq 0 \tag{61}$$

and

$$\gamma\neq 0 \tag{62}$$

$$R_i''>0 \tag{63}$$

so that

$$R_{ac}''>R_{ac} \tag{64}$$

These are then two points on either side of the point where the inductor design will have the proper R_{ac}. Linear interpolations may be used to find the approximate design point.

The Design Method for Inductors Limited by Total Loss Heating

General Equations

As copper loss heating was considered in an earlier section, heating by the total resistance will be considered now. The total power density is

$$K_{ac}=\frac{u\rho I_{\mathrm{rms}}^2 L10^8[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]}{0.4\pi p v w \ell_i^4}+\frac{0.4\pi I_\Delta^2 L10^8}{p\ell_i^2[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]} \tag{65}$$

The equation is of the same form as equation 45 and will be treated in the same way.

For equal loss case

$$\ell_i=\sqrt[3]{\frac{I_{\mathrm{rms}}I_\Delta L10^8}{p(K_{ac}/2)}\sqrt{\frac{u\rho\gamma}{vw}}} \tag{66}$$

and

$$\frac{1}{\mu_{\Delta i}}+\frac{\beta}{\mu_{\Delta g}}=0.4\pi\sqrt[3]{\frac{vw\gamma I_\Delta^4 L10^8}{pu\rho I_{\mathrm{rms}}^2(K_{ac}/2)}} \tag{67}$$

This equation can be used for comparison with Chart 2A, or with Charts 2B or 2C when they apply, to determine whether this value $[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]$ can be realized. From equation 28 a value of index n_2 may be calculated for the condition that

$$K_c=(K_{ac}/2) \tag{68}$$

where K_{ac} is determined by the allowable temperature rise. The chart will then give application function g_2.

The minimum value of $[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]$ is obtained for the condition of equation 68. Equation 67 will be used to calculate the value of $[(1/\mu_{\Delta i})+(\beta/\mu_{\Delta g})]$ required for minimum K_{ac} and this value will be symbolized by G_2^4 so that

$$G_2^4=0.4\pi\sqrt[3]{\frac{vw\gamma^2 I_\Delta^4 L10^8}{pu\rho I_{\mathrm{rms}}^2(K_{ac}/2)}} \tag{69}$$

The quantities g_2^4 and G_2^4 may now be compared. If $G_2^4 < g_2^4$ the value of $[(1/\mu_{\Delta t})+(\beta/\mu_{\Delta g})]$ for minimum K_{ac} cannot be reached and the optimum design will be one of the copper-loss-limited designs of Chart 2A, 2B, or 2C. If $g_2^4 \leqq G_2^4$ the value of $[(1/\mu_{\Delta t})+(\beta/\mu_{\Delta g})]$ for minimum K_{ac} can be realized and used for the design. If $g_2^4 = G_2^4$, the design will be identical to the copper loss heating limited design; but if $g_2^4 < G_2^4$, the design may be different from any copper-loss-limited design.

Design with Equal Copper and Core Loss

If $g_2^4 \leqq G_2^4$, equation 66 will provide the formula for ℓ_t. A plot of $\{u(s)w(1)/[w(s)u(1)]\}^{1/6}$ is shown in Fig. 7, Chart 3A, as curve 2, for convenience in calculating equation 66 for various stack heights after an initial calculation for a square stack has been made.

The formula for N is

$$N=\sqrt{L10^8}\ \sqrt[4]{v\gamma I_\Delta^2/[uw\rho I_{rms}^2]} \qquad (70)$$

The equation for B_Δ is

$$B_\Delta=\sqrt[12]{\frac{p^8 v(K_{ac}/2)^8}{uw^6\rho\gamma^7 I_\Delta^2 I_{rms}^2 (L10^8)^2}} \qquad (71)$$

The other unknowns, β, B_m, μ_t, and $\mu_{\Delta t}$ can be found by a method similar to that for the total-resistance-limited case.

By similar derivation

$$B_m\left(\frac{\mu_{\Delta g}H_c}{\mu_{\Delta t}B_r}-\frac{1}{\mu_t}\right)+\frac{\mu_{\Delta g}H_c}{\mu_{\Delta t}} = B_m\mu_{\Delta g}G_2^4\frac{H_c}{B_r}-\frac{B_\Delta I_m G_2^4}{I_\Delta}+\mu_{\Delta g}G_2^4 H_c \qquad (72)$$

Chart 3 can be used to solve this equation in the same way as it was used for equation 54. The construction line is now a line with a slope, $(\mu_{\Delta g}H_c G_2^4)/B_r$, and with B_m axis intercept $[B_\Delta I_m B_r/(I_\Delta \mu_{\Delta g} H_c)]-B_r$. The intersection of this line and the appropriate curve is the solution of equation 72. The value of B_m is now known and $\mu_{\Delta t}$ can be obtained from the basic iron data.

From equation 67 and equation 69

$$\beta=\mu_{\Delta g}[G_2^4-(1/\mu_{\Delta t})] \qquad (73)$$

The copper resistance of the choke may be derived from equation 33 by inserting $K_{ac}/2$ for K_c.

$$R_c=G_2^2\sqrt{\frac{pu\rho L10^8(K_{ac}/2)}{0.4\pi vwI_{rms}^2}} \qquad (74)$$

The iron loss component of resistance may be derived from equation 44 as

$$R_t=\frac{0.4\pi\gamma I_\Delta^2 L10^8}{G_2^4(I_{rms}^2-I^2)} \qquad (75)$$

Design Limited by Copper Loss

All the dimensions of the $g_2^4 \leqq G_2^4$ design have been found, so it is next necessary to consider the case where $G_2^4 < g_2^4$. This design will be one of the copper loss heating limited designs in which

$$K_t<(K_{ac}/2)<K_c<K_{ac} \qquad (76)$$

and the particular one for smallest size will be found in a manner analogous to the case of design limited by copper resistance. From inequality 76 the limiting values of K_c are $K_{ac}/2$ and K_{ac}. Denote these by K_c' and K_c''. Then find K_{ac}' and K_{ac}''. These two points are on either side of the point with the specified value of K_{ac} and linear interpolation between them will give the approximate design point.

Ceramic Core Data

The design method has been illustrated by charts of Figs. 1 through 9 for AISI-15 (Audio A) cores biased with unoriented barium ferrite gaps. The charts of Figs. 10 through 17 have been calculated for Ferramic H cores. These charts are similar to those for the metallic cores ex-

cept that the gap angling was such that the gap inductions were one half those of the main core, and the auxiliary axes are omitted because these ceramic cores are neither standardized nor laminated.

General Design Method

A general map of the synthesis method is shown in Fig. 18. Where the circuit imposes a resistance limitation, the design method follows the course in the upper part of the map. In the general case, the total resistance R_{ac} would be given and the method of design would be chosen by a test inequality. In some cases, only the copper d-c resistance R_c is specified and the R_c limited design method would be used.

Within the R_c-limited area, there are several charts. Normally Chart 1A is used first since it specifies the minimum size design otherwise unrestricted. It has a lower limit below which the air gap would be negative; and in this range, Chart IB will specify the zero air gap design, which is the best physically realizable design. Chart 1A has upper limits where a minimum ceases to exist, and in many cases considerations of linearity may restrict the maximum induction to be used. For design in these ranges, the Charts 1C provide designs.

Within the $R_c=R_t$ design area, the design method involves more algebraic equations and fewer curves than the R_c-limited area.

When the design has been made to meet a specified resistance figure, the thermal power density, which determines the temperature rise, should be checked. If the thermal power density of the design is too high or if there is no circuit requirement on the allowable resistance, the design should be made in the thermal power density limited area shown in the lower portion of Fig. 18.

The map of this area is similar to the map for specified resistance. Normally the designer would determine the specific method by means of a test inequality, although in the case of a small alternating current and large direct current, he would use the K_c-limited design immediately. There are several charts within the K_c-limited area, and these are analogous to the charts in the R_c-limited area. The design method within the $K_c=K_t$ area is similar to the method in the $R_c=R_t$ area and uses the same Chart 3. In most cases, the design synthesized by the method will be subject to a winding calculation, taking into account the actual wire size, local winding methods, etc.

The general method, insofar as the basic ideas are concerned, may also be used for transformers with superposed a-c and d-c magnetization. When so used, all the currents should be referred to one winding, and the design can then be based on the magnetizing current and the open circuit inductance requirements. The heating effects must be based on the total magnetizing and load currents. The copper area factor v must be that for the reference winding alone. In a 2-winding transformer, the value of v would be approximately half of the value used in the inductor design for the same winding methods since each coil should occupy half the window.

Conclusions

The theory developed indicates the feasibility of the ferrite-gapped inductor for miniaturization of inductive devices carrying unsymmetrical currents.

The mathematical relations developed

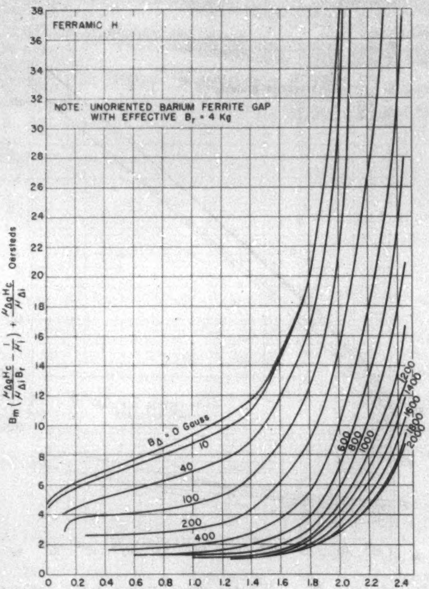

Fig. 16. Chart 3: equal loss designs with ferrite gap; Ferramic H

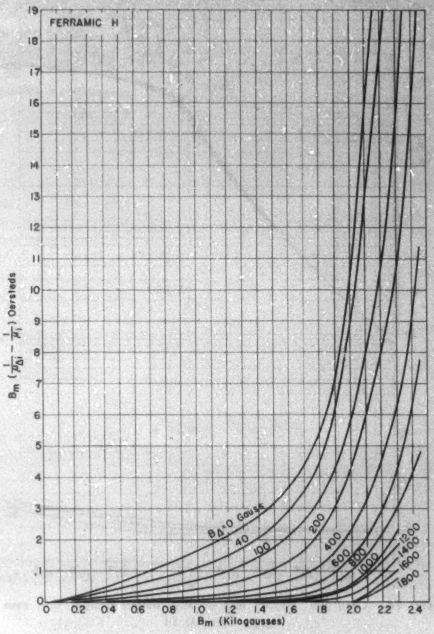

Fig. 17. Chart 3: equal loss designs with air gap; Ferramic H

provide a method of constructing design charts directly from the magnetic material characteristics. Those charts may then be used for the design (synthesis) of biased inductors without the usual trial-and-error procedures for the first design.

The charts provide a direct evaluation of the applicability of the various ferromagnetic materials. If, for example, for a given value of index n_1, two materials have application function numbers, g_1, which differ by a factor of two, the resulting optimum inductors constructed from these materials would have a factor of two ratio between their linear dimensions and a ratio of eight (2^3) between their weights and their volumes.

A secondary use of the method is that of providing a quick size estimate for the equipment designer who may need to weigh inductor specifications and size against the specifications and size of other components with which the inductor is connected.

The method is limited by the quantity and quality of the magnetic data available. No complete set of incremental data has been available from any one steel manufacturer in recent years, nor is the range of variation of these data generally available.

Nomenclature

Subscripts on Time Variable Quantities (period P)

m = maximum value during a cycle

rms = root-mean-square, $Z_{rms} = \sqrt{(1/P)\int_0^P z^2 dt}$

Δ = incremental, $Z_\Delta = (Z_{max} - Z_{min})/2$
no subscript = time average, $Z = (1/P)\int_0^P z\,dt$

General Subscripts

c = value within the coil (copper)
g = value within the gap
i = value within the iron

Letter Symbols

a_c = net copper cross-sectional area in cm²
a_i = net iron cross-section area in cm²
b = time variable induction in gausses
B_r = gap material effective residual induction in gausses
$D_\Delta = (1/\mu_\Delta'^2)d\mu_\Delta'/dB_m$
$D_N = (1/\mu^2)d\mu/dB_m$
g_1 = application function $\sqrt{(1/\mu_\Delta)+(\beta/\mu_{\Delta g})}$
g_1' = value of g_1 corresponding to $R_c' = R_{ac}/2$
g_{1r} = simplified application function, $l_i\sqrt{R_c/L}$
g_1'' = value of g_1 corresponding to $R_c'' = R_{ac}$
G_1 = value of g_1 for which $R_c = R_i$

g_2 = application function $\sqrt[4]{(1/\mu_\Delta')+(\beta/\mu_{\Delta g})}$

g_{2r} = simplified application function $\sqrt[4]{K_c/(LI_{rms}^2)}$

G_2 = value of g_2 for which $K_c = K_t$

H_c = gap material coercive force in oersteds

i = time variable current in amperes

K_{ac} = total heating power density in watts per cm^2

K_c = copper loss heating power density in watts per cm^2

K_t = iron loss heating power density in watts per cm^2

ℓ = generalized length in cm

ℓ_c = mean length of turn in cm

ℓ_g = effective length of gap in cm

ℓ_t = mean iron length in cm

L = inductance in henrys

n_1 = index function $(0.4\pi)^8 v^2 w I_m^4 R_c^2 10^{-8}/(u^2\rho^2 L)$

n_1' = value of n_1 corresponding to $R_c' = R_{ac}/2$

n_1'' = value of n_1 corresponding to $R_c'' = R_{ac}$

n_{1r} = simplified index function $I_m^4 R_c^2/L$

n_2 = index function $(0.4\pi)^7 p^2 v^3 L I_m^8 K_c^2 10^9/(u^2 w \rho^3 I_{rms}^6)$

n_{2r} = simplified index function $LI_m^8 K_c/I_{rms}^6$

N = number of turns

p = dimensionless ratio of the surface area to the square of the mean iron length S/ℓ_t^2

R_{ac} = total effective resistance in ohms

R_{ac}' = total resistance calculated from $R_c' = R_{ac}/2$

R_{ac}'' = total resistance calculated from $R_c'' = R_{ac}$

R_c = copper resistance in ohms

R_c' = assumed value of copper resistance $R_{ac}/2$

R_c'' = assumed value of copper resistance R_{ac}

R_t = core loss component of resistance in ohms

R_t' = core loss component of resistance corresponding to $R_c' = R_{ac}/2$

R_t'' = core loss component of resistance corresponding to $R_c'' = R_{ac}$

s = dimensionless ratio of stack height to center leg width

S = surface area in cm^2

u = dimensionless ratio of the mean turn length to the mean iron length, ℓ_c/ℓ_t

v = dimensionless ratio of the net copper cross-sectional area to the square of the mean iron length, a_c/ℓ_t^2

w = dimensionless ratio of the net iron core cross-sectional area to the square of the mean iron length, a_c/ℓ_t^2

W_t = iron core loss in watts

Greek Symbols

β = ratio of effective gap length to iron length, ℓ_g/ℓ_t

γ = core loss constant in watts/(cm^3 gauss^2)

μ = normal permeability in gausses per oersted

μ_Δ = incremental permeability in gausses per oersted

μ_Δ' = incremental permeability as a function of B_m alone for a fixed B_Δ/B_m ratio

ρ = coil resistivity in ohm-cm

An Approach to Dynamic Optimizing Control of the Continuous Process

J. F. SANDELIEN
NONMEMBER AIEE

Synopsis: Optimum performance of the multivariable continuous process under transient conditions is considered. A generalized performance criterion is formulated in terms of the cost of operation. Assuming that the essential process behavior is known and that the major disturbance variables may be measured, the necessary conditions for minimum cost of operation are derived by applying calculus of variations in conjunction with the Lagrange multiplers technique. In certain typical cases of process behavior and cost criteria, the resulting necessary conditions reduce to a form which will yield an analytical solution. In particular, by certain approximations of the system behavior in the vicinity of an operating point, the necessary condition for optimum performance is expressed in terms of an inhomogenous Wiener-Hopf integral equation of the second kind and the solution is obtained by spectral factorization. In general, the conditions to be satisfied for minimum cost of operation appear as a set of nonlinear integral equations. A method for handling the general case is suggested.

THE CONTINUOUS process is defined as a system in which there is a continuous conversion of raw material into product. In the steady state, the process variables are constant with respect to time; they are functions, however, of the spatial co-ordinates of the processing plant. In the nonsteady or transient state, the continuous process is characterized by changes in the level of operation caused by disturbances such as variations in quality of raw materials, changes in demand, product specifications, environment, etc. Maintaining peak performance during transient as well as steady-state conditions is a problem of considerable importance and complexity, depending on the interrelationships between the process variables.

Fig. 1 represents a generalized configuration of a continuous process in which the variables are classified as:

1. Manipulated variables $\overline{m}_i$ which are subjected to direct control and provide the means for guiding the process along the path of optimum performance.
2. Disturbance variables $\overline{\vartheta}_j$ which are independent and include load- and set-point variables.
3. Output variables $\overline{q}_k$ which represent product quality, yield, etc.
4. State variables $\overline{y}_l$ representing the intermediate variables which serve to establish the relationships between the input and output variables.

To obtain peak performance, the optimum combination of variables must be determined according to some criterion

Paper 60-247, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted November 4, 1959; made available for printing January 20, 1960.

J. F. SANDELIEN, formerly with the Case Institute of Technology, Cleveland, Ohio, is now with the IBM Research Center, Yorktown Heights, N. Y.

This paper represents a thesis investigation conducted at Case Institute of Technology in partial fulfillment of the requirements for an M.S. degree in Instrumentation Engineering. Dr. I. Lefkowitz was responsible for guidance and stimulation in the work, which was carried out in conjunction with a sponsored research project in computer and optimizing control. The author wishes to acknowledge the present support of this area of research at Case Institute of Technology by the General Electric Company, the International Business Machines Corporation, Republic Steel Corporation, Thompson-Ramo-Wooldridge Inc., and the Westinghouse Electric Corporation.

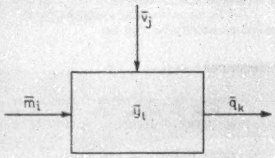

Fig. 1. Generalized configuration of a continuous process

$i=1,2,\ldots,n$
$j=1,2,\ldots,p$
$k=1,2,\ldots,r$
$l=1,2,\ldots,s$

of performance. A useful index or criterion is provided by the cost of production, which depends on such items as raw materials, energy, labor, by-product recovery, off-standard product, etc. It is assumed that the cost rate C' can be expressed as a function of the process variables:

$$C' = f_1(\bar{m}_i, \bar{q}_k, \bar{y}_s) \qquad (1)$$

where $i=1, 2, \ldots, n$; $k=1, 2, \ldots, r$; and $l=1, 2, \ldots, s$.

The techniques presently employed for the purpose of achieving minimum cost of production are listed and described briefly as follows:

1. *Model Methods.* Assuming that the steady-state relationships between the variables are known, the outputs $\bar{q}_k$ may be expressed in terms of the manipulated variables $\bar{m}_i$ and the disturbances $\bar{v}_j$. The necessary conditions for the steady-state optimum combination of values of the manipulated variables are obtained by differentiating equation 1 with respect to each of the n manipulated variables and equating the resulting partial derivatives to zero:

$$\frac{\partial C'}{\bar{m}_i} = 0, \quad i=1, 2, \ldots, n \qquad (2)$$

Implicit relationships may be handled by the introduction of Lagrangian multipliers. The necessary steps are often carried out as a continuous computer operation.

2. *Nonmodel Methods.* This technique is based in principle on a trial-and-error procedure which may be carried out with little or no knowledge about the relationships between the variables. First, the manipulated variables are altered according to a certain scheme. The resulting change in the performance is then evaluated relative to these alterations in order to determine the direction of further changes in the manipulated variables towards an optimum combination. This sequence repeats itself and may proceed continuously or in discrete steps.

These techniques, as presently applied, ignore process dynamics. The result is that operation during transient conditions cannot be optimum. In cases where disturbances occur at frequencies significant compared with the process dynamics, changes in the manipulated variables generated by an optimizing scheme that does not consider the dynamics may prolong a nonoptimum transient from one disturbance to the next. This means that the optimum steady state is never achieved, and the problem of optimizing during transient conditions becomes all-important. The optimum control of the continuous process under these dynamic conditions is the problem considered in this paper.

A mathematical formulation of the problem is provided by making the following stipulation:

1. It is assumed that through analysis, experimental observation, or self-checking, the steady-state relationships and dynamic functions for the system are known. (Self-checking is referred to as a method for determining system behavior from past and current information supplied by the process variables.[1])

2. It is assumed that the process is displaced from the steady state by action of one or more of the disturbance variables. The disturbances are assumed to be finite so that the process can be controlled to a new steady-state configuration corresponding to an optimum change in cost rate, designated C_s.

3. The initial steady-state values of the variables are used to provide a reference level for defining the variables during the transient period. Where the deviations of the variables from their respective reference values remain small during the transition period, certain approximations may be applied to the system equations.

The average cost of operation over an indefinite period of time is

$$\bar{c} = \lim_{T\to\infty} \frac{1}{T}\int_0^T f_1(\bar{m}_i, \bar{q}_k, \bar{y}_l)dt \qquad (3)$$

where $f_1(\bar{m}_i, \bar{q}_k, \bar{y}_l)$ is the cost rate given by equation 1. Now, defining the variables in terms of their steady-state reference values gives

$$\bar{m}_i = M_i + m_i$$
$$\bar{q}_k = Q_k + q_k$$
$$\bar{y}_l = Y_l + y_l$$
$$\bar{c} = C + c \qquad (4)$$

The bar refers to the total value of the variables, upper-case letters to the initial steady-state condition, and lower-case letters designate changes from the initial state.

Substituting into equation 3, the following equation is obtained:

$$\bar{c} = C + \lim_{T\to\infty} \frac{1}{T}\int_0^T f(m_i, q_k, y_l)dt \qquad (5)$$

where $f(m_i, q_k, y_l)$ is a function of the deviations in the variables.

The problem now reduces to finding the functions $m_i(t)$ that minimize the integral of equation 5. The optimizing conditions do not change if a constant

$$C_s = \lim_{T\to\infty} \frac{1}{T}\int_0^T C_s dt$$

is subtracted from the integral of equation 5. The new integrand, $f(m_i, q_k, y_l) - C_s$, converges to zero as T goes to infinity as a result of assumption 2, above. Thus the cost is minimized by minimizing the integral:

$$I = \int_0^\infty [f(m_i, q_k, y_l) - C_s]dt \qquad (6)$$

subject to the constraints imposed by the system equations. This formulation, together with the above stipulations, constitute the mathematical statement of the problem. (Equation 6 is a more convenient form than the last term of equation 5 from the standpoint of later manipulations.)

Related Problems

Calculus of variations provides a useful tool in the solution of engineering problems dealing with maximizing or minimizing quantities defined by a definite integral. Several applications are prominent in the area of automatic control referred to as "control design with specified criteria." A summary of these applications is presented here because of their resemblance to the present application problem.

Control design with specified criteria is discussed in references 2 and 3, where the objective is to guide a system from one essential operating level to another in an optimum fashion determined by some performance criterion. The constraints are expressed in terms of differential equations. The necessary conditions for optimum performance appear likewise as differential equations which are subjected to the required boundary conditions for solution. A stability consideration is necessary, once the system reaches the new operating level, in order to avoid its running away from the desired operating point.

This technique is successfully extended to the area of process control in reference 4 where the optimum control of a chemical batch process is considered. The product composition of the batch is guided along an optimum path from initial to final values by repetitive computer control action which is based on the solution of a set of differential equations satisfying given boundary conditions. Stability of the system, once the end point has been reached, is obviously of no consequence.

The analytic design of compensating elements for servomechanisms is treated extensively in reference 5. The performance index appears either as the integral square error, or the mean square error, depending on the input signals considered. The necessary condition for optimum performance, obtained by application of the Wiener theory of optimum filters, is expressed in the form of an integral equation. The present problem in its elementary configuration is analogous to developments in reference 5. The derivation of the necessary conditions on the basis of integral equations is a result of the problem formulation. The boundary conditions are an integral part of the problem and no separate considerations with regard to stability are required outside the criteria for optimum performance.

Derivation of the Necessary Conditions for Optimum Performance Using Generalized System Configuration

The relationships between the variables in the system, Fig. 1, are in general expressed by a set of consistent and independent nonlinear differential equations. It is reasonable to assume, however, that the steady-state relationships are of primary importance in the optimum control of the continuous process, and that a linear approximation of the system dynamics within a specified region about the operating point will cause negligible deviations from the theoretical optimum.

Although the minimizing conditions may be obtained with nonlinear dynamics included in the system equations, the form given by relations 8 in the following is considered adequate in most cases.

First, a generalized notation is adopted for the variables, q, y, and m:

$$\begin{array}{ll} q_k = w_k & k = 1, 2, \ldots, r \\ y_l = w_{r+l} & l = 1, 2, \ldots, s \\ m_i = w_{r+s+i} & i = 1, 2, \ldots, n \end{array} \tag{7}$$

Then the process behavior is expressed by the following set of equations:

$$\sum_{\alpha=0}^{N} a_\alpha \frac{d^\alpha w_u}{dt^\alpha} = H_u(w_z, v_j) \tag{8}$$

where

w_u is defined by relation 7: $u = 1, 2, \ldots, r, r+1, \ldots, r+s$
a_α = constants: $\alpha = 1, 2, \ldots, N$
t = time variable
$H_u(w_z, v_j)$ = general nonlinear functions of the arguments w_z and v_j, which in turn are functions of time.

$u = 1, 2, \ldots, r, r+1, \ldots, r+s$
$z = 1, 2, \ldots, r, r+1, \ldots, r+s, r+s+1, \ldots, r+s+n$
$j = 1, 2, \ldots, p$

Definition of the variables by equation 4 permits the transformation of equation 8 into an integral equation as follows: With Laplace transforms

$$\mathfrak{L}(w_u) = \frac{\mathfrak{L}[H_u(t)]}{\sum_{\alpha=0}^{N} a_\alpha s^\alpha} \tag{9}$$

where

$\mathfrak{L}$ = Laplace transform operator
s = Laplace transform variable

By the convolution theorem

$$w_u(t) - \int_{-\infty}^{\infty} H_u(t_1) h_u(t-t_1) dt_1 = 0 \tag{10}$$

where

$$h_u(t) = \mathfrak{L}^{-1} \frac{1}{\sum_{\alpha=0}^{N} a_\alpha s^\alpha}$$

is a known weighting function.

The integral of equation 6 is now minimized, subject to the constraint equations 10, by application of the method of Lagrange multipliers and the calculus of variations. The procedure is similar to that given in reference 6.

Equations 10 are multiplied by the arbitrary functions $\mu_u(t)$ and added to the integrand of equation 6:

$$I = \int_{-\infty}^{\infty} \left(f_s + \sum_{u=1}^{r+s} \mu_u \phi_u \right) dt \tag{11}$$

where

$f_s \equiv f(m_i, q_k, y_l) - C_s u(t)$; $u(t)$ = unit step at $t=0$
$\phi_u \equiv$ left-hand side of equation 10

Since the integrand of equation 11 is zero for $t<0$ (a result of definition 4), the lower limit of integration is extended to $-\infty$ for later convenience.

The following expressions are substituted into equation 11:

$$W_z(t) = w_z(t) + \epsilon \bar{w}_z(t); \quad z = 1, 2, \ldots, r+s+n \tag{12}$$

where $w_z(t)$ are the assumed minimizing functions; ϵ is an arbitrary parameter; and $\bar{w}_z(t)$ are some arbitrary realizable functions consistent with equation 9, and are such that $w_z(t) = 0$, for $t \leq 0$.

The resulting integral becomes a function of the parameter ϵ:

$$I(\epsilon) = \int dt \left[f(W_z) - u(t) C_s + \sum_{u=1}^{r+s} \mu_u W_u - \sum_{u=1}^{r+s} \mu_u \int dt_1 H_u(t_1) h_u(t-t_1) \right] \tag{13}$$

(The limits of integration, where not otherwise designated, are from minus to plus infinity.) Since $W_z = w_z$ for $\epsilon = 0$, a necessary condition for the minimizing functions is that the derivative of the integral with respect to ϵ vanish for $\epsilon = 0$:

$$\frac{dI(\epsilon)}{d\epsilon} = \int dt \left[\sum_{z=1}^{r+s+n} \frac{\partial f}{\partial W_z} \frac{\partial W_z}{\partial \epsilon} + \sum_{u=1}^{r+s} \mu_u \frac{\partial W_u}{\partial \epsilon} - \sum_{u=1}^{r+s} \mu_u \int dt_1 \times \sum_{z=1}^{r+s+n} \frac{\partial H_u(t_1)}{\partial W_z} \frac{\partial W_z}{\partial \epsilon} h_u(t-t_1) \right] \tag{14}$$

where

$$\frac{\partial W_z}{\partial \epsilon} = \bar{w}_z \tag{15}$$

For

$$\epsilon = 0: \quad \frac{\partial f}{\partial W_z} = \frac{\partial f}{\partial w_z}$$

$$\text{and } \frac{\partial H_u(t_1)}{\partial W_z} = \frac{\partial H_u(t_1)}{\partial w_z}$$

$$\text{and } \frac{dI(\epsilon)}{d\epsilon} = 0$$

Integrating term by term in the second integral, interchanging the order of integration and applying relationships 15:

$$\int dt_1 \left[\sum_{z=1}^{r+s+n} \frac{\partial f}{\partial w_z} \bar{w}_z(t_1) + \sum_{u=1}^{r+s} \mu_u(t_1) \bar{w}_u(t_1) - \sum_{u=1}^{r+s} \sum_{z=1}^{r+s+n} \bar{w}_z(t_1) \int dt\, \mu_u(t) \times \frac{\partial H_u(t_1)}{\partial w_z} h_u(t-t_1) \right] = 0 \tag{16}$$

Collecting terms with the same limits of summation and factoring out the variation function $\bar{w}_z(t)$:

$$\int dt_1\left\{\sum_{u=1}^{r+s}\bar{w}_u(t_1)\left[\frac{\partial f}{\partial w_u}+\mu_u(t_1)-\right.\right.$$

$$\left.\sum_{x=1}^{r+s}\int dt\,\mu_x(t)\,\frac{\partial H_x(t_1)}{\partial w_u}\,h_x(t-t_1)\right]+$$

$$\sum_{y=r+s+1}^{r+s+n}\bar{w}_y(t_1)\left[\frac{\partial f}{\partial w_y}-\sum_{x=1}^{r+s}\times\right.$$

$$\left.\left.\int dt\mu_x(t)\,\frac{\partial H_x(t_1)}{\partial w_y}\,h_x(t-t_1)\right]\right\}=0 \quad (17)$$

Defining

$$F(t_1)=f+\sum_{u=1}^{r+s}\mu_u(t_1)w_u-$$

$$\sum_{x=1}^{r+s}\int dt\,\mu_x(t)H_x(t_1)h_x(t-t_1) \quad (18)$$

will reduce equation 17 to the following form:

$$\int dt_1\left[\sum_{u=1}^{r+s}\bar{w}_u(t_1)\,\frac{\partial F}{\partial w_u}+\right.$$

$$\left.\sum_{y=r+s+1}^{r+s+n}\bar{w}_y(t_1)\frac{\partial F}{\partial w_y}\right]=0 \quad (19)$$

Because of the constraints specified by equation 10, only n of the variation functions are independent. However, the r+s arbitrary functions $\mu_1(t_1)$, $\mu_2(t_1)$ $\ldots$, $\mu_{r+s}(t_1)$ may be so chosen as to make r+s of the partial derivatives of equation 19 vanish. If, as an example, the vanishing terms are $\partial F/\partial w_u$, $u=1, 2, \ldots, r+s$; the remaining variation functions $\bar{w}_z$ may be independent and arbitrary within the defining equation 12. In particular, for $t_1>0$, these functions may be nonzero. Consequently, that equation 19 may be satisfied, the remaining partial derivatives must also vanish. Thus, by using relationships 7, the necessary conditions for the minimizing function may be expressed as

$$\frac{\partial F}{\partial w_z}=0,\ z=1, 2, \ldots, r+s+n;\ \text{for } t_1\geq 0 \quad (20)$$

These equations are solved in conjunction with the constraint equations 10 to determine the manipulated variables for optimizing performance.

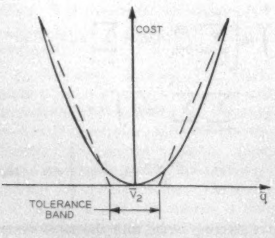

Fig. 2. Production cost versus deviation $\bar{q}$ in product quality

Optimum Performance Applied to Typical System Configurations

PERFORMANCE CRITERION

The general criterion for optimum performance, expressed in terms of the cost of production, must be evaluated by management in each individual case to establish the functional relationships of equation 1. The purpose here is not to discuss the different aspects of such evaluation, but to select a typical form of the cost function which is likely to satisfy a variety of process operations, and which will keep the complexity of the problem and its solution within the scope of practical utility.

The majority of operations demand a product quality within certain tolerances. Deviation from the given specifications may result in loss of product or a product of inferior quality which requires recycling, blending operations, etc.

The resulting increase in the cost of production may take the form shown graphically by the broken lines in Fig. 2, where the quality $\bar{q}$ is measured from a desired reference or set point $\bar{v}_2$. For mathematical convenience, this cost-quality relationship is approximated by the solid-line parabola in the same figure, and the cost of production resulting from a deviation in product quality is given by $C_2\bar{q}^2$, where C_2 is a constant.

The cost of raw material is considered proportional to the rate of consumption by a factor C_1. Assuming that the product flow rate is fixed, the cost equation for the system shown in Fig. 3 is

$$f_1(\overline{m}, \bar{q})=C_1\overline{m}+C_2\bar{q}^2 \quad (21)$$

This is the basic cost relationship used in the following system configurations.

SYSTEM WITH ONE SECOND-ORDER NONLINEARITY

Configuration

A system performing according to cost equation 21, and otherwise exhibiting linear characteristics, is referred to as a system with one second-order nonlinearity. A typical block diagram is shown in Fig. 4, where the product quality q is a function of a load variable v_1, a set point variable v_2, and a manipulated variable m. (Set point is referred to here as the desired value of the product quality.) The variables are defined according to equation 4. The system transfer functions are given by $K_1G(s)$ and $K_2N(s)$ where K_1 and K_2 are steady-state gain constants.

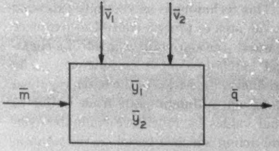

Fig. 3. Typical process configuration

The cost function, equation 21, is expressed in terms of an initial steady-state cost and a deviation, by application of relations 4:

$$f_1(\overline{m}, \bar{q})=C+f(m, q) \quad (22)$$

where $C=C_1M+C_2Q^2$, and $f(m, q)=C_1m+2C_2Qq+C_2q^2$.

Considering the case of fixed set point, the constraint equations expressed in the frequency domain are

$$q(s)=-y_1(s)-y_2(s)$$
$$y_1(s)=K_1G(s)m(s)$$
$$y_2(s)=K_2N(s)v_1(s) \quad (23)$$

In the time domain:

$$q(t)+\int[y_1(t_1)+y_2(t_1)]\delta(t-t_1)dt_1=0$$
$$y_1(t)-K_1\int m(t_1)g(t-t_1)dt_1=0$$
$$y_2(t)-K_2\int v_1(t_1)n(t-t_1)dt_1=0 \quad (24)$$

where

$\delta(t)$ = Dirac delta function defined, as

$$\delta(t)=0,\ \text{for } t\neq 0$$

$$\int_{-\infty}^{\infty}\delta(t)dt=1$$

Equations 22 and 24 completely define the over-all system behavior from the standpoint of cost of operation.

Solution

The necessary conditions for determination of the manipulated variable m

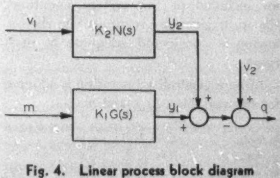

Fig. 4. Linear process block diagram

for optimum performance are obtained by application of equations 18 and 20. The relationships are

$$\begin{aligned} &w_1=q; && H_1=-(y_1+y_2); && h_1=\delta \\ &w_2=y_1; && H_2=K_1m; && h_2=g \\ &w_3=y_2; && H_3=K_2v_1; && h_3=n \\ &w_4=m && && \end{aligned} \tag{25}$$

Equation 18 yields

$$\begin{aligned} F(t_1)=&\,C_1m(t_1)+2C_2Qq(t_1)+C_2q^2(t_1) \\ &+\mu_1(t_1)q(t_1)+\int dt\ \mu_1(t)[y_1(t_1)+y_2(t_1)]\delta(t-t_1) \\ &+\mu_2(t_1)y_1(t_1)-K_1\int dt\ \mu_2(t)m(t_1)g(t-t_1) \\ &+\mu_3(t_1)y_2(t_1)-K_2\int dt\ \mu_3(t)v_1(t_1)n(t-t_1) \end{aligned} \tag{26}$$

for $t_1\geq 0$, with the use of relations 20:

$$\frac{\partial F}{\partial q}=2C_2Q+2C_2q(t_1)+\mu_1(t_1)=0$$

$$\frac{\partial F}{\partial y_1}=\mu_2(t_1)+\mu_1(t_1)=0$$

$$\frac{\partial F}{\partial y_2}=\mu_3(t_1)+\mu_1(t_1)=0$$

$$\frac{\partial F}{\partial m}=C_1-K_1\int dt\ \mu_2(t)g(t-t_1)=0 \tag{27}$$

which, combined with the constraint equations 24, reduces to

$$\begin{aligned} &K_1\int dt\ g(t-t_1)\int dt_2m(t_2)g(t-t_2)+ \\ &\qquad K_2\int dt\ g(t-t_1)\int dt_2v_1(t_2)n(t-t_2)- \\ &\qquad\quad Q\int dt\ g(t-t_1)+\frac{C_1}{2C_2K_1}=0 \text{ for } t_1\geq 0 \end{aligned} \tag{28}$$

Finally, interchanging the order of integration and introducing translation function

$$\begin{aligned} I_{gg}(w)&=\int dt\ g(t)g(t+w) \\ I_{gn}(w)&=\int dt\ g(t)n(t+w) \end{aligned} \tag{29}$$

gives the following equation:

$$\begin{aligned} &K_1\int dt_2m(t_2)I_{gg}(t_1-t_2)+ \\ &\qquad K_2\int dt_2v_1(t_2)I_{gn}(t_1-t_2)- \\ &\qquad\quad Q\int dt\ g(t-t_1)+\frac{C_1}{2C_2K_1}=0 \text{ for } t_1\geq 0 \end{aligned} \tag{30}$$

This is a nonhomogenous Wiener-Hopf integral equation of the first kind which is solved for $m(t)$ by the method of spectral factorization outlined in reference 7. The solution is obtained in the frequency domain by application of the bilateral Laplace transform to equation 30:

$$\begin{aligned} &\left[\frac{C_1}{2C_2K_1}-QG(-s)\right]2\pi\delta(js)+ \\ &\qquad K_1m(s)I_{gg}(s)+K_2v_1(s)I_{gn}(s)=A(s) \end{aligned} \tag{31}$$

where $A(s)$ is analytic in the entire LHP (left-half plane) since the inverse transform of $A(s)$ is zero for $t_1\geq 0$.

$$\bar{\mathfrak{L}}\int dt\ g(t-t_1)=2\pi\delta(js)G(-s) \tag{32A}$$

(See Appendix I.)

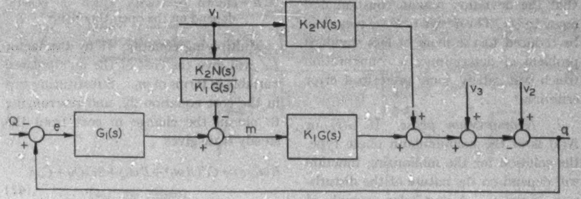

Fig. 5. **Optimum control of system with one second-order nonlinearity (minimum phase elements)**

$\bar{\mathfrak{L}}$ is the bilateral Laplace transform operator.

$\bar{\mathfrak{L}}(1)=2\pi\delta(js)$ is a valid transform for $Re(s)=0$ (reference 8), and

$$\begin{cases} \delta(js)=0 \text{ for } js\neq 0 \\ \displaystyle\int_{-\infty}^{\infty}\delta(js)d(js)=1 \end{cases} \tag{32B}$$

Condition 32B implies that the first term of equation 31 vanishes for all values of $s\neq 0$. When $s=0$, $G(-s)=1$ for all stable systems, and considerations of steady-state optimum performance shows that:

$$Q=\frac{C_1}{2C_2K_1} \tag{33}$$

(see Appendix II). Thus the first term of equation 31 vanishes identically for all values of s.

The solution of equation 31 is initiated by factorizing:

$$I_{gg}(s)=\gamma^+(s)\gamma^-(s) \tag{34}$$

where $\gamma^+(s)$ includes all factors with poles and zeros in LHP, and $\gamma^-(s)$ includes all factors with poles and zeros in RHP (right-half plane).

Then

$$K_1m(s)\gamma^+(s)+\frac{K_2v_1(s)I_{gn}(s)}{\gamma^-(s)}=\frac{A(s)}{\gamma^-(s)} \tag{35}$$

where $A(s)/\gamma^-(s)$ contains poles in the RHP only, since $A(s)$ is analytic in the entire LHP; and $K_1m(s)\gamma^+(s)$ contains poles in the LHP only.

Consequently, the nonsteady-state solution is

$$K_1m(s)\gamma^+(s)=-\left[\frac{K_2v_1(s)I_{gn}(s)}{\gamma^+(s)}\right]_+ \tag{36}$$

where []+ denotes partial fraction expansion terms for LHP poles of the bracketed expression.

If $[K_2v_1(s)I_{gn}(s)]/[\gamma^-(s)]$ is not rational, the left side of equation 36 is obtained by taking the inverse bilateral transform by complex inversion of the bracketed term and then performing a unilateral transformation of the resulting time function.

Implementation

The nature of the solution depends on whether the transfer functions $G(s)$ and $N(s)$ are minimum or nonminimum phase:

1. *Minimum phase.* From Appendix I:

$$I_{gg}(s)=G(-s)G(s) \tag{37A}$$

$$I_{gn}(s)=G(-s)N(s) \tag{37B}$$

Further:

$$\gamma^+(s)=G(s) \text{ and } \gamma^-(s)=G(-s) \tag{38}$$

and, since

$K_2N(s)v_1(s)$

has poles in the LHP only:

$$m(s)=-\frac{K_2}{K_1}\frac{N(s)}{G(s)}v_1(s) \tag{39}$$

A control system satisfying this relationship would be of the form shown in Fig. 5. Considering minimum phase elements, it is theoretically possible to achieve the ideal optimum by exact compensation in the variable m for a change in the variable v_1. This will maintain the deviation constant at the steady-state optimum value given by equation 33. In practice, however, exact compensation is not possible, due to saturation, inaccurate matching of parameters, etc. In addition, load variables, such as v_3 in Fig. 5 may exist which cannot be adequately compensated because of difficulties in measurement, etc. To take care of these imperfections and to provide the necessary bias for optimum steady-state operation, negative feedback is provided. In this particular example, the optimum deviation is a constant for the steady-state as well as the transient period, a result which perhaps could have been anticipated on the basis of steady-state relationships.

The purpose of the $G_1(s)$ function in Fig. 5 is to reduce the actuating signal $e(t)$ to zero, where

$$-e(t)=Q-q \tag{40}$$

This satisfies the optimizing condition

that the deviation remain constant and equal to Q. The design of $G_1(s)$ may then be reduced to the more or less standard problem of determining a configuration which will satisfy some prescribed error criterion.[5]

2. *Nonminimum phase.* If $G(s)$ or $N(s)$ is of the nonminimum phase type, the solution for the minimizing function will depend on the nature of the disturbance signal v_2. A particular example of interest is the presence of dead time in the control loop. Here, exact compensation is physically unrealizable; however, equation 36 may be solved for the best realizable compensation for a given disturbance function.

SYSTEM WITH TWO SECOND-ORDER NONLINEARITIES

Configuration

The development in the preceding section has severe limitations with regard to application to optimizing continuous processes because the configuration implies that the system is completely linear. The analysis is based on deviations from a steady-state operating point, which in conventional control problems permits the usual linearizing technique. This procedure of eliminating troublesome nonlinearities, however, defeats the purpose of optimizing control, and the case where nonlinearities appear in the process equations must be considered.

The example of the preceding section does provide some useful information with regard to the mathematical technique required, and the type of nonlinearities in the system equations which will permit an analytical solution by established mathematical procedures. The following approximations of the general system behavior is based on these observations.

The nonlinear process equations are first linearized in a conventional manner. Realizing the necessity for including the nonlinear gain characteristics, these are established and approximated by the first- and second-order terms in a power series expansion about the operating point. A mathematical model of the actual system is then constructed, as shown in Fig. 6. The model consists of an element containing the linearized dynamics with unity gain at zero frequency and a second element representing the approximated nonlinear gain in terms of deviations in the variables from a steady state:

$$m=Am_1^2+Bm_1 \tag{41}$$

where

m = manipulated variable
m_1 = a fictitious variable
A, B = known constants which in general depend on the operating point

Multiplying equation 41 by the factor C_1' will give the cost of the manipulated variable in terms of m_1. Substituting this in the cost equation 22, and rearranging to obtain the change in cost from the steady state gives

$$f(m_1, q)=C_1'(Am_1^2+Bm_1)+2C_2Qq+C_2q^2 \tag{42}$$

The constraint equations have been linearized at the expense of adding a second-order term to the cost equation, thus retaining the essential nonlinear gain characteristics. This is referred to here as a system with two second-order nonlinearities. The problem can be solved analytically for $m_1(t)$, which is substituted in equation 41 to obtain the manipulated variable $m(t)$.

To simplify the mathematical manipulations and to ease the interpretation of the final solution, the system configuration is changed to correspond to the process represented by Fig. 4, and having the following cost function (refer to equation 21):

$$\begin{aligned} f_1(\overline{m}, \bar{q})&=C_1\overline{m}^2+C_2\bar{q}^2\\ &=C+f(m, q) \end{aligned} \tag{43}$$

where

$$C=C_1M^2+C_2Q^2$$

$$f(m, q)=2C_1Mm+C_1m^2+2C_2Qq+C_2q^2 \tag{44}$$

Equation 44 contains the same terms as equation 42 and the procedure for obtaining a solution is identical.

Solution

Equations 23, 24, and 25 remain valid, and the optimizing conditions are obtained by use of equations 18 and 20:

$$\begin{aligned} F(t_1)={}&2C_1Mm(t_1)+C_1m^2(t_1)+2C_2Qq(t_1)+\\ &C_2q^2(t_1)+\mu_1(t_1)q(t_1)+\int dt\,\mu_1(t)\times\\ &[y_1(t_1)+y_2(t_1)]\delta(t-t_1)+\mu_2(t_1)y_1(t_1)-\\ &K_1\int dt\,\mu_2(t)m(t_1)g(t-t_1)+\mu_3(t_1)y_2(t_1)-\\ &K_2\int dt\,\mu_3(t)v_1(t_1)n(t-t_1) \end{aligned} \tag{45}$$

and for $t_1 \geq 0$

$$\frac{\partial F}{\partial q}=2C_2Q+2C_2q(t_1)+\mu_1(t_1)=0$$

$$\frac{\partial F}{\partial y_1}=\mu_2(t_1)+\mu_1(t_1)=0$$

$$\frac{\partial F}{\partial y_2}=\mu_3(t_1)+\mu_1(t_1)=0$$

$$\frac{\partial F}{\partial m}=2C_1M+2C_1m(t_1)-K_1\int dt\,\mu_2(t)g(t-t_1)=0 \tag{46}$$

which, combined with the constraint equations 24, reduces to

Fig. 6. Mathematical model of nonlinear process

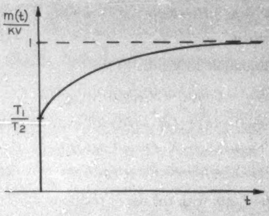

Fig. 7. Optimum response to step disturbance for system with two second-order nonlinearities

$$\begin{aligned} C_1M-C_2K_1Q\int dt\,g(t-t_1)+C_2K_1^2\int dt\times\\ g(t-t_1)\int dt_2m(t_2)g(t-t_2)+\\ C_2K_1K_2\int dt\,g(t-t_1)\int dt_2v_1(t_2)n(t-t_2)+\\ C_1m(t_1)=0 \text{ for } t_1\geq 0 \end{aligned} \tag{47}$$

Interchanging the order of integration and introducing translation function notation, obtains the following nonhomogenous Wiener-Hopf integral equation of the second kind:

$$\begin{aligned} C_1M-C_2K_1Q\int dt\,g(t-t_1)+C_2K_1^2\int dt_2m(t_2)\times\\ I_{gg}(t_1-t_2)+C_2K_1K_2\int dt_2v_1(t_2)I_{gn}(t_1-t_2)\\ +C_1m(t_1)=0 \text{ for } t_1\geq 0 \end{aligned} \tag{48}$$

The method of solution outlined in reference 7 is extended to include integral equations of the second kind as follows (a more extensive account is given in reference 9): the bilateral Laplace transform of equation 48 is

$$\begin{aligned} [C_1M-C_2K_1QG(-s)]2\pi\delta(js)+\\ [C_2K_1^2I_{gg}(s)+C_1]m(s)+\\ C_2K_1K_2v_1(s)I_{gn}(s)=A(s) \end{aligned} \tag{49}$$

Optimum steady-state relationships derived in Appendix II show that

$$C_1M=C_2K_1Q \tag{49A}$$

Then, in view of relation 32B, the first term of equation 49 vanishes identically. By factorization

$$[C_2K_1^2I_{gg}(s)+C_1]=\gamma^+(s)\gamma^-(s) \tag{50}$$

The solution is obtained as before:

$$m(s)\gamma^+(s)=-\left[\frac{C_2K_1K_2v_1(s)I_{gn}(s)}{\gamma^-(s)}\right]_+ \tag{51}$$

In this case no simplification of the solution formula for minimum phase elements is possible since $\gamma^-(s)\neq G(-s)$. In general, the solution depends on the nature of the disturbance (v_1).

One particular solution is derived in Appendix III for the simple case where

Vol.
Pt. 1
196

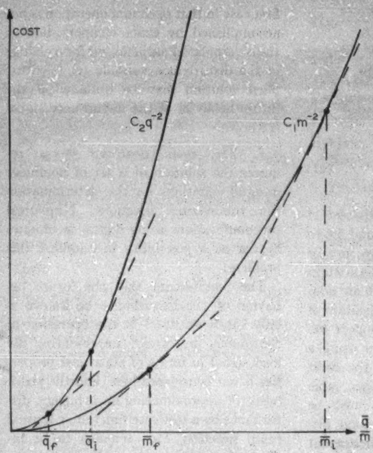

Fig. 8 (left). Cost relationship for system with two second-order nonlinearities

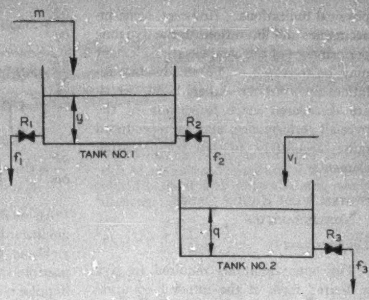

Fig. 10 (right). Hydraulic analog of system with higher-order nonlinearities

$$G(s)=N(s)=\frac{1}{1+Ts} \tag{52}$$

and

$$v_1(s)=V/s \tag{53}$$

Here T is the time constant of the first order elements and V is the magnitude of the step disturbance. Then

$$m(s)=-K\frac{1+T_1s}{1+T_2s}v_1(s) \tag{54}$$

where $T_2>T_1$ and K, T_1 and T_2 are known constants determined by the values of system gains (K_1 and K_2) and cost coefficients (C_1 and C_2).

The corresponding time function is

$$m(t)=-KV\left[\left(\frac{T_1}{T_2}-1\right)\epsilon^{-t/T_2}+1\right] \tag{55}$$

which is plotted in Fig. 7.

To evaluate this solution, the steady-state cost characteristics (see equation 43) are displayed in Fig. 8. In any one optimum steady state the corresponding values of the manipulated variable ($\bar{m}$) and the quality ($\bar{q}$) are located on the cost curves of Fig. 8 in such a manner that the incremental costs, identified by the slope of each curve, are the same. When the process is subjected to a step change in the disturbance variable (see equation 53) the initial and final optimum steady-state values for the variables ($\bar{m}$), and ($\bar{q}$) are given in Fig. 8 by ($\bar{m}_i$, $\bar{q}_i$) and ($\bar{m}_f$, $\bar{q}_f$) respectively. The optimum path between these steady states may be explained qualitatively as follows: Assume that $\bar{m}(t)$ is changed directly to the final value in the form of a step change. As a result, $\bar{q}(t)$ is reduced exponentially to the new steady state, and from Fig. 8 it is observed that the incremental cost of $\bar{q}(t)$ is higher than that of $\bar{m}(t)$ at all times during the transient. Thus, it is clear that an increased rate of reduction in $\bar{q}(t)$ at the expense of a slower reduction in $\bar{m}(t)$ will improve the transient performance from the standpoint of minimum cost. This agrees with the analytical solution for $\bar{m}(t)$ given by equation 55 and shown in Fig. 7.

Implementation

The analytical solution for the optimizing function using system configurations stipulated in this section is limited by the requirement that the disturbances be known. A control system for a process where the disturbance (v_1) enters the system in discrete steps, and otherwise performs according to equation 23, would be of the form shown in Fig. 9. Negative feedback is provided in order to maintain desired operating conditions in spite of extraneous load disturbances (such as v_2) which cannot be accounted for because of difficulties in measurement, etc. The desired value of the variable q is computed (see equation 76) in Appendix III on the basis of the essential disturbance (v_1). Any deviation (e) from this value during the course of operation is reduced to zero by the action of the controller element $G_1(s)$.

Since all relationships of Fig. 9 are linear, the principle of superposition is valid, and the solution as given by equation 54 can be applied to step disturbances taking place under nonsteady-state conditions. This may be extended to the system of Fig. 6 if the coefficients K, T_1, and T_2 in the solution formula 54 are adjusted to correspond to the level of operation at at which the disturbance takes place. The extent of the approximation involved depends largely on the procedure for adjusting the coefficients.

The matching of an actual compensating element to a given transfer function has

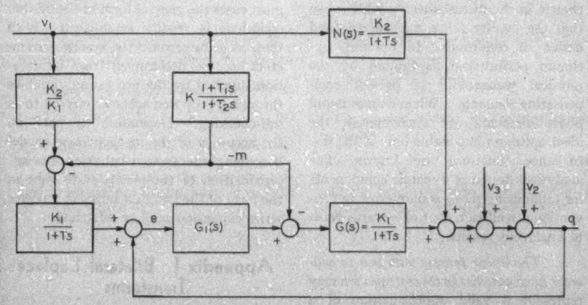

Fig. 9. Optimum control of system with two second-order nonlinearities subjected to step disturbances

physical limitations. However, some inaccuracies and limitations in the dynamic performance of the compensating element may be tolerated. The steady-state relationships on the other hand, which are considered more important in the over-all performance, may be reproduced quite accurately in the compensating elements.

SYSTEM WITH HIGHER-ORDER NONLINEARITIES

Configuration

The approximations required to give a desired form of the integral equation for analytical solution, as outlined in the preceding section, may not be feasible in certain cases.

In order to investigate the possibility of using the general nonlinear equations 8, a hypothetical process in the form of a hydraulic analog, shown in Fig. 10, is considered. The system is assumed to be completely linear except for a nonlinear resistance (R_2). The head-flow relationships are

$$f_1=y/R_1;\ f_2=\sqrt{y}/R_2;\ f_3=q/R_3 \qquad (56)$$

where f_1, f_2, f_3, y, and q are variables identified by Fig. 10, and R_1, R_2, and R_3 constants.

Then the constraint equations expressed in terms of the total value of the variables, are

$$E_1\frac{dy}{dt}+\frac{y}{R_1}=m-\frac{\sqrt{y}}{R_2}$$

$$E_2\frac{dq}{dt}+\frac{q}{R_3}=v_1+\frac{\sqrt{y}}{R_3} \qquad (57)$$

where E_1 and E_2 are the capacitances of tanks number 1 and 2 respectively.

In integral equation form, the constraints are (setting all constants equal to unity for convenience)

$$y-\int(m-\sqrt{y})g_1(t-t_1)dt_1=0$$
$$q-\int(v_1+\sqrt{y})g_2(t-t_1)dt_1=0 \qquad (58)$$

where $g_1(t)=g_2(t)=\mathfrak{L}^{-1}\,1/(s+1)$.

The cost function is the same as before:

$$f(m,\, q)=C_1m+C_2q^2 \qquad (59)$$

Possible Solution and Implementation

The necessary conditions for the optimizing function are obtained by equations 18 and 20:

$$\begin{aligned}F(t_1)=C_1m(t_1)+C_2q^2(t_1)+\mu_1(t_1)q(t_1)-\\ \int dt\ \mu_1(t)[v_1(t_1)+\sqrt{y(t_1)}]g_2(t-t_1)+\\ \mu_2(t_1)y(t_1)-\int dt\mu_2(t)[m(t_1)-\\ \sqrt{y(t_1)}]g_1(t-t_1)\end{aligned} \qquad (60)$$

and, for $t_1\geq 0$:

$$\frac{\partial F}{\partial q}=2C_2q(t_1)+\mu_1(t_1)=0$$

$$\frac{\partial F}{\partial y}=\mu_2(t_1)+\frac{1}{2}\int dt\,\frac{\mu_2(t)}{\sqrt{y(t_1)}}\,g_1(t-t_1)-\frac{1}{2}\int dt\,\frac{\mu_1(t)}{\sqrt{y(t_1)}}\,g_2(t-t_1)=0$$

$$\frac{\partial F}{\partial m}=C_1-\int dt\mu_2(t)g_1(t-t_1)=0 \qquad (61)$$

An analytical treatment of the set of nonlinear integral equations 61 and 58, to yield an explicit solution, may not be possible. Because the equations contain impulse response functions which are nonzero for negative time, the application of analog computer techniques appear remote, and a numerical solution using a digital computer seems to be the most promising possibility. The proper value of the manipulated variable must be available immediately upon a load disturbance, which requires a certain amount of precomputation of the response function for typical conditions. It appears that the feasibility of this procedure willl depend in particular on the type of disturbances encountered.

Conclusions

The problem of dynamic optimizing control of the continuous process is formulated and treated in considerable generality. The necessary conditions for optimum performance are derived and applied to system configurations of increasing degrees of complexity. The results may be summarized as follows:

1. *The linear process with one second-order nonlinearity in the cost equation*, and identified by minimum phase transfer functions, theoretically has no limitations in achieving the ideal optimum. The solution calls for a perfect compensation in the manipulated variable (m) for a change in the disturbance variable (v) so that the quality (q) is maintained fixed under all conditions. In practice, optimum performance is limited by the physical realizability of perfect compensating elements. When nonminimum phase elements are encountered, the ideal optimum is possible only if the disturbance functions are known. The analytical design of dynamic components for minimizing mean square error in conventional feedback control systems leads to analogous results.

2. *The linear process with two second-order nonlinearities in the cost equation* may represent a valid approximation of a general nonlinear configuration. The results are significantly different from the first case in that optimum operation is not accomplished by exact compensation in the manipulated variable (m) for a change in the disturbance variable (v). An explicit solution may be obtained if the future behavior of the disturbance signal is known.

3. *The general nonlinear process* requires the solution of a set of nonlinear integral equations for the determination the minimizing functions. Numerical precomputations using digital techniques appear as a possibility in handling this problem.

The requirement that the future behavior of the disturbance be known is only rarely satisfied in the operation of continuous processes. Representing the load signal in terms of statistical properties is not considered here, and the possibility of approximating an arbitrary disturbance by a staircase function, a limited ramp function, etc., remains to be investigated. In any case, the implication is that the ideal optimum cannot in general be achieved. However, proper design of compensating elements (or equivalent computer actions) based on typical load signals and operated on by the actual random disturbance to obtain the manipulated variable, will enable the system to seek an optimum steady state under any condition. Further, the transient performance is likely to be close to optimum for disturbances that do not deviate greatly from the design signal. Thus, continuous automatic adjustments toward an optimum combination of variables at any level of operation, and regardless of the magnitude of load fluctuations, appear possible. This means, of course, that conventional equipment for minimizing the effects of large load changes, such as storage tanks, surge vessels, etc., may be eliminated.

The technique developed here assumes that the system behavior is known. In most cases the general form of the system equations is readily established. With these as a framework, the system parameters may be determined from information supplied by the processing variables through a proposed scheme referred to as self-checking.[1] Depending in part on the accuracy of the mathematical model describing the system behavior, the approximation of the steady-state gain in the form of the two first terms in a power series expansion may be adequate.

Appendix I. Bilateral Laplace Transforms

The following particular transforms are used:

(a)

$$\overline{\mathfrak{L}}\int_{-\infty}^{\infty} dt\, g(t-t_1)=I_{g1}(s)=2\pi\delta(js)G(-s) \qquad (32\text{A})$$

which is obtained as follows, starting with the definition

$$I_{g1}(s)=\int_{-\infty}^{\infty} dt_1\, \epsilon^{-st_1}\int_{-\infty}^{\infty} dt\, g(t-t_1) \qquad (62)$$

Interchanging the order of integration and introducing the variable gives

$$t_2=t-t_1 \qquad (63)$$

Then,

$$I_{g1}(s)=\int dt\, \epsilon^{-st}\int dt_2\, \epsilon^{st_2}g(t_2) \qquad (64)$$

(Where the limits of integration, if not otherwise designated, are from minus to plus infinity) and equation 32(A) follows, since

$$\int dt\epsilon^{-st}=\overline{\mathfrak{L}}(1)=2\pi\delta(js) \qquad (65)$$

by reference 8.

(b)

$$\overline{\mathfrak{L}}[I_{gg}(w)]=I_{gg}(s)=G(-s)G(s) \qquad (37\text{A})$$

which is derived as follows:

$$I_{gg}(s)=\int dw\, \epsilon^{-sw}\int dt\, g(t)g(t+w) \qquad (66)$$

Interchanging the order of integration and introducing:

$$w_1=t+w \qquad (67)$$

Then,

$$I_{gg}(s)=\int dt\, g(t)\epsilon^{st}\int dw_1 g(w_1)\epsilon^{-sw_1} \qquad (68)$$

and equation 37(A) follows immediately

(c)

$$\overline{\mathfrak{L}}[I_{gn}(w)]=I_{gn}(s)=G(-s)N(s) \qquad (37\text{B})$$

This is obtained by the same procedure used for transform equation 37(A).

Appendix II. Derivation of Steady-State Optimum

System With One Second-Order Nonlinearity

From relationships 22, the steady-state cost rate is

$$C=C_1M+C_2Q^2 \qquad (69)$$

where the variables are defined according to equation 4.

The steady-state relationship (see Fig. 4)

$$Q=V_2-K_1M-K_2V_1 \qquad (70)$$

is substituted in equation 69, and the condition for minimum steady-state cost is obtained by differentiating the resulting equation with respect to the manipulated variable M. This yields:

$$M=\frac{V_2-K_2V_1}{K_1}-\frac{C_1}{2C_2K_1^2} \qquad (71)$$

and

$$Q=\frac{C_1}{2C_2K_1} \qquad (33)$$

System With Two Second-Order Nonlinearities

The steady-state cost rate is

$$C=C_1M^2+C_2Q^2 \qquad (44)$$

Substituting for Q from equation 70 and differentiating the cost rate equation 44 with respect to M, yield the following conditions:

$$M=\frac{C_2K_1}{C_1+C_2K_1^2}\,(V_2-K_2V_1) \qquad (72)$$

and

$$C_1M=C_2K_1Q \qquad (49\text{A})$$

Appendix III. Derivation of the Explicit Solution for a Particular System Configuration

The dynamics of a system with two second-order nonlinearities are given by the transfer functions (see Fig. 4)

$$G(s)=N(s)=\frac{1}{1+Ts} \qquad (52)$$

Then, from Appendix I

$$I_{gg}(s)=I_{gn}(s)=G(-s)G(s)=\frac{1}{(1+Ts)(1-Ts)} \qquad (73)$$

and equation 50 becomes

$$\frac{C_2K_1^2}{(1+Ts)(1-Ts)}+C_1=\gamma^+(s)\gamma^-(s) \qquad (74)$$

where

$$\gamma^+(s)=\sqrt{C_1}\,\frac{b+s}{a+s}$$

$$\gamma^-(s)=\sqrt{C_1}\,\frac{b-s}{a-s}$$

$$a=\frac{1}{T}$$

$$b=\frac{1}{T}\sqrt{\frac{C_2K_1^2+C_1}{C_1}}$$

For a step change in the disturbance variable

$$v_1(s)=V/s \qquad (53)$$

and the bracketed term of equation 51 is expanded in partial fractions as follows:

$$\frac{I_{gn}(s)v_1(s)}{\gamma^-(s)}=\frac{V}{T^2\sqrt{C_1}}\,\frac{1}{s(a+s)(b-s)}=\frac{V}{T^2\sqrt{C_1}}\left[\frac{1/ab}{s}-\frac{1/a(a+b)}{a+s}+\frac{1/b(a+b)}{b-s}\right] \qquad (75)$$

Eliminating the term with the RHP pole from equation 75 and substituting in equation 51 obtains the transform of the manipulated variable with some algebraic manipulations:

$$m(s)=-K\,\frac{1+T_1s}{1+T_2s}\,\frac{V}{s} \qquad (54)$$

where

$$K=\frac{K_1K_2C_2}{C_1+C_2K_1^2}; \qquad T_1=\frac{T}{1+\sqrt{1+\dfrac{K_1^2C_2}{C_1}}}$$

$$\frac{V}{s}=v_1(s); \qquad T_2=\frac{T}{\sqrt{1+\dfrac{K_1^2C_2}{C_1}}}$$

Inverse transformation of equation 54 yields the minimizing function in the time domain:

$$m(t)=-KV\left[\left(\frac{T_1}{T_2}-1\right)\epsilon^{-t/T_2}+1\right] \qquad (55)$$

where ϵ is the base of the natural logarithms.

The corresponding transform of the variable q is readily obtained (see Fig. 4):

$$q(s)=-[K_2N(s)v_1(s)+K_1G(s)m(s)]=-\left[\frac{K_1}{1+Ts}\right]\left[\frac{K_2}{K_1}v_1(s)+m(s)\right] \qquad (76)$$

A Method for the Design of Holding Electromagnets

J. T. LUDWIG
ASSOCIATE MEMBER AIEE

THE PROBLEM discussed is the optimum design of cylindrical holding electromagnets consisting of a ferromagnetic core, with stationary and movable portions, interlinking a coil of wire. These electromagnets are required to hold a switch or contact assembly in a given position as long as power is applied and to release it when power is removed. The electromagnet is not required to pull in the contact assembly; this is done by other means. It is desirable for the design method to proceed from the specified mechanical and electrical characteristics directly to the physical dimensions of the magnet without the use of trial-and-error methods.

The principal books on the subject are by Roters,[1] and Peek and Wagar.[2] Both treat the general problem of tractive magnet design from the trial-and-error analysis viewpoint. Here, the design of a holding electromagnet will be treated directly as a synthesis problem. The fundamental equations are used as a theoretical foundation for a straightforward design method.

A typical engineering design problem involves several conflicting factors, and its solution is usually a compromise between these conflicting factors. The usual method of attack on this type of problem is a trial-and-error approach. Certain aspects of the problem are guessed, estimated, or assumed; other aspects are sometimes calculated from these. This first trial solution is then analyzed by mathematical computation or by model measurement. If it does not meet the specifications, one or more of the assumed aspects are adjusted and the process is repeated until the specifications are met.

In some cases, this trial-and-error method is the only method of attack; but it is often used as an inferior substitute for more direct methods. The trial-and-error method usually wastes more engineering time and still does not lead to a design in which technically unspecified factors such as cost, size, weight, etc., are optimized.

When materials having nonlinear characteristics are involved, the direct design methods often make use of derived material characteristics. These are mathematical combinations of the traditionally measured fundamental characteristics. This approach has been used to relate the magnetic characteristics of core materials to their use in the magnetic circuits of inductors.[3–5] It is used here in the study of holding electromagnets.

Analysis, as distinguished from synthesis, is a calculation of the performance of a device when its physical dimensions are known. Synthesis, on the other hand, is the process of design and calculation of the physical dimensions of the inductor when its required performance is known. Analysis generally gives a unique solution. For a given operating point, a given device has a certain performance. Synthesis does not usually give a unique solution because an insufficient number of properties are specified. A large number of designs may meet a typical set of requirements. However, if the set of requirements is sufficiently complete, this large number will be reduced. The number of suitable designs will usually be reduced to one by an additional requirement to synthesize the smallest, the lightest, or the cheapest device meeting the other requirements.

Both calculations are useful in the design process since analysis is usually used as a check on the synthetic design. In this discussion, analysis will be presented first, and then synthesis.

The Basic Equations

The basic magnetic circuit under consideration is shown in Fig. 1. The hole in the center is provided for parts of the complete device. It is assumed that the iron cross-sectional area is everywhere constant. This would ideally require hyperbolic sections on the ends, but practical deviations from the ideal case probably do not introduce much error. For the cylindrical portions:

$$a_i = \pi(r_2^2 - r_1^2) \tag{1}$$

$$a_i = \pi(r_4^2 - r_3^2) \tag{2}$$

where a_i is the iron area in square centimeters, and r's are the radii shown in Fig. 1.

It should be noted that a mixed system of units is being used. All the magnetic and geometric units are in the centimeter-gram-second system while the electrical units are in the meter-kilogram-second practical system. This mixed system of units is used since, in U.S. practice, nearly all electrical specifications are in meter-kilogram-second units and nearly all magnetic material data are in centimeter-gram-second electromagnetic units.

The effective iron length is given by

$$l_i = 2c_1 t - r_1 - r_2 + r_3 + r_4 \tag{3}$$

where

l_i = effective iron length

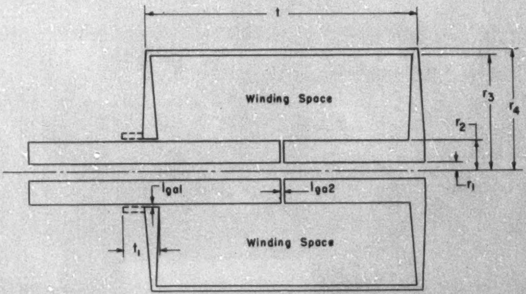

Fig. 1. Basic magnetic circuit

Paper 60-197, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted October 29, 1959; made available for printing December 11, 1959.

J. T. Ludwig is with Electronic Communications, Inc., St. Petersburg, Fla.

The author wishes to acknowledge the help of Prof. N. Paul Stucky, Kansas Wesleyan University, Salina, Kans., and Dr. Ennis E. Jones, Minneapolis-Honeywell Regulator Company, Minneapolis, Minn., who processed the data in the production of the charts.

c_1 = dimensionless geometrical constant determined by the end section shape
l = physical length shown in Fig. 1 in centimeters

The total effective air gap length, ℓ_g, is the sum of the effective lengths of the annular gap around the plunger and the plane gap at the plunger end. The gap lengths considered here are only those in the closed position of the plunger, because the hold-in force depends only on the closed magnetic circuit conditions.

The effective length of the air gaps is shortened slightly by the fringing flux. The effective length of the annular gap may be shortened still more by providing greater magnetic area at the annular gap face. In both these situations, the effective gap length may be determined by calculating the gap reluctance and multiplying it by iron area, a_i. For the annular gap in Fig. 1, the effective gap length ℓ_{g1} is

$$\ell_{g1}=\ell_{ga1}\frac{a_i}{2r_2(\ell_{ga1}+l_1)} \tag{4}$$

where

ℓ_{g1} = effective length of gap 1
ℓ_{ga1} = actual length of gap 1
a_i = iron area in sq cm (square centimeters) of the core circuit, not the increased area of the air gap face, if any
r_2 = gap radius in cm
l_1 = gap width in cm

The plane plunger gap has an effective length of

$$\ell_{g2}=\ell_{ga2}\frac{a_i}{\pi\left[\left(r_2+\frac{\ell_{ga2}}{2}\right)^2-\left(r_1-\frac{\ell_{ga2}}{2}\right)^2\right]} \tag{5}$$

when

$$\frac{\ell_{ga2}}{2}\leqq r_1 \tag{6}$$

and

$$\ell_{g2}=\ell_{ga2}\frac{a_i}{\pi\left(r_2+\frac{\ell_{ga2}}{2}\right)^2} \tag{7}$$

when

$$r_1\leqq\frac{\ell_{ga2}}{2} \tag{8}$$

where

ℓ_{g2} = effective length of gap 2
ℓ_{ga2} = actual length of gap 2

These effective gap length equations are equivalent to assuming a band of fringing induction half a gap length wide outside the gap with the same induction as inside the gap. The total effective gap length is the sum of the individual gap lengths and is frequently conveniently expressed by a relative measure α defined by

$$\alpha=\frac{\ell_g}{l_i} \tag{9}$$

For the winding, the net copper area is

$$a_c=F_c c_2(r_3-r_2)l \tag{10}$$

where

a_c = net copper area in sq cm
F_c = space factor of the winding
c_2 = dimensionless geometrical constant determined by the end section shape

The mean length of turn (MLT) is

$$l_c=c_3\pi(r_2+r_3) \tag{11}$$

where

l_c = MLT in cm
c_3 = dimensionless geometrical constant determined by the end section shape

The outside surface area, through which the generated heat is transferred, is

$$a_s=2\pi(r_4^2+r_4 l) \tag{12}$$

where a_s is the surface area in sq cm

ELECTRICAL RELATIONS

If this core has a coil of N turns, the resistance of the mean turn is

$$R_t=\rho l_c N/a_c \tag{13}$$

where

R_t = resistance of the mean turn in ohms
ρ = resistivity of the winding conductor in ohm-cm
N = number of turns

The total copper resistance is then

$$R_c=\rho l_c N^2/a_c \tag{14}$$

where R_c is the total winding resistance in ohms.

If a direct voltage E is impressed on this coil, the steady-state current is given by Ohm's law,

$$I=E/R_c \tag{15}$$

where

I = current in amperes
E = direct voltage in volts

THERMAL RELATIONS

The heat generated in the winding is

$$W_c=I^2R_c \tag{16}$$

where W_c is the heat generated in watts. This heat must all be transferred through the outside surface so the heat power density is

$$K_c=W_c/a_s=I^2R_c/a_s \tag{17}$$

where K_c is the heat power density in watts per sq cm due to copper loss. Substituting in R_c from equation 14 gives

$$K_c=\frac{\rho l_c N^2 I^2}{a_c a_s} \tag{18}$$

MAGNETIC RELATIONS

The magnetic equations introduce another degree of complexity into the problem because of the nonlinear magnetic characteristics of the core material.

The force acting on the plunger in its closed position is

$$F=\frac{B^2a_i}{8\pi} \tag{19}$$

where

F = force in dynes
B = induction in gausses

This equation assumes negligible fringing of flux in the gap as would be the case when the core is closed and there is only a small gap between the plunger face and the stationary core face.

Also needed is the relationship giving induction B in terms of the current I and the physical dimensions of the electromagnet. The magnetic properties of materials are normally expressed in terms of the relationship between the induction B and the magnetizing force H.

In the air gap portions of the circuit B and H are equal. In the iron, the BH relationship is very complicated. It is neither linear nor single-valued. It depends on past history, and it is this complicated relationship that makes the design of magnetic circuits a difficult and esoteric art. Most magnetic characteristic curves represent some part of the

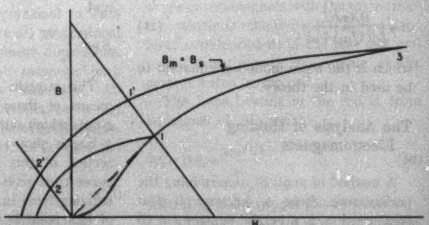

Fig. 2. Hysteresis loops and general air gap line analysis

BH function taken under particular conditions.

The most commonly available characteristic is the normal induction curve and, associated with it, the normal permeability. The normal induction curve is the locus of the tips of all symmetrical hysteresis loops, and Fig. 2 shows two of the symmetrical hysteresis loops that determine it. The co-ordinates of any point on the normal induction curve are then the maximum values of induction B_{mi} and magnetizing force H_{mi} for some symmetrical loop.

The normal permeability, μ_i, for any point on the normal induction curve is defined by

$$\mu_i = B_{mi}/H_{mi} \tag{20}$$

where

μ_i = normal permeability at the point in question

B_{mi} = induction in gausses at the point in question

H_{mi} = magnetizing force in oersteds at the point in question

This normal permeability is not a constant, but a variable; and it may be treated as a function of either B_{mi} or H_{mi}. Either the direct relationship of B_{mi} to H_{mi} or their ratio, μ_i, will be used in steps of the theory as convenient.

So far, only symmetrical (maximum and minimum values equal negatives of each other) magnetizations have been considered. When unsymmetrical magnetizations are allowed, another degree of freedom is added to the system. Ideally, data on a large group of minor loops would facilitate accurate analysis and synthesis. Often such complete data is not available; but some information can be gleaned from the fact that the tip of a minor loop farther from the origin lies on the normal induction curve.[6–9]

Referring to the magnetic circuit of Fig. 1, the cross-sectional iron area, a_i is essentially uniform around the circuit. Since the flux is continuous, the induction (flux density) is uniform around the circuit. For such a circuit

$$B = \frac{0.4\pi NI}{\ell_i[(1/\mu_i)+\alpha]} \tag{21}$$

which is the basic induction equation to be used in the theory.

The Analysis of Holding Electromagnets

A method of analysis, determining the performance from a known physical configuration, is a helpful supplement to the design procedure in providing a check on designs and in evaluating the effect of changes of the various physical dimensions.

The analysis problem is to answer the question: Given a device and its specified operating conditions, what is its performance or output?

In this case, the device is a holding electromagnet of known dimensions including core and coil. The operating conditions are the input voltage, current, and ambient temperature. The performance or output is the hold-in force when the coil is energized and the drop-out force due to residual induction which tends to hold the plunger in after the coil is de-energized.

The thermal aspects of the problem—calculating hot spot and mean temperature—are not detailed in this report, but reference is made to other literature on coil design.[10]

In analyzing a holding electromagnet, the first step is determining the current which flows through the coil. Depending on the external circuitry, the current, *I*, may or may not be influenced appreciably by the coil resistance. In the usual case of constant voltage power supply, the current is determined solely by the coil resistance, which must first be calculated for the operating temperatures by the usual methods. The current can then be obtained by Ohm's law, equation 15.

Karapetoff[11] described a method for finding the induction in a uniform magnetic circuit with air gaps when a known d-c magnetomotive force is applied. First, it is assumed that the relation between *B* and *H* in the iron is known and plotted as in Fig. 2. If the circuit is magnetized by a magnetomotive force, $0.4\pi NI$, the magnetomotive force equation is

$$0.4\pi NI = H\ell_i + B\ell_g \tag{22}$$

This is the equation of a straight line on the *BH* plane having intercepts

$$H = \frac{0.4\pi NI}{\ell_i} \tag{23}$$

and

$$B = \frac{0.4\pi NI}{\ell_g} \tag{24}$$

This straight line may be plotted by means of these intercepts or any two points which satisfy equation 22. Such a line is shown in Fig. 2. The intersection of this line with the iron *BH* curve then gives the induction and magnetizing force in the iron. The *B* value of this point is the induction and magnetizing force in the air gap.

To find the hold-in force, this method is applied to the normal induction curve, and the resulting induction *B* value is used in equation 19 to calculate the hold-in force.

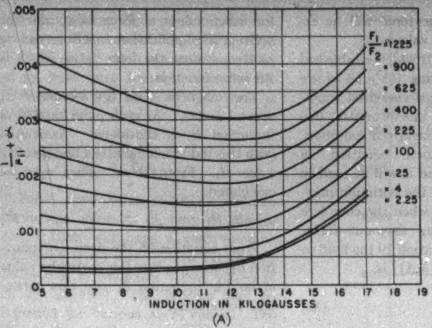
To find the drop-out force which tends to keep the plunger held in after the coil is de-energized, the appropriate descending branch of the *BH* characteristic must be used. Fig. 2 shows the Karapetoff line construction with the descending sides of two hysteresis loops as well. When the coil current is interrupted, the air-gap line moves to the left parallel to itself until it passes through the origin. Such a line is shown in Fig. 2. The induction is now that represented by the intersection of this second air-gap line with the appropriate descending *BH* curve. If the core had been magnetized to the value shown by the intersection with the first air-gap line at point 1, the de-energized induction would be that at point 2. One other possibility exists, however.

Sometime while the coil was energized, a voltage increase drove the air-gap line up to a higher value and the induction was that represented by point 3. When the voltage returned to normal, the operating point followed the saturated descending branch to point 1′. The induction is that represented by point 1′. When the coil is de-energized, the induction is that represented by 2′. If the latter value of induction is used in equation 19 to calculate drop-out force, the answer will be a maximum value of drop-out force. The actual operating value will always be equal to or less than this value since no possible magnetic history can arrive at an operating point above the descending branch of the saturated hysteresis loop. The de-energized operating point would lie on the line between 2 and 2′ for intermediate overvoltage occurrences.

It should also be noted that these drop-out induction values are only limits approached by the induction when the plunger remains closed. In an actual device, the restoring spring starts moving the plunger and opening the air gap when the induction force drops to the spring force value. On the air-gap line diagram, this is equivalent to rotating the air-gap line through the origin counterclockwise, which reduces the induction even lower.

Synthesis of Holding Electromagnets

The fundamental or traditionally measured characteristics of materials are not always in the most useful form for synthesis. This is particularly true when the



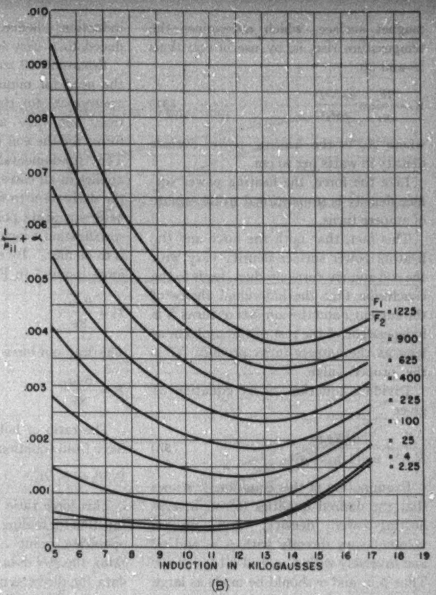


Fig. 3. Effective reluctivity curves for annealed Swedish charcoal iron

A—With no saturation (overvoltage) protection

B—With saturation (overvoltage) protection

characteristics are extremely nonlinear as in the case of ferromagnetics. An index function to guide the designer to the optimum operating point may be derived from the fundamental characteristics. Other application functions having unique values for each materials operating point may also be derived. If a graph is now constructed with the index function as the abscissa and the application functions as ordinates, the synthesis process becomes direct and straightforward. From the specifications, the index is calculated, the corresponding application functions are read from the graphs, and the physical dimensions are calculated.

This general approach requires that the index functions be matched only to specified quantities and not quantities which the designer sets out to determine. In other words, the synthesis process for the optimum holding electromagnet should not require the use of the core size in the calculations to find the core size.

The application functions are defined in a manner that makes the subsequent calculations as simple as possible.

When a holding electromagnet is to be designed, the following items will be known from the other considerations of the system:

Operating voltage
Ambient temperature
Allowable temperature rise
Duty cycle
Hold-in force
Drop-out force
Central hole size

The thermal problems may be treated separately to obtain a value of heating-power surface density through the outside surface of the magnet. This problem is discussed in other literature.[10]

In the mathematical formulation of the problem, it is possible and convenient to separate the determination of the optimum magnetic operating point and the determination of geometry (size and shape). The theory of the optimum magnetic operating point will be presented first and then the theory of the geometry will follow.

Optimum Magnetic Operating Point Effective Reluctivity: Optimum Size Criterion

The optimum magnetic operating point can be found by considering a holding electromagnet of fixed shape and finding the operating point which results in the smallest size. This operating point is independent of the shape. In the synthesis process, the optimum operating point is first determined, and then the size and shape are determined.

Consider the general geometry shown in Fig. 1. For a fixed shape, the linear dimensions are all proportional to each other, and the areas are all proportional to the squares of the linear dimensions. In this case, the mean magnetic path length is the reference dimension. All other lengths are proportional to it, and all surfaces are proportional to its square. If the mean iron length is ℓ_i, then the mean length of turn

$$\ell_c = u\ell_i \tag{25}$$

The net copper cross-sectional area,

$$a_c = v\ell_i^2 \tag{26}$$

The net iron cross-sectional area,

$$a_i = w\ell_i^2 \tag{27}$$

The total surface area for heat transmission,

$$a_s = p\ell_i^2 \tag{28}$$

The numbers, u, v, w, and p describe the shape while ℓ_i describes the size of the magnet. It should be noted that the number v includes the effect of coil space factor.

If the values of induction B from equation 21 and area a_i from equation 27 are inserted into force equation 19,

$$F = \frac{0.02\pi w N^2 I^2}{[(1/\mu_i)+\alpha]^2} \tag{29}$$

This equation shows that, for fixed shape electromagnets with the same effective magnetic reluctivity $[(1/\mu_i)+\alpha]$, the force is independent of the core size and varies directly with the square of the ampere turns in the coil.

The Joule heating in the coil is, from equations 14, 25, and 26,

$$W_c = I^2R_c = \frac{u\rho N^2 I^2}{v\ell_i} \tag{30}$$

where W_c is the copper loss in watts.

The density of heat flow through the

magnet surface, which determines the temperature rise, is, by use of equations 28 and 30,

$$K_c=\frac{W_c}{a_s}=\frac{u\rho N^2I^2}{pv\ell_i^3} \qquad (31)$$

where K_c is the heating power surface density in watts per sq cm.

Like the force, the heating power surface density is proportional to the square of ampere turns.

This fact, that both the force and the heating power surface density vary with the coil ampere-turns product, leads to the conclusion that the individual choice of the current I and the number of turns N is independent of the rest of the problem as long as the ampere-turns product NI is the proper value.

Dividing equation 29 by equation 31 gives

$$\frac{F}{K_c\ell_i^3}+\frac{0.02pvw}{u\rho[(1/\mu_i)+\alpha]^2} \qquad (32)$$

Examination of this equation 32 shows that the desired qualities (force, inverse heating-power density, and inverse volume) vary directly with p, v, and w; and inversely with u, ρ, and $[(1/\mu_i)+\alpha]^2$. Thus p, v, and w should be made as large as possible; u, ρ, and $[(1/\mu_i)+\alpha]$ should be made as small as possible. For a fixed shape electromagnet with a given surface area treatment, with or without fins, and with a given conductor material, the only quantity to be optimized is $[(1/\mu_i)+\alpha]$, the reluctivity, which is to be made as small as possible.

DETERMINATION OF EFFECTIVE RELUCTIVITY: GENERAL CASE

The quantity $[(1/\mu_i)+\alpha]$ requires detailed consideration. If the hold-in force (coil energized) were the only criterion, the best design would be that with minimum air gap α and the value of induction that gives maximum permeability μ_i. The hold-in force is not the only specification, however. The drop-out force when the coil is de-energized is also specified. It must not exceed some given value, in order that the return (spring) mechanism can function. The residual induction in the iron tends to maintain this force when the coil is de-energized. The air gap reduces this drop-out force.

The problem is then that of minimizing $[(1/\mu_i)+\alpha]$ subject to the constraint that the drop-out force (coil de-energized) be at or below some specified value. In actual operation, this value of drop-out force will not exist for more than an instant because the restoring spring will act before this force is reached, and the motion of the plunger will quickly reduce the induction; hence, the force will be reduced to a very low value.

Equations 29 and 32 which established the need for minimizing $[(1/\mu_i)+\alpha]$ are appropriate for the coil energized condition, but they are indeterminate 0/0 forms for the coil de-energized condition. The fundamental force equation 19 applies in all cases, and it will be used in the derivation to find the optimum magnetic operating point when the complete specification, including drop-out force, is to be met. By equation 19 the hold-in force [point 1 in Fig. 3(A)] is

$$F_1=\frac{B_1^2a_i}{8\pi} \qquad (33)$$

The drop-out force [point 2 in Fig. 3(A)] is

$$F_2=\frac{B_2^2a_i}{8\pi} \qquad (34)$$

The ratio of hold-in force to drop-out force from equations 33 and 34 is

$$F_1/F_2=(B_1/B_2)^2 \qquad (35)$$

This force ratio will become the index function for finding the optimum magnetic operating point. By use of the force ratio, the *BH* data can be translated into data for direct synthesis (design charts).

A fixed induction ratio derived from equation 35 is associated with a fixed force ratio,

$$B_1/B_2=\sqrt{F_1/F_2} \qquad (36)$$

The magnetic data can now be examined in terms of this fixed induction ratio, and the minimum value of $[(1/\mu_i)+\alpha]$ can be found for this value of induction ratio and the corresponding value of force ratio. The process can now be repeated for other values of force ratio, and the appropriate application functions can be plotted against the force ratio, which is the index function.

The magnetic data are examined at several points. At each point, a hold-in induction B_1 is considered. Associated with this induction value is a magnetizing force H_1. From these values may be calculated

$$\mu_{i1}=B_1/H_1 \qquad (37)$$

From equation 36 the drop-out induction B_2 corresponds to this particular value of hold-in induction B_1 and this particular force ratio,

$$B_2=B_1\sqrt{F_2/F_1} \qquad (38)$$

The demagnetizing leg of the hysteresis loop descending from point $(H_1,\ B_1)$ will at some point pass through the value of drop-out induction B_2 calculated by equation 38. If this occurs in the first quadrant, the particular combination of assumptions is not realizable. If, on the other hand, the appropriate demagnetizing leg of the curve passes through the calculated value of drop-out induction in the second quadrant, an air-gap line could be drawn through this point and the origin, and this point then represents the drop-out point of a magnetic circuit with relative air gap,

$$\alpha=-H_2/(B_1\sqrt{F_2/F_1}) \qquad (39)$$

where H_2 is the iron magnetizing force in oersteds corresponding to induction $B_2=B_1\sqrt{F_2/F_1}$ on the demagnetizing leg of the hysteresis loop descending from point $(H_1,\ B_1)$.

Since the point in question is in the

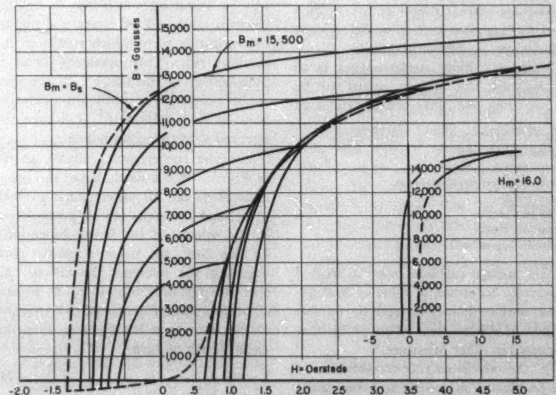

Fig. 4. Hysteresis loops for annealed Swedish charcoal iron

second quadrant, H_2 is negative and α is positive. For these assumed values of F_1/F_2 and B_1, the corresponding values of μ_{f1} have been found by equation 37. The quantity $[(1/\mu_{f1})+\alpha]$ may then be computed

$$\left(\frac{1}{\mu_{f1}}+\alpha\right)=\frac{H_1}{B_1}-\frac{H_2}{B_1}\sqrt{\frac{F_1}{F_2}} \qquad (40)$$

For a fixed value of F_1/F_2, a series of various values of B_1 may be considered. Each will have a corresponding value of $[(1/\mu_{f1})+\alpha]$. These values may be plotted as ordinates versus values of B_1 as abscissas. The process may be repeated for various F_1/F_2 values. The data in Roters' Electromagnetic Devices[12] are reproduced here as Fig. 4; the results of these calculations are shown in Fig. 3(A).

DETERMINATION OF EFFECTIVE RELUCTIVITY: PROTECTION AGAINST OVERVOLTAGE SATURATION

In a manner similar to that used for analyzing a holding electromagnet for dropout force under possible overvoltage saturation conditions, the magnetic data may be processed for synthesizing magnets having prescribed force ratios F_1/F_2, when subjected to overvoltage saturation conditions. Instead of using the demagnetizing portion of the hysteresis curve descending from the (H_1, B_1) point to locate the (H_2, B_2) point, the process uses the saturation demagnetization curve to locate the (H_2, B_2) point. This is the curve that the material would follow if it started at any unsaturated value and was subsequently saturated and then demagnetized. The results of these calculations are shown in Fig. 3(B).

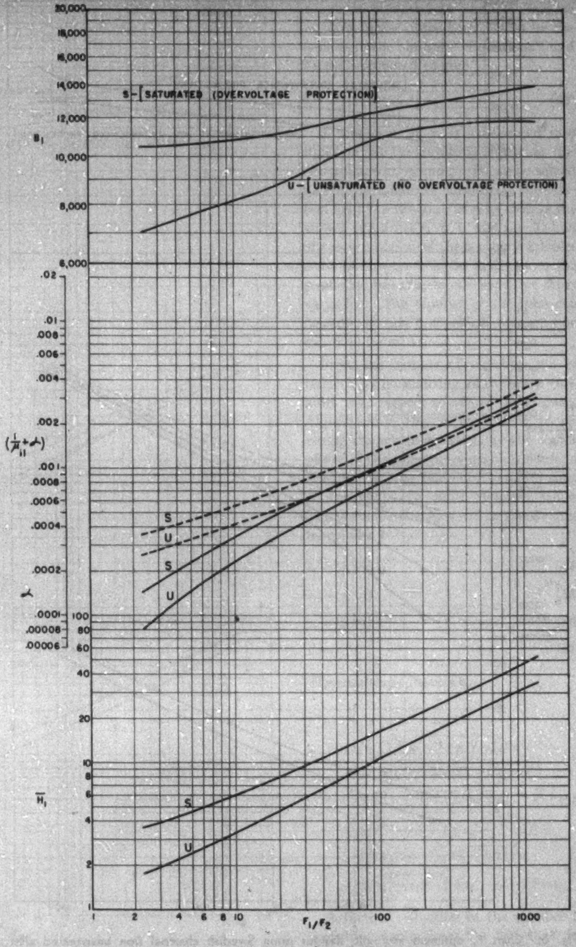

Fig. 5. **Chart 1, optimum magnetic designs using annealed Swedish charcoal iron**

CHART FOR OPTIMUM MAGNETIC OPERATING POINT

From the data calculated by the methods of the two previous paragraphs, and typified by Figs. 3(A) and (B), the optimum magnetic operating points are those of minimum $[(1/\mu_{f1})+\alpha]$. The data at the minimum points for the various materials and force ratios is most convenient for direct (free from trial-and-error methods) synthesis when plotted in the form of a design chart. Such a chart should have an index function for the abscissa and appropriate application functions for ordinates. In this case, the index function is the force ratio and the application functions are B_1, α, and a fictitious magnetizing force defined by

$$\overline{H}_1=B_1[(1/\mu_{f1})+\alpha] \qquad (41)$$

For each material there is a design chart with curves for designs with and without overvoltage saturation protection. Such charts are shown in Figs. 5 through 8. The curves labeled S (saturated) are curves in which saturation has been allowed and therefore represent self-protecting designs. For each chart, the data were taken from the minimum points of the corresponding effective reluctivity graph such as Fig. 3(A). For each force ratio point, the induction B_1 is obtained directly from the abscissa of the effective reluctivity graph. The value of α is obtained from equation 39 and the value of $\overline{H}_1$ from equation 41.

In use, the charts are entered at the specified index value, and the three application function values are read. These application function values are then inserted into the geometrical design procedures described later.

In addition, each chart has a comparison function $[(1/\mu_{f1})+\alpha]$ plotted as a dashed line for the cases with and without

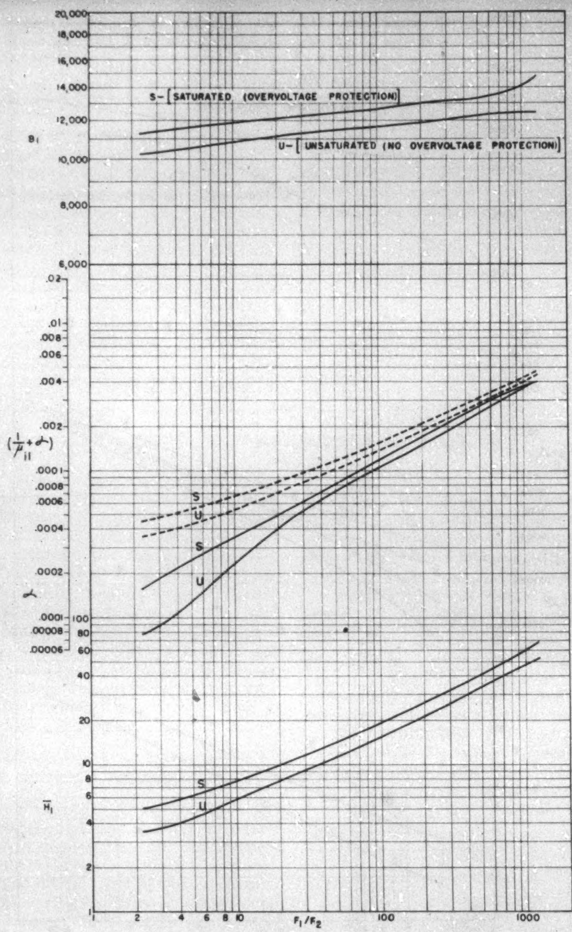

Fig. 6. Chart 1, optimum magnetic designs using Swedish charcoal iron unannealed after machining

saturation protection. The square of this function used in equation 32 will give the relative volumes occupied by magnets constructed of various materials.

AIR GAP LIMITED DESIGN

If the total effective air gap cannot be made as short as required for the optimum design with the specified F_1/F_2 ratio, a modified design procedure is necessary.

If the minimum physically realizable gap is very much larger than the one indicated by Chart 1, the optimum magnetic operating point is the point of maximum normal permeability, but the magnetic reluctance will then be nearly all in the gap, and there will be little advantage in operating on the precise maximum normal permeability point.

The maximum permeability point can readily be determined from the magnetic data of Fig. 2 by drawing a line through the origin tangent to the normal induction curve. The point of tangency is the point of maximum permeability. Such a line is shown dotted in Fig. 2. For this point, the permeability may be found from

$$\mu_{i1}=B_1/H_1 \tag{42}$$

Since the minimum physical gap is known, α can be estimated and $[(1/\mu_{i1})+\alpha]$ can be calculated. The application functions are now the known values of B_1, $[(1/\mu_{i1})+\alpha]$, α, and

$$\bar{H}_1=B_1[(1/\mu_{i1})+\alpha] \tag{43}$$

If the minimum physically realizable gap is only a little larger than the optimum indicated by Chart 1, the procedure of the last paragraph may result in too small an F_1/F_2 ratio. The optimum operating point will be farther above the point of maximum permeability and closer to the optimum point for gaps not having a limited minimum length. In this case, a design for the F_1/F_2 ratio corresponding to the minimum physically realizable α value will be very close to optimum.

OPTIMUM GEOMETRY

The optimum magnetic operating point determination is followed by the determination of the specific geometry. For some designs, it may be desired to realize absolute minimum volume. For other designs, either the length, t, or the outer radius r_4 may be specified, and the minimum value of the other (t or r_4) is desired. The method and chart here presented facilitate the solution of any of these problems.

From the specified hold-in force, F_1, and the optimum induction, B_1, the iron area, a_i, may be found from equation 19 as

$$a_i=8\pi F_1/B_1^2 \tag{44}$$

If a hole of radius r_1 is now specified in the center of the magnetic systems, Fig. 1, the plunger radius r_2 is then

$$r_2=\sqrt{r_1^2+\frac{a_i}{\pi}} \tag{45}$$

or substituting for a_i from equation 44

$$r_2=\sqrt{r_1^2+\frac{8F_1}{B_1^2}} \tag{46}$$

These last two equations include the case of no central hole by simply letting r_1 be zero.

If the value of a_c from equation 10, ℓ_c from equation 11, and a_s from equation 12 are inserted into equation 18, thus,

$$K_c=\frac{\rho c_3(r_2+r_3)N^2I^2}{2F_c c_2(r_3-r_2)(r_4+t)r_4 t} \tag{47}$$

From equations 22 and 43,

$$NI=(\bar{H}_1\ell_i)/(0.4\pi) \tag{48}$$

Inserting equation 3 into equation 48

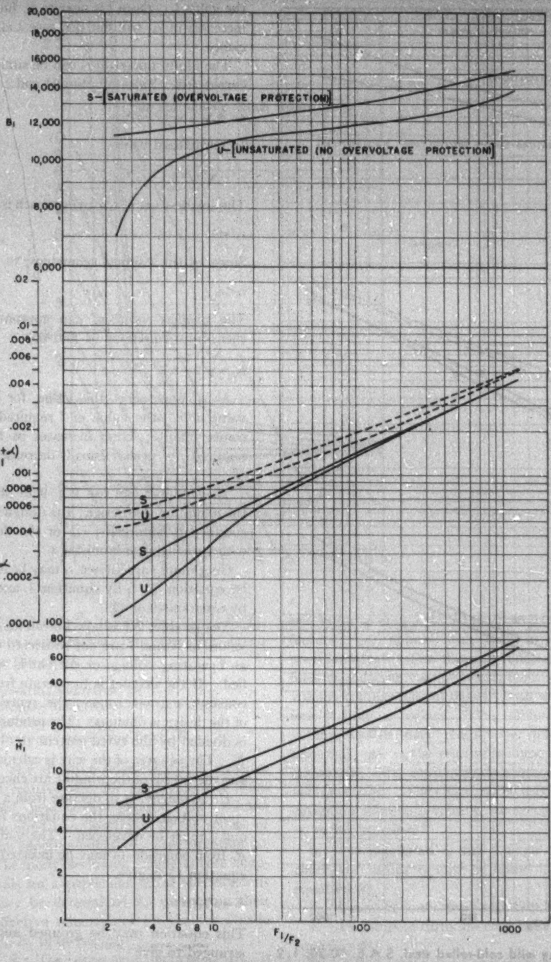

Fig. 7. Chart 1, optimum magnetic designs using mild cold-rolled steel, S.A.E. 10-10, dead soft unannealed after machining

$$NI=\frac{\bar{H}_1}{0.4\pi}(2c_1t-r_1-r_2+r_3+r_4) \qquad (49)$$

and equation 49 into equation 47 gives

$$K_c=\frac{\rho c_3\bar{H}_1^2(r_2+r_3)(2c_1t-r_1-r_2+r_3+r_4)^2}{0.32\pi^2F_cc_2(r_3-r_2)(r_4+t)r_4t} \qquad (50)$$

For simplification of notation, let a characteristic length, t_o, be defined by

$$t_o=\frac{\rho c_3\bar{H}_1^2}{0.08\pi^2c_2F_cK_c} \qquad (51)$$

Equation 50 may now be rewritten,

$$\begin{aligned}t^2[r_4(r_3-r_2)-c_1^2t_o(r_2+r_3)]+t[r_4^2(r_3-r_2)-\\ c_1t_o(r_2+r_3)(r_3+r_4-r_1-r_2)]+\\ (t_o/4)(r_2+r_3)(r_3+r_4-r_1-r_2)^2=0\end{aligned} \qquad (52)$$

This equation represents all the possible geometrical designs of the coil and outer core structure, the plunger radius having been determined by equation 46. In considering equation 52, the following quantities are known: r_1, r_2, t_o, and c_1. The unknowns are r_3, r_4, and t. Radius r_3 is not an independent variable because the area in the outer shell should be the same as in the plunger. Equations 1 and 2 may be equated to give

$$r_3=\sqrt{r_4^2-r_2^2+r_1^2} \qquad (53)$$

If this value of r_3 is substituted into equation 52 the resulting equation has two unknowns: r_4 and t. It can be solved for t by the quadratic formula. The solution for t is a function of r_4 as well as the known quantities r_1, r_2, t_o, and c_1. Tables of t as a function of these other variables could be prepared for use in designing the geometry, but they would have five other variables. The number of variables can be reduced, and a graphical presentation can then be made.

First, the number of variables can be reduced by normalizing all the other variables with respect to one of the knowns. Algebraically, this is equivalent to dividing the whole equation by the fourth power of the reference variable. Here, r_2 is chosen as the reference variable since it always has a finite nonzero value. The normalized values will be represented by primes:

$$r_1'=(r_1/r_2) \qquad (54)$$

$$r_4'=(r_4/r_2) \qquad (55)$$

$$t_o'=(t_o/r_2) \qquad (56)$$

$$t'=(t/r_2) \qquad (57)$$

The resulting equation is

$$\begin{aligned}t'^2[r_4'(\sqrt{r_4'^2+r_1'^2-1}-1)-\\ c_1^2t_o'(1+\sqrt{r_4'^2+r_1'^2-1})]+\\ t'[r_4'^2(\sqrt{r_4'^2+r_1'^2-1}-1)-\\ c_1t_o'(1+\sqrt{r_4'^2+r_1'^2-1})\times\\ (\sqrt{r_4'^2+r_1'^2-1}+r_4'-r_1'-1)]+\\ (t_o'/4)(1+\sqrt{r_4'^2+r_1'^2-1})\times\\ (\sqrt{r_4'^2+r_1'^2-1}+r_4'-r_1'-1)^2=0\end{aligned} \qquad (58)$$

A further reduction in the number of variables results from the fact that, for practical cases, t_o' is very small. Within the bracketed coefficients of t'^2 and t', the first terms predominate. The equation then becomes

$$\begin{aligned}t'^2[r_4'(\sqrt{r_4'^2+r_1'^2-1}-1)]+\\ t'[r_4'^2(\sqrt{r_4'^2+r_1'^2-1}-1)]-\\ (t_o'/4)(1+\sqrt{r_4'^2+r_1'^2-1})\times\\ (\sqrt{r_4'^2+r_1'^2-1}+r_4'-r_1'-1)^2=0\end{aligned} \qquad (59)$$

The positive root of equation 57 is

$$t'\cong\frac{t_o'(1+\sqrt{r_4'^2+r_1'^2-1})\times(\sqrt{r_4'^2+r_1'^2-1}+r_4'-r_1'-1)^2}{4r_4'^2(\sqrt{r_4'^2+r_1'^2-1}-1)} \qquad (60)$$

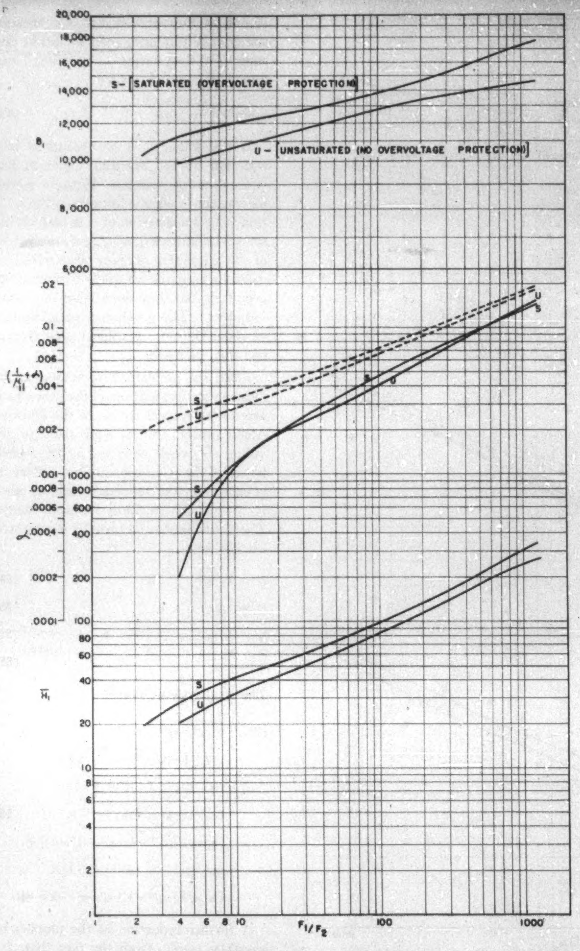

Fig. 8. Chart 1, optimum magnetic designs using mild cold-rolled steel, S.A.E. 10-20, 1/2 hard unannealed after machining

A general graph can be made by considering the ratio t'/t_o' which also equals t/t_o Thus,

$$\frac{t}{t_o}=\frac{t'}{t_o'}=\frac{(1+\sqrt{r_4'^2+r_1'^2-1})\times(\sqrt{r_4'^2+r_1'^2-1}+r_4'-r_1'-1)^2}{4r_4'^2(\sqrt{r_4'^2+r_1'^2-1}-1)} \tag{61}$$

Graphs of t/t_c versus r_4' for various values of r_1' are plotted in Fig. 9. The volume of the magnetic circuit is proportional to $r_4'^2\,t/t_o$. The diagonal lines are lines of constant $r_4'^2t/t_o$, and therefore constant volume lines. The relative volumes of various designs, resulting from various proportions of r_4 and t, may be determined directly from these lines.

The asymptotes of the curves are also of some value. For large r_4',

$$\frac{t}{t_o}\rightarrow 1 \tag{62}$$

In physical terms, no matter how much radial space is allowed for the circuit (unlimited r_4'), the length t will approach the value t_o. Once t is near to t_o, further increases in r_4' will not decrease t appreciably.

The useful ranges of r_4 can be similarly considered. From equations 1 and 2,

$$r_4.=\sqrt{r_3^2+r_2^2-r_1^2} \tag{63}$$

In normalized values,

$$r_4'-\sqrt{r_3'^2+1-r_1'^2} \tag{64}$$

The smallest value r_3' can approach is

$$r_3'=1 \tag{65}$$

Since, by the assumed geometry,

$$r_2<r_3 \tag{66}$$

The smallest value r_4' can approach is then, from equations 64 and 65,

$$r_4'=\sqrt{2-r_1'^2} \tag{67}$$

As r_4' approaches this value, for each value of r_1', the value of t required becomes infinite; large increases in t are required to permit small decreases in r_4'.

The designer can use Fig. 9 to obtain the minimum size design; the design with specified t, minimizing r_4; or the design with specified r_4, minimizing t.

Once r_1 and t are known, r_3 may be found by equation 53, ℓ_t by equation 3, and NI by equation 48 or 49.

The product NI is now known and the values of N and I are not restricted until an operating voltage or current is specified. If the magnet is to operate from a constant current source, the remainder of the design is obvious. The product NI is divided by the rated current to obtain N. The net area of the wire is calculated, and the details of the winding are checked.

If the magnet is to operate from a constant voltage source, the equations for N and I must be developed. The value of R_c from equation 14 may be inserted into equation 15 to give

$$E=\rho\ell_cN^2I/a_c \tag{68}$$

This equation may be grouped and rearranged to give

$$N=Ea_c/[\rho\ell_c(NI)] \tag{69}$$

and

$$I=\rho\ell_c(NI)^2/Ea_c \tag{70}$$

From equations 70 and 15,

$$R_c=E^2a_c/[\rho\ell_c(NI)^2] \tag{71}$$

SUMMARY OF SYNTHESIS STEPS

1. The first step in the synthesis of a holding electromagnet is the determination of the optimum magnetic operating point from Chart 1, Figs. 5 through 8. The index function (abscissa) is the ratio

Vol.
Pt. 1
196

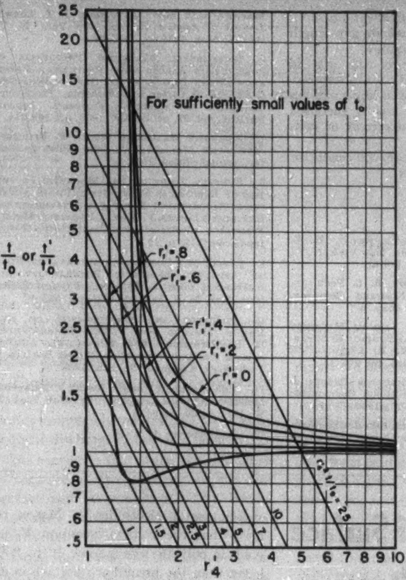

Fig. 9. Chart 2, geometrical designs

of hold-in force to drop-out force, F_1/F_2. Four application functions are given on the chart:

Operating induction, B_1
Effective reluctivity $[(1/\mu_{\Delta})+\alpha]$
Functional air gap, α
Effective magnetizing force, $\mathcal{H}_1$

The effective reluctivity is a measure of relative size, for fixed values of force and heat-power density, the volume required is proportional to the square of the effective reluctivity; see equation 32. The merit of various magnetic core materials for a particular set of specifications may be determined by comparing their effective reluctivities for the force ratio F_1/F_2, in question.

2. The operating induction, B_1, is used with the hold-in force, F_1, and the central hole size, radius r_1, to determine plunger size, radius r_2, by equation 46.

3. The effective magnetizing force, $\mathcal{H}_1$, is used, with the other known factors to calculate the characteristic thickness, t_o, by equation 51. This characteristic thickness is the asymptotic value that the thickness t approaches for large r_4 values.

4. Chart 2, Fig. 9 is a plot of the t/t_o versus r_4/r_2 with r_1/r_2 as a parameter. The thickness, t, has been normalized in terms of t_o; and the hole radius, r_1, and the outside radius, r_4, have been normalized in terms of r_2. Both the normalizing factors t_o and r_2 have been found in the previous steps. The diagonal lines are lines of constant volume which facilitate volume comparisons of designs with various t and r_4 values. The minimum volume design may readily be determined as well as the relative volume increase with shifts away from the minimum volume design. The chart can be used to design for minimum volume, for specified r_4, or for specified t.

5. Having found r_4 and t from the chart, the radius r_3 may be found from equation 53.

6. ℓ_i may be found from equation 3.

7. The ampere turns are computed by equation 48.

8. If the magnet is to operate from a constant current source, the rest of the design is straightforward. The number of turns can be found from the current and the ampere-turns, and the specific winding design worked out.

If the magnet is to be operated from constant voltage source, equations 69, 70, and 71 give turns, current, and resistance, respectively.

Conclusions

The theory developed presents direct methods for analysis and synthesis. These methods are free from successive approximation or trial-and-error procedures.

The first type of chart, Chart 1, provides a direct evaluation of the relative merits of various ferromagnetic materials. If, for example, for a given force ratio, F_1/F_2, two materials have reluctivities in the ratio of 2:1, the holding electromagnets would have volumes in the ratio 4:1 (two squared).

The second type of chart, Chart 2, shows the various possible geometrical proportions and sizes after the magnetic operating point has been established from the first type of chart.

The method is, of course, limited by the available magnetic material data. The minor loop (incremental) data is not always readily available.

Nomenclature

a_c = net (copper) winding area in sq cm
a_i = net iron area in sq cm
a_s = total outside surface area in sq cm
B = general induction in gausses
B_1 = induction in gausses when the coil is energized with normal design current or voltage
B_2 = induction in gausses when the coil is de-energized without allowing plunger movement
B_g = induction in the gap in gausses
B_{mi} = maximum induction in the iron in gausses
c_1 = dimensionless iron length geometrical constant determined by the end section shape; see equation 3
c_2 = dimensionless copper area geometrical constant depending on end section shape; see equation 10
c_3 = dimensionless mean-length-of-turn geometrical constant depending on end section shape; see equation 11
E = applied voltage in volts
F = general force in dynes
F_1 = hold-in force in dynes
F_2 = drop-out force in dynes
F_c = space factor of the (copper) winding
H = general magnetizing force in oersteds
H_1 = magnetizing force in oersteds in the iron when the coil is energized

The Measurement and Influence of Surface Charges on the Inception Voltage Between Dielectric and Metal Dielectric Surfaces

S. I. REYNOLDS
NONMEMBER AIEE

THE CHARGES left on the surface of solid insulating materials which have been subjected to an electrical discharge were first discovered by Lichtenberg when he observed the peculiar formation of resin dust on the surface of a resin sheet which had been exposed to discharges.[1]

Many investigators since that time have studied charged surfaces by dusting techniques, by photographic plates exposed to the discharge, and by heat development of certain materials. They have shown by these methods that the extension and shape of the patterns are determined to some extent by the magnitude and polarity of the voltage transient. In addition semiquantitative measurements have been made by induced charge techniques with a suitable electrometer.

In this report results of measurements carried out by means of the rotating probe electrometer are given which show the magnitude and polarity of charges existing on small areas of a dielectric after breakdown has occurred between dielectric and metal dielectric surfaces.[2] Such results would be difficult to obtain using the other described methods.

With this new technique, charged areas as small as 0.3 cm (centimeters)^2 in area and 1 mm (millimeter) apart can be measured at a rate fast enough to show changes within intervals of 30 milliseconds. The minimum detectable charge density is about 0.6×10^{-9} coulomb cm^{-2}.

Finally, the methods used for charge measurements at the exact discharge inception voltage of a gap, the influence of these charges on the next breakdown, and its dependence on the polarity of the system are given.

Theoretical

The electric strength of a gas enclosed between dielectric surfaces is approximately the same as between equally spaced metal electrodes.[3,4] Mason reports that the voltage inception V_i for voids in polyethylene is some 10 to 20% lower than the breakdown voltage in air between metal electrodes, and refers to previous reports which give even lower values for cellulose acetate and photographic plate surfaces.

It is believed that the shape of the positive and negative "Lichtenberg" figures left on the surface of dielectrics, when the applied potential is of sufficient magnitude to produce ionization, is due to the greater mobility of electrons as they traverse paths in the gas adjacent to the dielectric surface.[5] This brings about a deposition or removal of electrons from the surface which depends on the polarity of the applied voltage. When the polarity is negative the bulk of the surface charge is supplied by emission from the metal cathode; when positive, electrons are removed from the dielectric.

Once a dielectric surface becomes charged in this manner, the charges transferred at the initial polarity are trapped. When the polarity is reversed the vector sum of the applied field and the reverse field due to these bound charges increases the field near the trapped charge and causes breakdown at a lower value of V_i.[6]

Mason has shown that if the initial

breakdown occurs just above the inception voltage V_1 at one polarity, and if the polarity of the field is reversed, the breakdown voltage can then be reduced to values as low as 0.5 V_1.[6]

Thomas has shown that the charge left by an electric discharge of one polarity is not completely neutralized by a subsequent discharge of opposite polarity.[5]

He concludes that when the discharge is negative, electrons penetrate into the surface and become so strongly bound that they cannot be easily reached by positive ions.

Gross shows that the "homo" charge on electrets arises from discharges between electrodes and dielectric surfaces, and states that when breakdowns occur at one point the charge distribution of the dielectric at any other point remains unaffected if the surface charge is immobile.[7]

Purpose of Measurements

The foregoing theoretical discussion on breakdown voltage of a gas and its influence on surface charges produced on the surface of dielectrics as reported by a number of investigators, suggests that the following experiments may lead to a better understanding of these phenomena.

Fig. 2. Test gap with dielectric surface plate

With a slowly rising direct voltage applied, the discharge inception voltage of a uniform field gap will be determined by short-circuiting the gap by means of an electronic circuit, initiated by the first discharge. A series of tests will be made to compare the inception voltage of a metal to metal gap to that of a metal to dielectric gap using a number of different dielectric surfaces.

It will be shown that, when the breakdown occurred very close to the inception voltage, the area of surface charge remaining on the dielectric surface is smaller than the test electrode area and within the uniform field. The polarity, position, and magnitude of the surface charge will be determined by means of the rotating probe electrometer. Following the d-c tests, a-c breakdowns will be made just above the inception voltage for one and one-half cycles, between dielectric surfaces to determine the polarity of charge on the opposite and adjacent dielectric surfaces in its relation to the polarity of the last one-half voltage cycle.

Measurement of Surface Charge

The magnitude and polarity of small charged areas formed on dielectric surfaces by a discharge can be measured by means of the rotating probe electrometer.[2] The measurement technique is described under Apparatus and Procedure.

The voltage induced on the probe as it passes over the surface at a distance of 1 mm is capacitively coupled to the input of a vacuum tube electrometer, then amplified and presented on an oscilloscope where it can be calibrated and photographed.

From measurements of the input capacity to the electrometer, C (with the probe connected), and the oscilloscope deflection for a measured peak to peak sine wave voltage applied across this input capacity, the charge, Q, on the probe leading to an oscilloscope deflection d can be calculated. This is given by $Q=Cd/k$, where $k=d/V_s$, V_s being the peak to peak sine voltage applied to C. If fringing is neglected, the charge density on the surface being scanned is given by $\sigma=Cd/Ak$, where A is the area of the probe (0.284×10^{-2} cm^2), and C is 189 $\mu\mu$f (micromicrofarad), and $k=0.125\times10^{-4}$ cm/volt scope deflection.[2]

To measure the area on which the charge resides, marker pips are generated by placing two small wire electrodes embedded in polystyrene 3.48 mm apart and located in such a manner that the probe passes beneath the wires between passages over the areas being measured. By this means the polarity of the battery connected to the wires determines the polarity of the charge, and the distance between pips is used to measure the charge diameter.

Apparatus and Procedure

An electronic circuit was developed in order to prevent the slowly rising direct voltage from exceeding the discharge inception voltage. The first discharge across the gap is used to trigger a hydrogen thyratron which short circuits the gap in parallel with it within a fraction of a microsecond. The remaining parts of the circuit open the primary of the supply transformer, and operate a motor driven autotransformer to reduce the voltage to zero. A block diagram of the complete test circuit is shown in Fig. 1.

In order to maintain a uniform field gap for breakdown tests and to manipulate the dielectric sheets for surface charge measurements, the insulating material is fastened to the surface of flat 5×6 cm dural plates 1 mm thick, by

Table I. Observed Values of Various Materials

Metal surfaces	±4.6		(±)

means of double-coated pressure-sensitive tape. The insulation surface in this manner is maintained flat in the uniform field gap facing the high potential electrode as shown in Fig. 2, and also later placed on the slide manipulator by means of suction cups shown in Fig. 3 for scanning with the rotating probe. Charge location, polarity, and magnitude can then be obtained by movement of the dielectric surface over the probe as it passes beneath the surface.

By this procedure any detectable unwanted charge which might influence the applied field can be detected and removed before initial breakdown tests are made. After a discharge has occurred, the surface charge is then measured by photographing the trace which is presented on the oscilloscope screen synchronized with the rotating disk.

This technique of measurement has been found suitable for all of the dielectric materials tested, because the resulting bound charges remain fixed with no measurable change in area or magnitude during any of the tests reported in this paper.

Test Results

Discharges at the Inception Voltage

A large number of d-c breakdown tests were made between a 6.4 sq (square) cm circular stainless steel electrode and a number of different insulating materials at a gap distance of 1 mm with the high-voltage electrode negative and positive using the test gap shown in Fig. 2. The direct voltage was increased at a rate of 400 volts/sec (per second), and the total applied voltage was recorded when the electronic circuit short-circuited the gap and cut off the supply voltage.

The sparking potential of the gap was then calculated using the a-c potential division formula which takes into consideration the time constant of the system and assumes that the applied voltage V_0 is divided capacitively between the capacitance of the gap and the series capacitance of the dielectric as follows[8]

$$V_0 = V_a\left(\frac{\tau_1-\tau_2}{\tau\epsilon'}+1\right)$$

where

V_a = sparking potential of the gap
τ = air gap setting in mm
τ_1 and τ_2 = thickness of the dielectric sheet and the sticker film respectively, in mm
ϵ^1 = measured dielectric constant of the test sheet plus the sticker film

The observed values of the inception voltage V_a and the approximate charge area are listed in Table I.

Surface Charge Effect on Breakdown

In order to determine the influence of positive and negative surface charges on the breakdown of a dielectric gap caused by the resulting enhanced field in the charged region, a series of tests were run starting with uncharged dielectric surfaces by measuring the inception voltage before and after field polarity reversal.

An example of results which are typical of many such tests repeated on insulating surfaces is illustrated as follows. After an initial breakdown at 4.6 kv to the surface of a polyethylene sample with the high potential electrode negative, the surface was measured for charge position, polarity, and pulse height, and the cro (cathode-ray oscillograph) trace was photographed. The surface charge pattern was then made visible by dusting the surface with lycopodium powder so that it could be photographed. The photograph of the charge pattern was then placed beside the cro trace of the rotating probe, as shown in Fig. 4(A). The charged surface was then placed in the breakdown gap, and with the polarity reversed, the inception voltage occurred at (+) 2.3 kv.

The resulting charge pattern and voltage trace shown in Fig. 4(B) indicate that the discharge took place at the previous charged site and was responsible for reducing the inception voltage to 50% of the initial value, with the remaining surface charge still negative, showing that the positive discharge did not completely neutralize the initial negative charge. A second positive breakdown at +3.6 kv is shown in Fig. 4(C), with charge pattern extended beyond the original site with a very slight negative voltage trace remaining. After a third positive breakdown

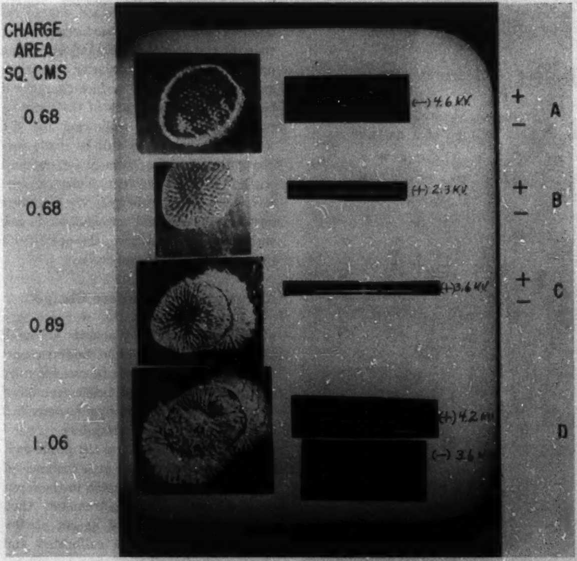

Fig. 4. Powder developed charges and cro trace of positive and negative discharge to polyethylene surface

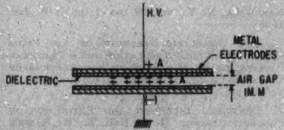

Fig. 5. Schematic of dielectric air gap and polarity of surface charges when high-voltage electrode is positive

at +4.2 kv, all of the negative charge appears to have been neutralized, but its effect on voltage breakdown still remains. This is shown Fig. 4(D) for two positions of the probe voltage trace across the charge pattern. Finally, a negative breakdown at −3.6 kv with charge probe voltages taken at three positions across the charge area are shown in Fig. 4(D). The charge pattern is the result of all the breakdowns made at this site.

CHARGE PATTERNS FROM ALTERNATING VOLTAGES

Results of the direct voltage tests show that the polarity of the charge on the dielectric surface opposite and facing the high-voltage electrode has the same polarity as the high-voltage electrode. If voltage breakdown tests are made with alternating voltages between parallel dielectric surfaces, the polarity on the surface opposite the high-voltage electrode should have the same sign as the last one-half cycle, and the charge on the other surface at the same site will be the unlike sign of the last half-cycle, as shown in Fig. 5.

Consequently, a series of experiments was run with 60-cycle voltages applied to dielectric surfaces separated by a 1-mm gap with the voltage just above the inception voltage for one and one-half cycles. The voltage was triggered on and off at zero voltage with an electronically controlled vacuum switch in series with the high potential winding of the supply transformer. The polarity of the last half-cycle was determined by an oscilloscope connected across a capacitor divider in parallel with the test gap.

Test results from breakdown tests between polyester resin surfaces are shown in Fig. 6, which shows the charge measured by means of the probe electrometer at several different positions on both dielectric surfaces.

Photographs of the oscilloscope trace numbered 1, 2, 3, and 4 show negative charges measured with the probe on the polyester resin surface opposite to the low voltage electrode which was negative on the last half cycle, and photographic traces of the polyester resin surface opposite the high-voltage electrode are shown in traces marked 5, 6, 7, and 8 located at the same positions and directly opposite to 1, 2, 3, and 4, respectively, to give positive charges in the surface with the same sign as the last half voltage cycle.

MEASUREMENT OF CHARGE MAGNITUDE FROM SINGLE DISCHARGES

Thomas has measured the total amount of charge left on a dielectric surface, using the lifted electrode technique of Gross. He found that the total charge from a negative breakdown at voltages above the inception voltage of a 0.5-mm gap and at rise times in the order of 0.4 microseconds using a 7.9-sq-cm uniform field brass electrode to be about 9,100 $\mu\mu$c (micromicrocurie), and total charge from positive wave front with same rise time to be about 6,200 $\mu\mu$c. He estimated that the central charged area had a negative charge of 7,000 $\mu\mu$c allowing 20% for the edge discharge.

By limiting the discharge from a metal electrode across a 1-mm gap to a dielectric surface in a uniform field, to the inception voltage V_i, we have found by virtue of the sharp resolution of the rotating probe that the negative and positive charge areas are much smaller than the test electrode area and that their location is within the central uniform field area.

This sharp resolution requires that the total charge must be measured by making many passes of the probe at intervals of 2 mm from one edge of the charged surface to the other in order to obtain a total integrated charge of the whole area.

A typical charge voltage trace corresponding to a given charge density is shown in Figs. 4 and 6. The height of the voltage trace on the oscillograph for a 1-cm deflection on the oscilloscope corresponds to a Ve value of 8 millivolts peak to peak of a sine wave across the input capacitance C of the electrometer. This corresponds to a Q value of 1.51×10^{-12} coulombs where $Q=CVe$.

Dividing this by the probe area of 0.284×10^{-2} cm^2 we obtain a charge density of 533×10^{-12} coulombs/sq cm for 1-cm cro deflection and calibrated at a probe distance of 1 mm. It has been determined that the width of the voltage trace at the points of inflection is within 8% of the true charge diameter. This width calibration is found by knowing the number of millimeters per division for the two marker pips which the probe also sees as it passes over the charged area. By scanning the charged area in one direction at intervals of 2 mm, starting at zero deflection on one side to zero deflection on the other side of the charged area, the charge Q for each sweep can be determined. Then, by adding the different charges for each sweep of the probe, the total charge for a measured area can be integrated.

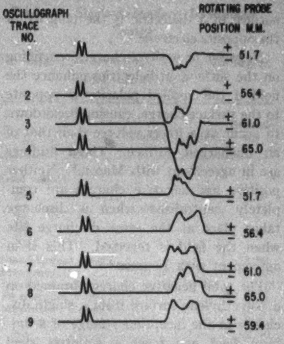

Fig. 6. Cro trace of charge patterns from one and one-half alternating voltage cycles

To determine the charge area for each sweep of the probe let x equal the voltage deflection in $\mu\mu$c/volt. Let y equal the charge width determined by the points of inflection as the probe passes over the charge area, then the $\mu\mu$c charge for each sweep is equal to $0.2\,xy$ cm, where 0.2 cm is the width of the probe slice. A good analogy of this measurement is to consider that the total charge corresponds to a loaf of bread which is being sliced by a bread slicer until the whole loaf is sliced. Each slice is weighed and the total weight corresponds to the total charge.

The total charge obtained from a negative and a positive charge remaining on a polyethylene surface obtained at the inception voltage of a 1-mm gap and measured with the rotating probe was measured to be 1,260 $\mu\mu$c for a +4.6-kv positive breakdown and 1,300 $\mu\mu$c for a negative breakdown at −4.7 kv.

Conclusions

The discharge inception voltage of a 1-mm gap in a uniform field between a metal electrode and a number of different insulating materials when the metal electrode is negative or positive has been found to be the same as the sparking potential between metal electrodes at 20 C (degrees centigrade) and 760-mm pressure in agreement with results obtained by Dubsky and Hall and Russek.[3,4]

The polarity of the charge left on the

surface of a dielectric is the polarity of the opposite electrode.

Negative or positive charges remaining on the surface of dielectrics enhance the field if the applied polarity is opposite to the surface charge, causing breakdown to occur at a lower voltage than that of an uncharged surface. These findings are in agreement with Mason.[6] Neither positive nor negative charges are completely neutralized when a discharge takes place at the same discharge site when the field is reversed. This is in agreement with Thomas.[5]

The total negative charge obtained on a polyethylene surface from a single discharge at the inception voltage of a uniform field gap from a stainless steel electrode is 1,300 $\mu\mu$c and, from a positive charge, 1,260 $\mu\mu$c. Thomas found a greater charge from a negative overvoltaged uniform field gap than from a positive breakdown.[5] Unlike Thomas it would appear that the negative and positive charges are essentially the same when the discharge is limited to the inception voltage in the uniform field.

It is hoped that this work can be continued with dielectric surfaces which have been subjected to ionization for extended periods of time and in the presence of different types of gases.

REUBEN LEE
MEMBER AIEE

THE USE of computers in designing transformers for electric power transmission has been described previously.[1] For such transformers the design calculations are lengthy and may take many hours of engineering time. A large-scale computer requires only a few minutes to do the same work and is therefore of immense and obvious benefit. In contrast, small electronic transformer designs are simple, but a great many designs of these are used. To reap any advantage, computer design of electronic transformers must be rapid and easy, and adapted to the several kinds encountered in practice. This paper describes the procedures, results, and benefits pertaining to the application of digital computers to the design of electronic transformers.

Close co-operation between the engineer and the programer is necessary to achieve effective computer programs. The programer is usually a mathematician specializing in computer techniques. The precise method of storing information and using it differs with each computer and is so involved that it is a concern primarily of the programer and not of the engineer. In other words, if the engineer states his problem clearly, the programer can translate it into terms which the computer can use. This paper is concerned with the engineering use of computers in design work, rather than in the very involved mechanisms of computers. The main features of several computer programs are presented; more detailed descriptions are given in the appendixes and tables.

Simple 2-Winding Transformers

The starting point for the application of computers was a series of standard Hipersil cores which were tabulated, and maximum va (volt-ampere) rating assigned to each core based on experimental data, for the following conditions:

1. Line frequency of 60 cps (cycles per second).
2. Primary and secondary each single section.
3. Maximum voltage insulation in each winding, 1,000-volt operating value.
4. Resistive load.
5. Winding temperature rise 40 C (degrees centigrade) at ambient temperature of 65 C.
6. Maximum regulation 15%, no load to full load.
7. Open-coil assemblies encapsulated in polyester resin.
8. Equal copper loss in each winding.
9. Operating induction 16,000 gausses.

In adapting these simple transformers to computer design, provision is made for three primary voltages and four secondary voltages by means of winding taps, and for electrostatic shields between windings. At several points in the program, the computer is instructed to stop if individual calculations exceed practical limits. For example, the winding height, the temperature rise, or regulation or secondary terminal voltage limits might require the next larger core. On the other hand, if some of these quantities were below a minimum limit a smaller core might be used.

Usually the computer requires two iterations of programed design steps for the right answer. Sometimes it gives the right design the first time; sometimes it requires three iterations. The machine prints the following information for both primary and secondary windings:

1. Number of turns for whole winding and for each tap.
2. Wire sizes.
3. Number of layers.
4. Turns per layer.
5. Winding height.
6. Winding resistance.
7. Weight of wire.

Paper 59-120, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, February 1–6, 1959. Manuscript submitted July 10, 1958; made available for printing December 4, 1959.

L. F. DEISE, WADE ETCHISON, and REUBEN LEE are with the Westinghouse Electric Corporation, Baltimore, Md.

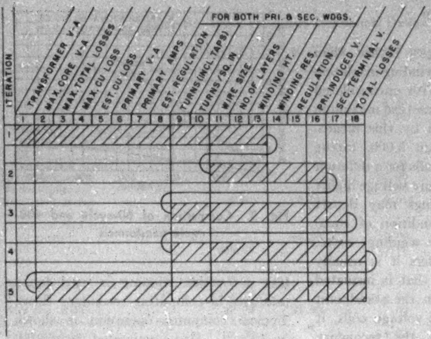

Fig. 1. Flow of work through computer for simple transformer design

8. Copper loss.

For the whole transformer the machine also prints:

1. Total losses.
2. Temperature rise.
3. Output voltages.
4. No-load to full-load regulation.

This program is shown in diagram form in Fig. 1. It consists of the following steps, each of which may have one or more substeps, adding up to a total of 87 programed calculations:

1. Transformer va rating is fed into the machine
2. A core is chosen with maximum va rating nearest to the transformer va
3. For the limiting temperature rise each core is assigned a maximum value for total losses
4. Maximum copper loss is step 3 minus core loss at assumed induction
5. Estimated copper loss = step 4 [(step 1)/(step 2)]^2
6. Primary va = step 1 + step 5 + core loss
7. Primary amp (amperes) = (step 6)/(primary volts)
8. Approximate regulation = (step 4)/(2.6 step 2) for each winding. (The factor 2.6 is 2×1.3, to change over-all regulation to regulation per winding, and to allow for maximum winding temperature; see Appendix I, step 29)
9. Primary turns are calculated for rated primary volts and an assumed value of core induction. Secondary turns = (secondary volts)/[(step 1+2δ) primary volts per turn], where

$$\delta=\frac{IR\text{ drop}}{\text{rated volts for either winding}}$$

where IR = winding resistance

10. Turns per square inch for each winding = ratio of turns to useful window area = N/WD_p
11. Wire sizes are picked from the wire table
12. Number of layers = turns/(turns per layer). Additional layers are required if taps are specified
13. Winding height = number of layers × (wire outside diameter + paper thickness)/(space factor)
14. Winding resistance is found from wire table, number of turns, and calculated mean length of turn
15. Regulation for resistance loads is sum of IR drops in percentage of rated voltages
16. Primary induced voltage is (primary terminal voltage)(1−δ)
17. Secondary terminal volts = (primary induced voltage × turns ratio)(1−δ)
18. Total losses = revised copper loss + core loss; should not exceed step 3

Note that copper loss in step 18 is calculated from actual currents and winding resistances, rather than the value estimated in step 5. Primary turns are based on rated primary volts in step 9. In Fig. 1 the action of the computer is shown for a design example having a va rating near, but slightly under, the maximum va rating assigned to a given core. Several winding taps are provided, and this increases the number of layers in each winding. Thus the winding height (step 13) is found to be too great for this core on iteration 1. The machine then repeats steps 11, 12, and 13 with the next smaller wire size. Now, the winding height is within limits, but the regulation is excessive. The machine then computes the primary induced voltage (step 16) and this allows the turns to be reduced in iteration 3. All limits are now met except secondary terminal volts, step 17. This step usually requires some trimming of turns in order to obtain the exact voltage. This is the final design, unless total losses exceed the allowed amount. If they should, the whole design would have to be done over on the next larger core, as indicated by iteration 5. Machine output for a simple transformer is given in Table I.

Core induction is chosen so that these transformers can be given the so-called overload test, in which voltage is raised

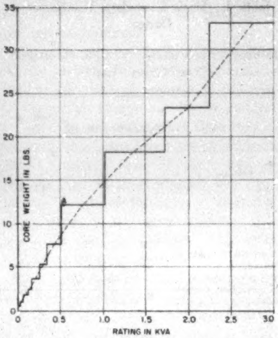

Fig. 2. Sixty-cycle transformer ratings versus core weight

12% above normal for duration of the test, without saturating the core. Coil margins, paper thickness, and coil form thickness are all fixed by winding-machine requirements. This minimum coil insulation with thorough encapsulation in a thermosetting resin, provides the necessary dielectric strength for 1,000 volts maximum.

Under these conditions, each core has the limiting va assigned to it on the program. Ratings increase stepwise, as shown in Fig. 2. Over a large number of designs, the average rating will be somewhere near the middle of the step as indicated by the irregular dashed line. Voltage regulation corresponding to the maximum rating in each case is shown in Fig. 3.

Essentially, these data represent experience; once they are incorporated in the computer program, the computer produces a maximum percentage of optimal, reliable designs. This percentage is never 100, because marginal ratings such as point *A*, Fig. 2, occasionally arise which might be designed better by a good engineer. But it is precisely to save the good engineer for more complex technical problems that the run-of-mine transformer designs are programed on the computer. Hence these cases are dealt with by one of three methods: 1. altering the program to accommodate the marginal case, 2. (if method 1 is not practicable, and size, weight or other attributes are important enough to warrant it) providing flags to detect the condition and checking for better results in longhand, or 3. (if the difference is trivial) by using the computer design, even if it deviates from optimum.

High-Voltage Program

For working voltages higher than 1,000, the margins and winding insulation must be increased. With encapsulated coils, 5,000 volts is the practical maximum which can be achieved by this means. At voltages higher than 5,000, taping must be used, but this calls for a different type of program. For any voltage higher than 1,000, the windings may depart materially from the condition of equal copper loss or equal winding space. In electronic transformers it is usually the secondary winding that is insulated for high voltage. From the standpoint of ease of winding high-voltage coils, it is preferable to place the secondary winding last. Of course, the core ratings for these high voltages are much less than Fig. 2 would indicate. Consequently, in this program, cores are assigned lower ratings as voltage increases.

Multiple Secondary Windings

A common instance of multiple secondary windings is the combined filament and plate transformer, usually requiring two or three secondaries. In setting up programs for this kind, it was found most convenient to proceed with the secondary turns calculations first, because for filament voltages the transformer has only a few secondary turns, and one turn is a large percentage of the total. Once the integral numbers of turns for these secondary voltages are established, then the primary turns may be calculated in reverse order. Regulation must be added to the secondary terminal voltage in computing induced voltage, and again in computing primary impressed voltage.

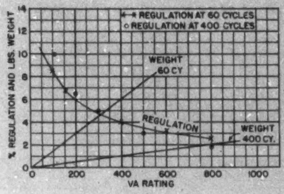

Fig. 3. Comparison of 60-cycle and 400-cycle transformers

Winding space is allotted to the various windings on the basis of turns and CM/amp (circular mils per ampere) which are given for each core. The last or outside winding is used for a reference in computing secondary turns. Typical computer operation is shown in Fig. 4. Since estimated regulation must be added to required output voltage to determine secondary induced voltage, frequently the calculated core induction on the second iteration is too high.

This requires an increase in secondary turns, and to obtain integral numbers of turns in all secondaries, the machine usually reduces core induction on the third iteration to a figure somewhat below the limiting value. Secondary turns are next computed inversely as the decrease in core induction and secondary voltages are found to be high. Then, on the fourth iteration, primary turns are changed accordingly. If equal CM/amp are used in all windings, the regulation problem is minimized, and all secondary voltages deviate from rated values by nearly the same percentage. This percentage is corrected on the fifth iteration.

If total losses are exceeded, the design process is repeated on the sixth iteration with a larger core. Fig. 4 shows the procedure in a condensed form. Calculation steps increase to 174. The total number of iterations increase as $n!$ where n is the number of secondary windings, but on a fast computer the

Fig. 5. Single-phase rectifier circuits

increase in machine time is a matter of seconds. Printed output for a 4-winding transformer with center-tapped secondaries is given in Table II.

A single-secondary design run through this procedure shows that practically the same result is obtained by this method and that described in the section "Simple 2-Winding Transformers." Hence it is expected that the single-secondary program will be gradually replaced. Adding more than one secondary, of course, reduces the rating for a given core. It is feasible to modify this program for high voltages only if the high-voltage winding is located on top of the low-voltage windings.

Operating Frequencies

The foregoing programs are all for 60-cycle applications. For 400 cycles, or other frequencies, different core materials, ratings, operating induction, maximum temperature, and distribution of losses obtain. Hence it is necessary to modify the programs for these different frequencies.

As a practical matter, a double set of programs, one for 60 cycles and one for 400, has been sufficient for the large majority of applications to date. From the computer standpoint no additional problems are encountered in the 400-cycle programs. As indicated by Fig. 3, 400-cycle transformers weigh only a fraction of their 60-cycle counterparts, but have nearly the same regulation for a given rating.

Metal Enclosures

If for any reason a transformer must be enclosed in a metal case, the rating for a given core decreases, because of the inevitable temperature differential between the coil and the case. The ratio of the rating in a metal case to that in an open type of transformer for a given core may be less than 1 to 2. This ratio depends on the rating in several respects, and also on the kind of core material.

If it is possible to fill the metal case with punched laminations instead of type *C* cores, then laminations would be preferable. If a type *C* core is used, a double coil arrangement usually fills up the case to better advantage than a single coil. Each of these variations would require a special program of its own, and in order to avoid too many programs a reasonable compromise is to adopt one type of core material which covers most designs adequately. The kind of impregnating and filling materials also has a large influence on ratings.

Rectifier Plate Transformers

In the circuits of Fig. 5 are two common types of transformers used in single-phase rectifiers. In the case of bridge rectifiers, primary and secondary va are equal, so that the ratings are not appreciably different from those described in the section "Simple 2-Winding Transformers." In the tapped secondary case, the secondary va are appreciably greater than the primary, and the primary winding occupies less space than the secondary. Regulation loss and copper loss are figured differently for the secondary winding; hence for this kind of transformer two alternatives are open:

1. An engineer can interpret these secondary requirements and modify the resistive load program by reproportioning the winding space. This was done for the plate winding in Table II by means of the va multiplier.
2. A separate program can be made for rectifier transformers. In thyratron plate transformers, the transformer va ratings depart to a still larger extent from the output power, so that further modification is necessary.

Power Supply Inductors

Cores for inductors are rated in terms of LI^2 per unit volume. This is subject to qualification by the ratio of inductance to coil resistance. For computer design purposes, each core is assigned a constant $C=\sqrt{LI^2}\times L/R$, which relates inductor rating to core size. Separate programs must be used for inductors because, since these inductors carry direct current, both a-c and d-c components of induction must be calculated. In designing inductors by longhand, the designer may use these components in any proportion, so long as the sum does not exceed a limit fixed by the type of core material. In a computer program, turns are computed from the requirements of inductance I_{dc}, ripple voltage, and frequency. Then a-c induction, d-c induction, and air gap are calculated, and turns are adjusted, until the inductor is within rated limits.

Notes on Programs

Programs such as that of Appendix I are stored in the computer in binary form by means of either cards or magnetic tapes. To feed into the computer the data or specifications (operations 1 through 11 of Appendix I) for a new transformer design, an operator punches cards on a special machine. The cards are placed in the computer card reader, which then stores the data, also in binary form. As illustrated in Fig. 1, the stored program utilizes the data for the new design in performing the computations of steps 1 through 13 of Fig. 1. At this point, a comparison is made between the available winding height and the computed winding height for the wire used. If the computed winding height is the larger, the program automatically transfers to a section of the computer which reduces the wire size by one, and then returns to step 11; see Fig. 1. It will repeat this as many times as necessary to arrive at a computed winding height that is not greater than the available winding height.

At the end of step 16, Fig. 1, the primary induced voltage is checked in like manner with the specified voltage. If it is different by more than the permissible tolerance, the number of turns is adjusted and the program transfers back to the beginning of step 9. Similar checks are made on the secondary terminal voltage and allowable temperature rise. If the latter is too large, a new core is selected and the calculations are recommenced. All this is done automatically by the computer in accordance with the stored program. Other information stored in the computer will be mentioned in the course of the following program descriptions.

To refer to Appendix I, operations 1, 1a, 2, 3, etc., are items of information fed into the computer for a new transformer design. Voltages are arbitrarily given as zero volts for *E0P* and *E0S* and full rated voltage for *E3P* and *E4S*. Provision is for two primary taps *E1P* and *E2P*, and three secondary taps *E1S*, *E2S* and *E3S*, if taps are required. Voltages like *E3P* and *E1P*, terminal numbers, frequency, secondary current, voltage tolerances, and maximum regulation all change with the design requirements and represent input to the computer. For low-voltage designs (less than 1,000 volts on either winding) a minimum of 15 mils of paper insulation is provided by the program for primary, shield, and secondary for mechanical reasons. At 70 peak volts per mil this provides 1,000-volt insulation whether it is needed or not. Allowable temperature rise is the same for all transformers in this program and is 40 C. In operation 12 the core can be chosen by the computer from Table III (which is stored in another section). Associated with this core are several properties which have been determined by previous test or experience as follows (the operation numbers appear at the left):

13. Va rating.

14. Core loss. For a nominal flux density of 16,000 gausses, these cores have a limit on watts per pound of core loss, which, multiplied by the weight of the chosen core, gives a stored figure 14 for core loss.

15. Core weight.

16. Core area.

17. Allowable transformer loss (based on maximum rating 13).

18. Maximum coil width.

19. Total winding build-up.

20. Coil form periphery.

21. Temperature rise, C per watt loss.

22. Width of winding, calculated as indicated in the program. The margin is based on good winding practice, necessary to keep wire from falling into the margin and causing collapse of the wound coil.

23. Build-up per winding D_p is the allowable build-up for either primary or secondary, and contains allowances for insulation, coil form, shield, and clearances. Equal winding spaces are provided for primary and secondary. This does not provide exactly the same copper loss in both windings because ordinarily there is a difference of up to 20% in the average length of turn of the two windings. This difference in copper loss is at least partly mitigated by the fact that the outside winding is nearer to the ambient air, and consequently cools better.

All the information up to this point has been set up in the computer in tabular form, or has been fed in for a particular design. The computer goes to work with operation 24. Succeeding operations are self-explanatory except for the following:

29. The symbol δ represents the approximate regulation for each winding, from no load to full load, in volts per volt at room operating temperature. The factor 2.6 is 2×1.3. The factor 2 is to reduce from over-all regulation to regulation for each winding and 1.3 is the ratio of winding resistance for copper at 100 C to that at 25 C (the wire tables give winding resistance at 25 C). Operation 30 is an equation used when dimensions are in English units and flux density is in gausses. This is equation 34; see page 83 of reference 2. Turns *N3P* correspond to voltage *E3P*; turns *N4S* correspond to voltage *E4S*, etc. The symbol α is the property known as volts per turn.

Ratios such as 38 and 39 are really functions of the wire table. As used in these programs, they give turns per square inch of winding area $W\times D_p$ for each winding. It can be shown that N/WD_p=(turns per inch)/(wire outside diameter+paper thickness), or that the ratio N/WD_p is a function of the wire table. This ratio has been figured in Table IV (which is also stored in the computer) for wire sizes with cross-sectional areas from 10 to 36,500 CM. The column "Layer Insulation" of Table IV is the paper thickness used for wire sizes based on standard winding practice. From this table, the computer chooses the approximate wire size based on available winding space WD_p.

Operation 52 is a tabulation of standard winding practices to guide the winder. The practices include kind and length of leads, direction of windings, turn tolerances, and joint insulation.

In operations 54 through 56 and 60 through 63, a whole layer is used for the number of turns between taps even though it would be possible to get the required number of turns in a fraction of a layer. This is to allow taps to be brought out at the end of a layer, which is necessary on multiple-winding machines. However, if the taps are in the top layer, the layers may be reduced as in operation 64.

In operations 58 and 65 the revised winding build-ups are based on actual turns rather than on space available. If total build-up exceeds the available space, it is caught in operation 66, and wire sizes are then revised. If a wire shield (one layer of wire) has been specified, there may be insufficient room for it; this is also dealt with in operation 66, paragraph *c*.

Primary regulation 73 is figured at 75 C, which is an average operating condition; therefore copper resistances are multiplied by 1.2 in operations 73 and 78. However, to figure the total I^2R in step 80, an additional 1.08 is used to figure the maximum copper loss at 100 C. Operation 89 is a check on flux density.

Appendix I has been modified for several other programs. The first of these is for high-voltage (up to 5-kv) transformers. Where the original program specified the same winding insulation for all designs, the high-voltage program permits the engineer to specify definite thicknesses for primary, shield, and secondary insulation. Correspondingly, the winding margins are increased. These insulation thicknesses and margins affect the total winding build-up and coil width in operations 22 and 23. Increased space for the high-voltage secondary is provided in operation 24 by a proportionality factor. This affects the copper loss distribution, and a new table of core properties must be used in place of Table III.

Rectifier transformers of the kind shown at the right of Fig. 5 require larger space for the secondary than for the primary. This is handled by a "va multiplier," by which the computer may be instructed to redistribute the winding space so that the secondary has approximately 41% more winding area than the primary. For low-voltage transformers this does not affect operation 19, but does affect operations 24, 26 through 28, and subsequent winding calculations.

In the multiple secondary program, the computer provides a redistribution of winding space similar to that mentioned above, but based on the secondary va in each winding. Thus, the secondaries become the starting points for the program. This includes insulation as well as va rating. Initially, the turns are based on secondary rather than primary turns, and *IR* drops are added to the output and primary induced voltages, rather than subtracted from the primary impressed voltage.

Transformers of 400 cycles are designed on another set of cores wound from 4-mil rather than 13-mil strip. The program is similar to that of Appendix I, except that 80-degree temperature rise is allowed. Average ambient is figured at 20 C and maximum ambient at 70 C. These transformers are used in portable apparatus, where weight is especially important. They are characterized by small dimensions, light weight, and high operating temperature. With a large operating temperature range, regulation becomes important. No-load to full-load regulation is limited so that filament voltages may be maintained within the tube book values throughout the operating temperature range. Regulation is figured at 100 C and I^2R at still higher temperature. A 4-mil core table replaces Table III, and a number of design constants are modified for 400 cycles.

The computer program for inductor design in Appendix II is different in several respects from a transformer program. The inductors programed here are smoothing inductors for d-c power supply filters, with Hipersil cores, and are for maximum peak voltages of 1,000 or less. These are linear inductors, in which the air gap is large compared to l_c/μ, where l_c is the mean core length and μ is the core permeability. For such inductors, equations 35, 36, and 38 of reference 2 are valid. These equations can be combined to yield an expression for coil turns:

$$B_{dc}=0.6NI/l_g \text{ gauss} \tag{35}$$

$$B_{ac}=3.49E\times10^6/fA_cN \text{ gausses} \tag{36}$$

$$L=\frac{3.19N^2A_c\times10^{-8}}{l_g+l_c/\mu} \text{ henrys} \tag{38}$$

Adding equation 35 to equation 36,

* This and subsequent numbers in this column are AWG.

and neglecting l_c/μ in equation 38, yields

$$N=\frac{10^6(18.75LI+3.49E/f)}{(B_{dc}+B_{ac})A_c}$$

For a tentative design limit on $B_{dc}+B_{ac}$ of 15,000 gausses,

$$N=\frac{1}{A_c}\left(1{,}250LI+233\,\frac{E}{f}\right)$$

This relation is used in operation 20 of Appendix II.

For the inductor program, each core is assigned an inductor rating indicator $C=\sqrt{LI^2}\times L/R$. It can be shown that C is proportional to the fourth power of a core dimension (e.g., the core window width G), if the ratios of the same dimensions are maintained throughout the range of core sizes used. The computer is thus provided with a sensitive indicator of core size, and can select a core for any rating which is fed into it.

In Appendix II, computer operations 1 through 6 represent information fed in for a new inductor design. From this information the computer can calculate the size indicator C in operation 7 and thus select core 8. Associated with this core are properties 8 through 18 used in later computations.

There is but one winding in these inductors, so that build-up 14 is for the whole winding rather than part of it as in the transformer programs. Items 2a and 2b are tolerances on rated inductance. This is an important matter from the standpoint of manufacturing, because cores have variations in permeability, and air gaps are likely to vary from unit to unit, depending on the size of the gap. The rated inductance is the average of the two limits in operation 19. Inductor turns are based on this inductance in operation 20. The equation is based on a maximum flux density of 15,000 gausses. This is somewhat conservative for Hipersil cores but allows for adjustment to be made in operation 27. A fringing factor of 15% was included in the derivation. After the air gap is calculated in operation 26, fringing is indirectly refigured in operation 27 and the number of reactor turns adjusted accordingly.

Incremental permeability is stored in the computer as a separate double-entry table with two arguments: a-c and d-c induction. Intersections of rows and columns provide four values of incremental permeability which enclose the value to be used. The value used is then found by double linear interpolation in operation 30, with the use of operations 27 and 28.

Conclusions

Co-ordination of engineering and mathematicians' viewpoints is necessary before computer programs become effective. The International Business Machines Corporation *704* computer is presently used for these programs. Computing time averages one second, with an average of less than one minute for the operator, including machine input and output time. Algebraic functions are used most, which makes transformer programs easy to arrange. Such information as wire tables, core data, layer paper, and incremental permeability must be tabulated and stored in the computer.

Over-all gains are improvement in reliability because of better transformer standardization, great reduction in design engineering time, and more effective use of engineering talent. Because of the flexibility and adaptability of existing programs, it may be predicted that further applications of these programs to audio transformers, carrier, and pulse transformers will soon appear. Computer designs tend to be more uniform than those done by hand, and less dependent on individual whims. Therefore they are easier to check and control. It is possible to tabulate the computer output so as to produce manufacturing information without transcription, thus eliminating a chore distasteful to engineers. It is not difficult to envisage further transitions from the computer design of transformers to automatic manufacture and test.

Appendix I. Transformer Design Program

This transformer design program is concerned with a single secondary transformer of 60 cps, 40-degree temperature rise, and open-frame Fosterite coils under 1 kv.

The numbers at the left refer to computer operations in sequence. Heavy type indicates that the number is used in later operations.

17. Allowable transformer losses, watts
18. Width of coil, inches
19. Total winding build-up, inches
20. Coil form periphery
21. Temperature rise, C per watt
22. Width of winding, inches $=\mathbf{18}-2\times$ margin $=W$
23. Build-up per winding $D_p=\dfrac{\mathbf{19}-3\times\text{insulation thickness}}{2}$
24. Va of secondary winding $=\mathbf{5}\times\mathbf{9}$
25. Allowable copper loss, watts $=\mathbf{17}-\mathbf{14}$
26. Estimated copper loss, $\mathbf{25}\times\mathbf{24}/\mathbf{13}$
27. Primary va $=\mathbf{24}+\mathbf{14}+\mathbf{26}$
28. Primary current $=\mathbf{27}/\mathbf{1}$ amp
29. $\delta=\mathbf{25}/(2.6\times\mathbf{13})$
30. $N3P=\dfrac{3.49\times\mathbf{1}\times10^6}{\mathbf{4}\times\mathbf{16}\times16{,}000}$ turns. (Use whole number; drop decimal.)
31. $\alpha=E3P/N3P=\mathbf{1}/\mathbf{30}$
32. $N4S=(1+2\times\mathbf{29})\mathbf{5}/\mathbf{31}$ turns. (Use whole number; drop decimal.)
33. $N1P=\mathbf{2}\times\mathbf{30}/\mathbf{1}$ turns. (Use whole number; drop decimal.)
34. $N2P=\mathbf{3}\times\mathbf{30}/\mathbf{1}$ turns. (Use whole number; drop decimal.)
35. $N1S=\mathbf{6}\times\mathbf{32}/\mathbf{5}$ turns. (Use whole number; drop decimal.)
36. $N2S=\mathbf{7}\times\mathbf{32}/\mathbf{5}$ turns. (Use whole number; drop decimal.)
37. $N3S=\mathbf{8}\times\mathbf{32}/\mathbf{5}$ turns. (Use whole number; drop decimal.)
38. $N3P/WDP=\mathbf{30}/(\mathbf{22}\times\mathbf{23})$
39. $N4S/WDP=\mathbf{32}/(\mathbf{22}\times\mathbf{23})$
40. Select primary wire size from Table IV by **38** (next number smaller than **38**)
41. Turns per inch for primary wire
42. Winding height per layer
43. Resistance in ohms per 1,000 feet
44. Weight in pounds per 1,000 feet
45. Primary layer insulation
46. Select secondary wire size from Table I by **39** (next number smaller than **38**); print wire size
47. Turns per inch for secondary wire
48. Winding height per layer
49. Resistance in ohms per 1,000 feet
50. Weight in pounds per 1,000 feet
51. Secondary layer insulation
52. Winding practices
53. Primary turns per layer $=\mathbf{22}\times\mathbf{41}$. (Use whole number; drop decimal.)

54. Number of layers for $N1P$=**33/53**. (Use next largest whole number.)

55. Number of layers from $N1P$ to $N2P$=(**34**−**33**)/**53**. (Use next largest whole number.)

56. Number of layers from $N2P$ to $N3P$=(**30**−**34**)/**53**. (Use next largest whole number.)

57. Number of primary layers=**54**+**55**+**56**

58. Height of primary winding=**57**×**42**

59. Secondary turns per layer=**22**×**47**. (Use whole number; drop decimal.)

60. Number of layers for $N1S$=**35/59**. (Use next largest whole number.)

61. Number of layers $N1S$ to $N2S$=(**36**−**35**)/**59**. (Use next largest whole number.)

62. Number of layers $N2S$ to $N3S$=(**37**−**32**)/**59**. (Use next largest whole number.)

63. Number of layers $N3S$ to $N4S$=(**32**−**37**)/**59**. (Use next largest whole number.)

64. Number of secondary layers=**60**+**61**+**62**+**63**. If **32**−**35** is less than **59**, subtract two layers from **64**. If **32**−**35** is more than **59** but **32**−**36** is less than **59**, subtract one layer from **64**. (Use revised value of **64** as determined above.)

65. Height of secondary=**64**×**48**. (Use revised value of **64** as determined above.)

66. Height of primary, secondary, and shield=**58**+**65**+**42**. This number must not exceed 2×**23**
    a. If the primary wire size is no. 22 or larger, and if 2×**23** is exceeded, check height of primary+secondary+solid shield as follows: **65**+**58**+0.005. If this is not right, go to the following condition:
    b. If **66** still exceeds 2×**23**, revert to **40** and choose primary wire and wire wound shield one size smaller. Test solid shield again if 2×**23** is still exceeded. If not right, go to the following conditions:
    c. If **66** still exceeds 2×**23** after adjustment 66b, revert to step **46** and choose secondary wire one size smaller. If it will not go with primary and wire wound shield, test with solid shield

67. Shield wire size: print AWG (American Wire Gage) size or solid as in operation **66**

68. Height of shield=**42** or 0.005 (based on **67**)

69. Build-up ratio=2×**23**/**66**

70. Primary mean turn=**20**+π **58** inches

71. Primary resistance = **30** × **70** × **43**/12,000 ohms

72. Primary wire weight=**30**×**70**×**44**/12,000 pounds

73. Primary IR drop=1.2×**28**×**71** volts

74. Primary I^2R loss=**73**×**28** watts

75. Secondary mean turn=**70**+π[**58**+**65**+2 (insulation+**68**)]

76. Secondary resistance = **32** × **75** × **49**/12,000 ohms

77. Secondary wire weight=**32**×**75**×**50**/12,000 pounds

78. Secondary IR drop=1.2×**9**×**76** volts

79. Secondary I^2R loss=1.2×**9**²×**76** watts

80. Total I^2R losses=1.08×(**74**+**79**) watts

81. Total losses=**80**+**14** watts

82. Total temperature rise=**21**×**81** C. This result should be less than 40 C. If it is not, choose core with next larger va rating

83. Primary induced voltage=**1**−**73** volts

84. Output voltage

$$E_s=\left(\frac{83}{30}\times 32\right)-78$$

If E_s is outside of tolerance given by **10**, adjust primary turns by

$$N3P=\frac{83\times 32}{5+78}$$

Then, revert to step **31** and repeat calculations

85. No-load output voltage=(**1**×**32**)/**30**

86. Regulation=(**85**−**84**)/**84**. If regulation exceeds that specified by **11**, choose next larger core size and repeat calculations

87. A-c flux density in gausses is

$$\frac{3.49\times 83\times 10^6}{4\times 16\times 30}$$

Appendix II. Computer Design of Linear Inductors

This computer design of linear inductors uses Hipersil cores, open-type Fosterite encapsulated coils up to 1.0 kv peak.

1. Maximum winding resistance, ohms
2. Inductance, henrys

2a. Minimum inductance multiplier

2b. Maximum inductance multiplier

3. Current, amperes
4. A-c voltage, volts (ripple)
5. Frequency, cps
6. Allowable temperature rise, C
7. C is

$$L/R\times\sqrt{LI^2}=\frac{2}{1}\times\sqrt{2\times 3^2}$$

8. Core type
9. Core weight, pounds
10. Core area, square inches
11. Temperature rise, C per watt
12. Width of coil, inches
13. Winding margin, inches
14. Winding buildup, inches
15. Coil form periphery, inches
16. Core mean length, inches
17. Core periphery, inches
18. Core G dimension, inches
19. Average multiplier=(**2a**+**2b**)/2
20. Number of reactor turns=

$$\frac{1}{10}\left(1{,}250\times 2\times 19\times 3+\frac{233\times 4}{5}\right)$$

(Use whole number only; drop decimal.)

21. A-c flux density, gausses=

$$\frac{3.49\times 4\times 10^6}{5\times 10\times 20}$$

22. D-c flux density, gausses=15,000−**21**
23. Total air gap, inches=(0.6×**19**×**3**)/**22**
24. Air gap per leg, inches=**23**/2. Round off to next largest number in third decimal place.
25. Effective gap per leg, in inches, is

$$24/\left(1+\frac{17\times 24}{2\times 10}\log_e\frac{18}{24}\right)$$

26. Number of reactor turns adjusted=

$$25\times\sqrt{\frac{25\times 2}{23}}$$

27. A-c flux density, in gausses adjusted=(**20**×**21**)/**26**
28. D-c flux density, in gausses adjusted=(0.5×**26**×**3**)/(2×**25**)
29. Total flux density, in gausses=**27**+**28**. This number must not exceed 16,000; if it should, choose next larger core size
30. Incremental permeability from table
31. Inductance in henrys:

$$\frac{3.2\times 26^2\times 10\times 10^{-8}}{2\times 25+(16/30)}$$

32. Minimum inductance limit=**2a**×**2**
33. Maximum inductance limit=**2b**×**2**
34. Item **31** must be more than **32** but less than **33**. If not within limits, multiply **26** by the factor$\sqrt{19\times 2/31}$ and repeat computer operations from **27** on. (Provide for two increases or decreases of turns)
35. $\dfrac{N}{WD_p}=\dfrac{26}{14(12-2\times 13)}$
36. Select wire size from Table IV by **35** (next number smaller than **35**)
37. Turns per inch for wire size
38. Winding height per layer
39. Resistance in ohms per 1,000 feet
40. Weight in pounds per 1,000 feet
41. Layer insulation as in Table IV. (Print thickness of layer insulation.)
42. Turns per layer=**37**×(**12**−2×**13**) (Use whole number; drop decimal.)
43. Number of layers=**26**/**42**
44. Height of winding=**38**×**43**. This number must not exceed **14**; if it should, use wire one size smaller.
45. Mean turn in inches=**15**+π**44**
46. Winding resistance in ohms=(**26**×**45**×**39**)/12,000. This number not to exceed **1**; if it should, use next larger core

47. Weight of wire in pounds $=(\mathbf{26}\times\mathbf{45}\times\mathbf{40})/12{,}000$

48. *IR* drop in volts $=\mathbf{3}\times\mathbf{46}\times1.2$

49. I^2R loss in watts $=\mathbf{3}\times\mathbf{48}$

50. Core loss in watts $=1.59\times10^{-11}\times\mathbf{5}^{1.89}\times\mathbf{27}^{1.84}\times\mathbf{9}$

51. Total reactor loss in watts $=\mathbf{49}+\mathbf{50}$

52. Total temperature rise in C $=\mathbf{11}\times\mathbf{51}$. This should not exceed **7**; if it does, use next larger core

53. Winding tolerance ±1%

Discussion

L. W. Kirkwood (Bell Telephone Laboratories, Inc., Whippany, N. J.): The computer age is still in its infancy and a paper which indicates a computer application which offers a number of advantages is certainly valuable. It can provide the impetus for more general use of computers, especially in the field of small electronic transformer design. It should be recognized that this paper, first presented as a conference paper, was the first report involving the use of digital computers to design electronic transformers. The specific application here is electronic power transformers and of particular interest is an appreciation of the numbers of such design required. One would think that over the years a design would be available for about every circuit or system application that could be conceived, but it is only in isolated instances that a circuit or equipment designer will specify an existing design for a transformer supplier. It is true that many of these designs are "simple" variations of existing designs, such as other arrangements of windings on a given mechanical structure, but it is here that the computer program is a great asset. As the paper points out, a technician by simply punching a few appropriate holes in a card can relieve an engineer for more "glamorous" work. The design program contained in the Appendix is a significant contribution. There may be many programs considered to be proprietory, but the authors of the paper present transformer and inductor step-by-step programs in detail. A person not skilled in the art of power transformer design, and who may not have a digital computer, can easily follow the step-by-step program.

As stated, the program is flexible and can be readily adapted to the many varieties and kinds of transformers. It is very easy to adjust the program to emphasize any specific design characteristic, namely, regulation, size, weight, etc. The speed of operation is such that any number of complete designs can be obtained for as many numbers of variations one wishes to make. We have a program for an International Business Machines Corporation *704* computer that, once it is fed into the machine, will grind out a 4-secondary winding design in a few seconds. Because of the speed in obtaining an answer, the effects of any variation of any parameter on the over-all design can readily be determined simply by introducing changes on punch cards and rerunning the program for each change. Thus a program can be adjusted to do optimum designs in whichever area one wishes.

Cost and justification for a computer have been a matter of discussion. A computer for the type of design work discussed must be a large one. Aside from the storage of information required for many interrelated calculations, much space must be provided for the storage of complete wire tables, core loss and magnetizing current characteristics of cores, dielectric characteristics of insulation systems, heating data, etc. In some instances, where a *650* computer is not sufficient, one will require a *704* or its equivalent, but it is only in the larger companies doing a lot of work involving varied calculations, the sum total of which will justify their own machine.

Some, however, use the services of a neighbor. We did this temporarily, until our machine was installed. The growth of electronics and the increasing complexity of systems promotes a trend toward sharing effort. In some instances design programs are no longer considered proprietory. By extension, a standardized design program may be in a library of a computing center and can be rented, as is the case with many standardized services.

Allen B. Rosenstein and **Gerald Estrin** (University of California at Los Angeles, Los Angeles, Calif.); and **Arthur H. Hadley** (Robert M. Hadley Company, Inc., Los Angeles, Calif.): Since design is central to all engineering, it is hoped that this constructive paper will encourage similar efforts with respect to other probems, with subsequent publication of results. Our comments on the paper concern the computer application, and a few technical questions.

In connection with computer application, and the authors' introductory comments about the difference between small and large transformer design, the paper does not follow up sufficiently to demonstrate whether their computer program meets the standards they set up. The questions that come immediately to mind are of the following type: Given a customer specification, how long does it take to obtain a design? How much editing of the specification is required? What if the specification deviates slightly from the assumed conditions in the program? How do these over-all times compare with the over-all time to effect a design now?

In other words, it is observed in the conclusion that computing time is one second and operator time is one minute. No estimate is given for the preparation of the problem.

There is also the question of optimum design. The computer program appears to have been tailored with enough pretabulated data to effect a unique answer. Is would be of interest to learn what measures of "best" have been assumed and how well the computer design compares to these measures. Further, the question occurs of how does this design procedure differ from that practiced by humans? What has been lost or gained in the process of being forced to specify every step in the design?

In connection with design details, from the viewpoint of electronic transformers, the paper presents a logical approach to their design by means of digital computers. The sequence of steps (1 through 18) of the section "Simple 2-Winding Transformers" seems to be quite adequate.

In the section "Operating Frequencies" the statement is made "As indicated by Fig. 3, 400-cycle transformers weigh only a fraction of their 60-cycle counterparts, but have nearly the same regulation for a given rating." For equal va and identical ambients, and the final winding temperatures, a 400-cycle transformer will have considerably better regulation than a 60-cycle transformer. From the fact that, for equal va rating and equal temperature rise, a 400-cycle transformer is considerably smaller than a 60-cycle transformer, it can be seen that the over-all volume and surface area will be much less for a 400-cycle transformer. This means that in this smaller volume much less wattage can be generated. Less wattage, of course, means less copper loss and therefore better regulation. In the light of this condition the regulation curve of Fig. 3 should not give the same regulation at a given va for both 60-cycle and 400-cycle transformers if all other design criteria remain unchanged. It is, of course, probable that there has been a significant change in criteria which would account for similar 60- and 400-cycle regulation curves.

For example while it is stated earlier that the 60-cycle transformers were designed for 40 C rise and 65 C ambient, it is noted in the section "Notes on Programs" that the 400-cycle transformers are figured with an average ambient of 20 C and a maximum ambient of 70 C, while allowing a 80 C rise. This, coupled with Fig. 3, could cause some confusion as 400-cycle regulation is stated as being figured at 100 C. With further reference to Fig. 3, the weight in pounds should be stated as "core weight in pounds" as this checks with the core weight as shown in Fig. 2.

With a more complex computer programming, it can be seen that other types of electronic transformers such as audio transformers could be designed by digital computers. Of considerable future interest would be a computer program to examine the optimum values of the materials and data (i.e., core configurations, core materials, temperature rise, etc.) used as the foundations for the given design procedure.

L. F. Deise, W. Etchison, and **Reuben Lee:** Mr. Kirkwood's comments are appreciated. He manifests a good understanding of the value and use of computers for small electronic power transformers, which portends wider use of this design tool.

Several of the questions raised by Prof. Rosenstein and his associates are answered in the paper; the following will answer the remainder. Editing the customer's specifications has not been programed, nor does it appear practicable to foresee all the possible questions that may arise. At present, an engineer reviews all such specifications, regardless of whether the computer is used. With reasonable performance requirements, and even with deviations from assumed conditions, preparation of the problem is a matter of minutes. It is facilitated by the use of forms on which pertinent electrical values may be filled in. Depending upon the requirements and upon engineering efficiency, the total saving is anywhere from 1 to 2 days for a new transformer design.

For a given list of standard cores, the computer design depends wholly upon the assumed conditions. The design procedure follows closely that of a design engineer. Gains and losses, and the degree of optimization, are mentioned in the section "Simple 2-Winding Transformers." Weight minimization is limited only by the number of standard cores, and this in turn is an economic consideration. Weights shown in Fig. 3 are core weights.

Regulation in transformers for 400-cycle operation has been calculated at 100 C, compared with 75 C for 60 cycles. This, together with different cores, induction, current density, and maximum temperature rise, accounts for the percentage regulation's being nearly the same at both frequencies.

With due regard for the possibility of computer optimization in reducing weight from present practice, this is highly dependent on the properties of materials used. Computer designs described in this paper compare very favorably with other extant designs. Further progress hinges largely on improvements in transformer materials.

The Synthesis of Linear Filters with Real or Imaginary Transfer Functions

ELMER G. GILBERT
NONMEMBER AIEE

JOSEPH OTTERMAN
NONMEMBER AIEE

THE SYNTHESIS of linear filters with symmetrical (even-function) or antisymmetrical (odd-function) impulse responses has both theoretical interest and practical value. Such filters which can be called "time-symmetric" or "time-antisymmetric," following the terminology of Storey and Grierson,[1] are characterized by transfer functions which are purely real or purely imaginary. Alternate names, proposed and employed in this paper, are real or imaginary filters. Applications of real or imaginary filters include compensating systems which must have no phase distortion, such as those often used in the field of acoustics and in the compensation of signals generated by picture scanning devices.[2,3]

In the past, little work of a general nature has been done. Although Kallmann,[4] Wiener and Lee,[5,6] and others[7,8] consider delay-line tranversal filters which have real or imaginary transfer functions, their emphasis is on transfer functions periodic in frequency. An excellent paper by Levy[9] describes some of the properties and the usefulness of real and imaginary transfer functions; however, it limits synthesis to a lumped-element delay-line filter with many experimentally adjusted reflections. Storey and Grierson[1] have used a tape-recorder scheme which involves storing the input signal on magnetic tape and processing the signal through reverse playback. Since these past contributions are restricted to limited types of transfer functions and physical realizations, their significance has not generally been appreciated.

It is the purpose of this paper to extend previous work by developing fully the conditions under which real and imaginary filters can be realized and by utilizing an orthogonal function approach for solving the approximation problem. Filter realizations presented in this paper do require a delay element. And although it is true that real or imaginary filters can be realized with arbitrarily small errors by means of conventional lumped-element filters, it is felt that the filters presented here can often be more simply and economically realized particularly when phase accuracy requirements are high.

Statement of the Problem

The problem of synthesis is to realize physically and as closely as practicable a prescribed mathematical operation an an input function of time. For a linear time invariant system the prescribed operation may be expressed by the superposition integral

$$f_0(t)=\int_0^{\infty} h(\tau)f_i(t-\tau)d\tau \tag{1}$$

where t is time, f_i is the input function, f_0 is the output function, and $h(t)$ is the response of the prescribed system to the unit impulse $u_0(t)$ occurring at $t=0$. The operation may also be expressed in terms of the Fourier transforms of f_i, f_0, and h by

$$F_0(j\omega)=H(j\omega)F_i(j\omega) \tag{2}$$

(The upper-case-letter functions denote the transforms of the lower-case-letter functions; i.e., $H(j\omega)=\int_{-\infty}^{\infty}\epsilon^{-j\omega t}h(t)\,dt$. It is tacitly assumed that the transforms exist when employed.) $H(j\omega)$ is the sinusoidal response function or the transfer function. The Fourier transform is used rather than the Laplace transform because impulse responses $h(t)$ will be considered which are nonzero for negative t. Synthesis is assumed complete when a physical system is determined which has an impulse response $h^*(t)$ which approximates $h(t)$ sufficiently well for a given purpose.

An approximation generally results because the physical system imposes the realizability condition, $h^*(t)=0$ for $t<0$, and possible practical conditions, such as being realized by a lumped-element system ($H(j\omega)$ rational in $j\omega$). In the present case either H_R or H_I (both real functions) in

$$H=H_R+jH_I \tag{3}$$

is zero. To approximate as closely as possible such an H, we will develop the conditions under which it is possible to realize an

$$H^*=H_R^*+jH_I^* \tag{4}$$

(H_R^* and H_I^* are real functions) where either $H_I^*=0$ or $H_R^*=0$, i.e., where the realized filter is either real or imaginary.

Conditions for Realizability

From the Fourier transform we have

$$H_R^*=\int_{-\infty}^{\infty} h^*(t)\cos\omega t\,dt$$

$$H_I^*=-\int_{-\infty}^{\infty} h^*(t)\sin\omega t\,dt \tag{5}$$

Thus it is clear that a symmetric impulse response

$$h^*(t)=h^*(-t) \tag{6}$$

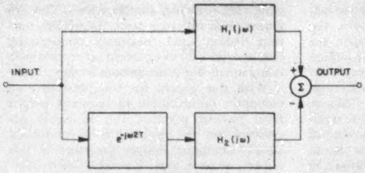

Fig. 1 (left). Single delay element realization of H*(jω)

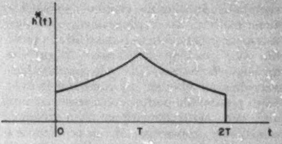

Fig. 2 (right). An h*(t) utilizing more than one delay element

yields a real filter ($H_I{}^*=0$) and an antisymmetric impulse response

$$h^*(t)=-h^*(-t) \tag{7}$$

yields an imaginary filter ($H_R{}^*=0$).

Since realizability requires $h^*(t)=0$ for $t<0$, it is clear from equations 6 and 7 that realizable real and imaginary filters require $h^*(t)=0$ except at $t=0$. The only functions which satisfy this condition are the unit impulse u_0 and its derivatives, u_1, u_2, ... But the impulse derivatives have no value as approximating functions and are not realizable by physical systems having finite gain at infinite frequency. Hence real and imaginary filters cannot be realized directly

By introducing a time delay T, certain real and imaginary filters can be realized. The time delay allows $h^*(t)$ to be symmetric or antisymmetric about $t=T$ instead of $t=0$. Realizability then means that

$$h^*(t)=0, \qquad t<0,\ t>2T \tag{8}$$

$$h^*(t+T)=h^*(-t+T), \qquad 0\le t\le T \tag{9}$$

(a delayed real filter)

$$h^*(t+T)=-h^*(-t+T) \qquad 0\le t\le T \tag{10}$$

(a delayed imaginary filter)

Fortunately, in most practical applications the added delay T does not limit the usefulness of these filters.

Since lumped-element systems have impulse responses of the form

$$h^*(t)=\sum_{n=1}^{N} c_n t^{k_n} e^{\alpha_n t}+c_0u_0(t),\ t\ge 0 \tag{11}$$

(k_n = zero or positive integer, α_n = real, imaginary, or complex number) and have infinite memory, it is obvious that they cannot satisfy equation 8 which states that $h^*(t)$ has a finite memory of $2T$. Only through the introduction of distributed elements may equations 8 and 9 or 8 and 10 be satisfied.

Physical Realization

Fig. 1 shows how a single delay-element transfer function $\epsilon^{-j\omega 2T}$ and two lumped-element transfer functions, $H_1(j\omega)$ and $H_2(j\omega)$, may be used to realize $H^*(j\omega)$. For $t\le 2T$ the impulse response is simply $h_1(t)$; for $t>2T$ the impulse response is $h_1(t)-h_2(t-2T)$. To make $h^*(t)=0$ for $t>2T$ it is necessary to make the responses of the two paths cancel for $t>2T$, i.e., to make $h_1(t)=h_2(t-2T)$ for $t>2T$. Thus

$$\begin{aligned} h^*(t)&=0, && t<0\\ &=h_1(t), && 0\le t\le 2T\\ &=0, && t>2T \end{aligned} \tag{12}$$

and

$$\begin{aligned} h_2(t)&=0, && t\le 0\\ &=h_1(t+2T), && t>0 \end{aligned} \tag{13}$$

Since h_1 must symmetric or antisymmetric about $t=T$ in $(0, 2T)$ it is clear that h_1 can have no terms with an exponential function of time as a factor. That is, the terms in h_1 must be of the following type:

Type of Functions	Form of Realization
$1, t, t^2, \ldots, t^k$	$(k+1)$ integrators
$\cos\omega_1 t$, $\sin\omega_1 t$, $\cos\omega_2 t$, $\sin\omega_2 t$, ...	undamped filter with poles at $j\omega=\pm j\omega_1$, $\pm j\omega_2$, ...
$\cos\omega_1 t$, $\sin\omega_1 t$, $t\cos\omega_1 t$, $t\sin\omega_1 t$, ..., $t^k\cos\omega_1 t$, $t^k\sin\omega_1 t$	undamped filter with $(k+1)$ order poles at $j\omega=\pm j\omega_1$

In every case the poles of H_1 (and also the poles of H_2 since by equation 13 the poles of H_2 must also be the poles of H_1) are on the imaginary axis in the complex p plane. In a later section approximating series based on the first two types of terms will be described.

Since passive circuit realization of H_1 or H_2 demands lossless inductors and capacitors, active circuitry is preferred for high accuracy realization. Actually, active circuit realization is mandatory where H_1 or H_2 are voltages ratios and have poles at $p=0$.

Other forms for $h^*(t)$ can be obtained if more delay elements are introduced. Fig. 2 shows an example. Here

$$h^*(t)=h_T(t)+h_{2T}(t) \tag{14}$$

where

$$\begin{aligned} h_T(t)&=0, && t<0, && t>T\\ h_{2T}(t)&=0, && t<T, && t>2T \end{aligned} \tag{15}$$

and

$$h_{2T}(t+T)=h_T(-t+T), \qquad 0\le t\le T \tag{16}$$

(a delayed real filter)

or

$$h_{2T}(t+T)=-h_T(-t+T), \qquad 0\le t\le T \tag{17}$$

(a delayed imaginary filter)

The functions h_T and h_{2T} are realized as $h^*(t)$ was realized in Fig. 1. In addition to requiring more than one delay element, the realization possesses practical limitations. If either h_T or h_{2T} contains a term with a decaying exponential factor, then by the symmetry conditions of equations 16 or 17 the other contains a term with a corresponding growing exponential factor which leads to an active unstable lumped-element filter in the over-all realization. Since the matching of gains in the unstable lumped-element filters cannot be exact, it is impossible to make $|h^*(t)|<\infty$ as $t\to\infty$. When the lumped element filters in h_T and h_{2T} have all their poles on the imaginary axis in the p plane a gain matching problem is still present, though it is not nearly so severe. Further remarks on accuracy of realization are given in the section titled "Illustrative Examples."

Many other types of responses are available from filters which contain both lumped elements and delay elements. Various authors have discussed limited classes of such filters.[10,11] For the realization of real and imaginary filters it does not seem worth-while to use more than a single delay element unless several delay elements will allow exact or nearly exact synthesis of the prescribed impulse response (at least within the time-delay T). Certainly, when $h(t)$ consists of sections of rather simple functions this is the case. Another example occurs when

$$h^*(t)=\sum_{n=1}^{N} a_n u_0(t-t_n) \tag{18}$$

t_n = real number

a_n = real number

Such an $h^*(t)$ can be realized with a tapped delay line and a summing amplifier and leads to the periodic transfer functions described by Kallmann,[4] Wiener and Lee,[5,6] White and Ruvin,[7] and Urkowitz.[8]

The Approximation Problem

Approximation involves the representation of a prescribed system function, $h(t)$

Table I

Time Domain		Frequency Domain	
	$\theta_0=1$	$\Theta_0=\frac{2\sin\omega}{\omega}$		$\theta_1=t$	$\Theta_1=j\left(-\frac{2\sin\omega}{\omega^2}+\frac{2\cos\omega}{\omega}\right)$		$\theta_2=\frac{1}{2}(3t^2-1)$	$\Theta_2=-\frac{6\sin\omega}{\omega^3}+\frac{6\cos\omega}{\omega^2}+\frac{2\sin\omega}{\omega}$		$\theta_3=\frac{1}{2}(5t_3-3t)$	$\Theta_3=j\left(\frac{30\sin\omega}{\omega^4}-\frac{30\cos\omega}{\omega^3}-\frac{12\sin\omega}{\omega^2}+\frac{2\cos\omega}{\omega}\right)$		$\theta_4=\frac{1}{8}(35t^4-30t^2+3)$	$\Theta_4=\frac{210\sin\omega}{\omega^5}-\frac{210\cos\omega}{\omega^4}-\frac{90\sin\omega}{\omega^3}+\frac{20\cos\omega}{\omega^2}+\frac{2\sin\omega}{\omega}$		$\theta_5=\frac{1}{8}(63t^5-70t^3+15t)$	$\Theta_5=j\left(\frac{-1890\sin\omega}{\omega^6}+\frac{1890\cos\omega}{\omega^5}+\frac{840\sin\omega}{\omega^4}-\frac{210\cos\omega}{\omega^3}-\frac{30\sin\omega}{\omega^2}+\frac{2\cos\omega}{\omega}\right)$		$\theta_6=\frac{1}{16}(231t^6-315t^4+105t^2-5)$	$\Theta_6=\frac{-20790\sin\omega}{\omega^7}+\frac{20790\cos\omega}{\omega^6}+\frac{9450\sin\omega}{\omega^5}-\frac{2520\cos\omega}{\omega^4}-\frac{420\sin\omega}{\omega^3}+\frac{42\cos\omega}{\omega^2}+\frac{2\sin\omega}{\omega}$		$\theta_7=\frac{1}{16}429t^7-693t^5+315t^3-35t)$	$\Theta_7=j\left(\frac{270270\sin\omega}{\omega^8}-\frac{270270\cos\omega}{\omega^7}-\frac{124740\sin\omega}{\omega^6}+\frac{34650\cos\omega}{\omega^5}+\frac{6300\sin\omega}{\omega^4}-\frac{756\cos\omega}{\omega^3}-\frac{56\sin\omega}{\omega^2}+\frac{2\cos\omega}{\omega}\right)$	
or $H(j\omega)$, in terms of a physically realizable system function ($h^*(t)$ or $H^*(j\omega)$). If the physical system is lumped, then $H^*(j\omega)$ is rational in $j\omega$; if the physical system has a delay real or imaginary transfer function, then $h^*(t)$ and $H^*(j\omega)$ assume the forms discussed in the previous section. Of the many approximating techniques available, this paper will present a minimum integral-square-error approach based on orthogonal approximating functions. Orthogonal function approximation has the following advantages: 1. The integral-square-error is minimized andeasily computed. 2. The approximation may be computed readily in either the time or frequency domains. 3. Approximation error tends to be small throughout the interval of expansion (as opposed to a Taylor expansion where the approximation tends to be good only at one point). 4. Orthogonal functions suitable for realization of real and imaginary filters are well known and tabulated. 5. Additional terms may be added to an approximating series to further reduce error without forcing a new calculation of the terms already determined. Orthogonal functions have been employed by many authors for the synthesis of lumped element systems.[12-16] However, because of the objectives of this paper, different types of approximating functions must be considered here. Whereas the orthogonal time functions which appear in the series for $h^*(t)$ for a lumped-element filter consist of exponential functions defined in the time interval $(0, \infty)$, the functions used in real or imaginary filter approximation must be orthogonal in $(0, 2T)$ and be symmetric or antisymmetric about $t=T$.

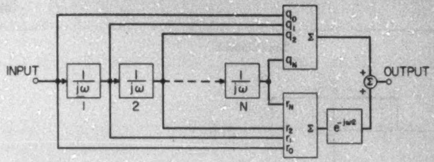

Fig. 3. Realization of real or imaginary filter based on Legendre function approximation

Orthogonal Approximating Functions

Legendre Polynomials

When $h^*(t)$ is a polynomial in t, as is the case when a real or imaginary filter is realized by a delay line and a number of integrators, Legendre polynomials are employed to form an orthogonal set $\theta_0(t)$, $\theta_1(t)$, ... Since Legendre polynomials are orthogonal in $(-1, 1)$ it is necessary to time scale the prescribed response so $h(t)$ is satisfactorily represented in $(-1, 1)$. Once the approximation has been completed, $h^*(t)$, which is in $(-1, 1)$, may be delayed and time scaled to $(0, 2T)$ for physical realization. A later example will illustrate how these delaying and scaling steps are carried out.

Following the usual definition of the Legendre polynomials the θ_n are given by[16]

$$\begin{aligned}\theta_n &= 0, && |t|>1,\ n=0, 1, 2, \ldots\\ &= 1, && -1\leq t\leq 1,\ n=0\\ &= \frac{1}{2^n n!}\,\frac{d^n(t^2-1)^n}{dt^n}, && -1\leq t\leq 1,\ n=1, 2, 3,\end{aligned} \tag{19}$$

This is known as Rodriques' formula. Several of the θ_n are tabulated and plotted in Table I. If higher order functions are required they can be obtained most conveniently from the recursion relation[16]

$$n\theta_n=(2n-1)t\theta_{n-1}-(n-1)\theta_{n-2} \tag{20}$$

The approximating series assumes the form

$$h^*(t)=\sum_{n=0}^{N} c_n\theta_n(t) \tag{21}$$

where

$$c_n=\left(n+\frac{1}{2}\right)\int_{-1}^{1} h\theta_n dt =\left(n+\frac{1}{2}\right)\int_{-\infty}^{\infty} h\theta_n dt \tag{22}$$

The factor $(n+{}^1/_2)$ occurs in equation 22' because the θ_n are not normalized, i.e., $\int_{-1}^{1}\theta_n{}^2dt=(n+{}^1/_2)^{-1}\neq 1$. Since N is finite (filter complexity grows directly with N) the integral-square error,

$$E=\int_{-\infty}^{\infty}(h-h^*)^2dt=\int_{-\infty}^{\infty}h^2dt-\sum_{n=0}^{N}\frac{c_n{}^2}{n+\frac{1}{2}} \tag{23}$$

is in general not zero. Approximation accuracy requirements set an upper bound on E which in turn establishes the minimum N.

From Table I it is seen that the θ_n are symmetric functions for even n and antisymmetric functions for odd n. Thus the even terms are used for a real filter approximation and the odd terms for an imaginary filter approximation. This can also be seen from equation 22 which gives $c_n=0$ for n odd when h is a symmetric function and $c_n=0$ for n even when h is an antisymmetric function.

In the frequency domain equations 21, 22, and 23 become respectively

$$H^*(j\omega)=\sum_{n=0}^{N} c_n\Theta_n(j\omega) \tag{24}$$

$$c_n=\frac{1}{2\pi}\left(n+\frac{1}{2}\right)\int_{-\infty}^{\infty} H\bar{\Theta}_n d\omega \tag{25}$$

and

$$E=\frac{1}{2\pi}\int_{-\infty}^{\infty}|H|^2d\omega-\sum_{n=0}^{N}\frac{c_n{}^2}{n+\frac{1}{2}} \tag{26}$$

where $\Theta_n(j\omega)$ is the Fourier transform of $\theta_n(t)$ and $\bar{\Theta}_n$ is the complex conjugate of Θ_n. Expressions 25 and 26 are derived from 22 and 23 by application of Parseval's theorem.[17]

The formulas for Θ_0 and Θ_1 are

$$\Theta_0=\int_{-\infty}^{\infty}\epsilon^{-j\omega t}\theta_0 dt=\int_{-1}^{1}\epsilon^{-j\omega t}dt=\frac{2\sin\omega}{\omega} \tag{27}$$

and

$$\Theta_1=\int_{-\infty}^{\infty}\epsilon^{-j\omega t}\theta_1 dt=\int_{-1}^{1}\epsilon^{-j\omega t}t\,dt =j2\left[\frac{\cos\omega}{\omega}-\frac{\sin\omega}{\omega^2}\right] \tag{28}$$

Although the higher order functions can be obtained in the same way, a much more rapid procedure is to use the recursion formula

$$\Theta_n=\frac{2n-1}{j\omega}\Theta_{n-1}+\Theta_{n-2} \tag{29}$$

which is developed in the Appendix. The Θ_n are also tabulated and plotted in Table I. As should be expected, the Θ_n are real for even n and imaginary for odd n.

Table I shows that the approximation H^* contains terms of the type

$$\frac{j\sin\omega}{(j\omega)^n}=\frac{\epsilon^{j\omega}-\epsilon^{-j\omega}}{2(j\omega)^n}$$

and

$$\frac{\cos\omega}{(j\omega)^n}=\frac{\epsilon^{j\omega}+\epsilon^{-j\omega}}{2(j\omega)^n}$$

When $h^*(t)$ is delayed by $T=1$ to the interval $(0, 2)$ for realization (time scaling to $(0, 2T)$ will not be considered here) functions of the type

$$\frac{1-\epsilon^{-j\omega 2}}{2(j\omega)^n}$$

and

$$\frac{1+\epsilon^{-j\omega 2}}{2(j\omega)^n}$$

are obtained. Thus H^* assumes the form

$$H^*=\sum_{n=0}^{N} q_n\frac{1}{(j\omega)^n}+\epsilon^{-j\omega 2}\sum_{n=0}^{N} r_n\frac{1}{(j\omega)^n} \tag{30}$$

where the q_n and r_n are determined from the c_n and the expressions for the Θ_n. Fig. 3 shows the realization.

Sine and Cosine Functions in the Time Domain

If a real or imaginary filter is realized with a single delay line and an undamped lumped element filter, h^* consists of sections of sine and cosine functions and the most obvious orthogonal series is a Fourier series in the time domain. (It is possible to generate other orthogonal series from sine and cosine functions. For example the sine and cosine functions would not have to be harmonic.) For convenience we will consider a Fourier series with the interval of expansion $(-1, 1)$. Then the previous remarks which were made concerning time scale still hold.

Since the period of expansion is 2 the Fourier series can be written as

$$\begin{aligned}h^*&=\frac{a_0}{2}+\sum_{n=1}^{N}(a_n\cos\pi nt+b_n\sin\pi nt), && -1\leq t\leq 1\\ &=0, && |t|>1\end{aligned} \tag{31}$$

Because two types of approximating functions are involved for each n ($\sin\pi nt$ and $\cos\pi nt$) the functions

Table II

Time Domain		Frequency Domain	
	$\alpha_0(t)=1$	$A_0(\omega)=\frac{2\sin\omega}{\omega}$		$\beta_1(t)=\sin\pi t$	$B_1(\omega)=-j\frac{2\pi\sin\omega}{\pi^2-\omega^2}$		$\alpha_1(t)=\cos\pi t$	$A_1(\omega)=+\frac{2\omega\sin\omega}{\pi^2-\omega^2}$		$\beta_2(t)=\sin 2\pi t$	$B_2(\omega)=+j\frac{4\pi\sin\omega}{4\pi^2-\omega^2}$		$\alpha_2(t)=\cos 2\pi t$	$A_2(\omega)=-\frac{2\omega\sin\omega}{4\pi^2-\omega^2}$		$\beta_3(t)=\sin 3\omega t$	$B_3(\omega)=-j\frac{6\pi\sin\omega}{9\pi^2-\omega^2}$		$\alpha_3(t)=\cos 3\pi t$	$A_3(\omega)=+\frac{2\omega\sin\omega}{9\pi^2-\omega^2}$		$\beta_4(t)=\sin 4\pi t$	$B_4(\omega)=+j\frac{8\pi\sin\omega}{16\pi^2-\omega^2}$	
$$\begin{aligned}\alpha_n(t)&=\cos\pi nt, && -1\le t\le 1\\ &=0, && |t|>1\end{aligned}\qquad(32)$$

$$\begin{aligned}\beta_n(t)&=\sin\pi nt, && -1\le t\le 1\\ &=0, && |t|>1\end{aligned}\qquad(33)$$

are defined. The Fourier series in equation 31 then becomes

$$h^*(t)=\frac{a_0}{2}\alpha_0+\sum_{n=1}^{N}a_n\alpha_n+\sum_{n=1}^{N}b_n\beta_n\qquad(34)$$

where the coefficients are given by

$$a_n=\int_{-\infty}^{\infty}h\alpha_n dt=\int_{-1}^{1}h\cos\pi nt\,dt\qquad(35)$$

and

$$b_n=\int_{-\infty}^{\infty}h\beta_n dt=\int_{-1}^{1}h\sin\pi nt\,dt\qquad(36)$$

For a real filter $b_n=0$ and for an imaginary filter $a_n=0$. Thus the α_n form real filter approximations and the β_n form imaginary filter approximations.

In the frequency domain the real-filter functions are given by the Fourier transform of the α_n

$$\begin{aligned}A_n&=\int_{-\infty}^{\infty}\epsilon^{-j\omega t}\alpha_n dt=\int_{-1}^{1}\epsilon^{j\omega t}\cos\pi nt\,dt\\ &=\frac{j\omega(-1)^n(\epsilon^{j\omega}-\epsilon^{-j\omega})}{(j\omega)^2+(\pi n)^2}\\ &=-\frac{2\omega(-1)^n\sin\omega}{(j\omega)^2+(\pi n)^2}\end{aligned}\qquad(37)$$

Similarly for the imaginary-filter functions

$$\begin{aligned}B_n&=\int_{-\infty}^{\infty}\epsilon^{-j\omega t}\beta_n dt=\int_{-1}^{1}\epsilon^{-j\omega t}\sin\pi nt\,dt\\ &=\frac{\pi n(-1)^n(\epsilon^{j\omega}-\epsilon^{-j\omega})}{(j\omega)^2+(\pi n)^2}\\ &=j\frac{2\pi n(-1)^n\sin\omega}{(j\omega)^2+(\pi n)^2}\end{aligned}\qquad(38)$$

Table II summarizes these results and shows plots of the functions α_n, β_n, A_n, and B_n. (A brief tabulation of the A_n

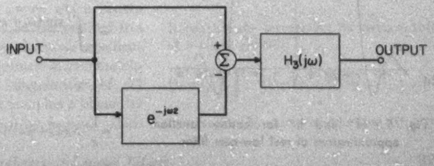

Fig. 4. Realization of real or imaginary filter based on Fourier series approximation

Table III. E_{rel} for Cosine Function Approximation of Real Low Pass Filter, ω_c

N	π	2π	3π	3.5π	4π	4.5π	5π	6π	7π
3	0.0978	0.0511	0.0363	0.0307	0.0869	0.2176	0.3125		
4	0.0976	0.0506	0.0345	0.0287	0.0275	0.0230	0.0702	0.2600	
5	0.0975	0.0504	0.0340	0.0286	0.0260	0.0221	0.0222	0.0589	0.2226

and B_n, and also the Θ_n is given in reference 18.)

The approximation coefficients can be evaluated in the frequency domain by the following equations (obtained by applying Parseval's theorem to equations 35 and 36

$$a_n=\frac{1}{2\pi}\int_{-\infty}^{\infty} H\bar{A}_n d\omega \tag{39}$$

$$b_n=\frac{1}{2\pi}\int_{-\infty}^{\infty} H\bar{B}_n d\omega \tag{40}$$

The integral-square-error is

$$\begin{aligned}E&=\int_{-1}^{1} h^2dt-\frac{a_0^2}{2}-\sum_{n=1}^{N}(a_n^2+b_n^2)\\&=\frac{1}{2\pi}\int_{-\infty}^{\infty}|H|^2d\omega-\frac{a_0^2}{2}-\sum_{n=1}^{N}(a_n^2+b_n^2)\end{aligned} \tag{41}$$

When h^* is delayed to the interval (0, 2) for realization the functions A_n and B_n become

$$A_n\epsilon^{-j\omega}=\frac{j\omega(-1)^n(1-\epsilon^{-j\omega 2})}{(j\omega)^2+(\pi n)^2} \tag{42}$$

and

$$B_n\epsilon^{-j\omega}=\frac{\pi n(-1)^n(1-\epsilon^{-j\omega 2})}{(j\omega)^2+(\pi n)^2} \tag{43}$$

Thus H^* assumes the form

$$H^*=(1-\epsilon^{-j\omega 2})H_3 \tag{44}$$

and may be realized as shown in Fig. 4. For a real filter

$$H_2=\frac{a_0}{2j\omega}+\sum_{n=1}^{N}\frac{a_n(j\omega)(-1)^n}{(j\omega)^2+(\pi n)^2} \tag{45}$$

For an imaginary filter

$$H_3=\sum_{n=1}^{N}\frac{b_n\pi n(-1)^n}{(j\omega)^2+(\pi n)^2} \tag{46}$$

H_3 can be realized as a voltage ratio with lossless passive circuits except for the $a_0/2j\omega$ term.

Illustrative Examples

For the first example a real, ideal low-pass filter is approximated in the time interval $(-1, 1)$ by sine and cosine functions. If the ideal filter has a cut-off frequency ω_c, then the transfer function is

$$\begin{aligned}H=H_R&=1, &&-\omega_c\le\omega\le\omega_c\\&=0, &&|\omega|>\omega_c\end{aligned} \tag{47}$$

and

$$h=\frac{\sin\omega_c t}{\pi t} \tag{48}$$

The coefficients a_n (the $b_n=0$) are determined most easily from equation 35 with h given by equation 48

$$\begin{aligned}a_n&=\int_{-1}^{1}\frac{\sin\omega_c t}{\pi t}\cos\pi nt\,dt=2\int_0^1\frac{\sin\omega_c t}{\pi t}\times\cos\pi nt\,dt\\&=\frac{1}{\pi}\int_0^1\frac{\sin(\omega_c+\pi n)t}{t}dt+\frac{1}{\pi}\int_0^1\frac{\sin(\omega_c-\pi n)t}{t}dt\\&=\frac{1}{\pi}[S_i(\omega_c+\pi n)+S_i(\omega_c-\pi n)]\end{aligned} \tag{49}$$

$S_i(x)=\int_0^x \sin y/y\,dy$, the sine integral function, for which tables are available. The integral-square error is given by equation 41 as

$$E=\frac{\omega_c}{\pi}-\frac{a_0^2}{2}-\sum_{n=1}^{N}a_n^2 \tag{50}$$

A measure of the fractional approximation error is the relative integral square error

$$E_{rel}=\frac{E}{\int_{-\infty}^{\infty}h^2dt} \tag{51}$$

which in this case is

$$E_{rel}=1-\frac{\pi}{\omega_c}\left(\frac{a_0^2}{2}+\sum_{n=1}^{N}a_n^2\right) \tag{52}$$

Since E_{rel} varies with ω_c (the a_n depend on ω_c) it is natural to ask what cut-off frequency yields the best approximation. Table III gives some results for $N=3$, 4, 5. For $N=3$ (four nonzero terms in h^*) the smallest E_{rel} is obtained for $\omega_c=3.5\pi$. Fig. 5 gives the a_n and shows $h^*(t)$ and $H^*(j\omega)$ for $\omega_c=3.5\pi$ and $N=3$. It is not surprising that $\omega_c=3.5\pi$ gives the best approximation since $3.5\pi\cong 3\pi$, the highest frequency component in $h^*(t)$ for $N=3$.

Inasmuch as the $\omega_c=3.5\pi$ design gives the smallest E_{rel} it should serve as the prototype for other cut-off frequencies. Thus, where a cut-off frequency of 3.5π yields $T=1$, a cut-off frequency of ω_c yields $T=3.5\pi/\omega_c$. The transfer function is

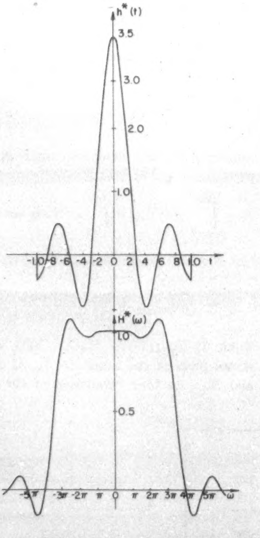

Fig. 5. H* and h* for cosine function approximation of real low-pass filter

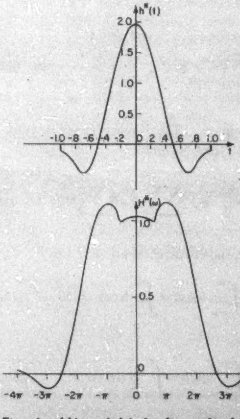

Fig. 6. H* and h* for Legendre function approximation of real low-pass filter

$$H^*=2\left(\frac{3.5\pi\omega}{\omega_c}\right)\sin\frac{3.5\pi\omega}{w_c}\times$$
$$\left[0.5025\left(\frac{\omega_c}{3.5\pi\omega}\right)^2+\frac{-0.9937}{\pi^2-\left(\frac{3.5\pi\omega}{\omega_c}\right)^2}+\right.$$
$$\left.\frac{1.0130}{4\pi^2-\left(\frac{3.5\pi\omega}{\omega_c}\right)^2}+\frac{-0.9356}{9\pi^2-\left(\frac{3.5\pi\omega}{\omega_c}\right)^2}\right] \tag{53}$$

and can be realized in the form of Fig. 4 with an added delay $T=3.5\pi/\omega_c$.

Proceeding in a similar fashion the real, ideal low pass filter can be approximated by Legendre polynomials. The c_n are given by equation 22 with h given by equation 48 and θ_n by Table I. Of course, $c_n=0$ for odd n. Equation 22 involves integrals of the form $\int_0^1 t^k \sin\omega_c t\ dt$ ($k=-1, 1, 3, 5\ldots$) which are readily evaluated. From equations 23 and 51

$$E_{rel}=1-\frac{\pi}{\omega_c}\sum_{n=0}^{N}\frac{1}{n+\frac{1}{2}}c_n^2 \tag{54}$$

In this case the smallest E_{rel} is obtained for $\omega_c=2\pi$ when $N=6$ (four nonzero terms in h^*). Fig. 6 gives the c_n and shows $h^*(t)$ and $H^*(j\omega)$ for $\omega_c=2\pi$ and $N=6$. Note that $E_{rel}=0.0506$ which is somewhat higher than obtained for the same number of terms in the cosine function representation. Using the forgoing design for an $N=6$ prototype yields $T=2\pi/\omega_c$ and the transfer function

$$H^*=\sin\frac{2\pi\omega}{\omega_c}\left[-0.1988\frac{\omega_c}{2\pi\omega}+\right.$$
$$115.6\left(\frac{\omega_c}{2\pi\omega}\right)^3-5{,}195\left(\frac{\omega_c}{2\pi\omega}\right)^5+$$
$$\left.12{,}140\left(\frac{\omega_c}{2\pi\omega}\right)^7\right]+\cos\frac{2\pi\omega}{\omega_c}\times$$
$$\left[-2.747\left(\frac{\omega_c}{2\pi\omega}\right)^2+1{,}148\left(\frac{\omega_c}{2\pi\omega}\right)^4-\right.$$
$$\left.12{,}140\left(\frac{\omega_c}{2\pi\omega}\right)^6\right] \tag{55}$$

Realization in the form of Fig. 3 requires an additional delay $T=2\pi/\omega_c$

The last example is a sine and cosine function approximation of the imaginary, ideal low-pass filter characteristic

$$\begin{aligned}H=jH_I&=+j, & 0<\omega\le\omega_c\\ &=-j, & -\omega_c\le\omega<0\\ &=0, & \omega=0,\ |\omega|>\omega_c\end{aligned} \tag{56}$$

and

$$h=\frac{\cos\omega_c t-1}{\pi t} \tag{57}$$

The coefficients b_n (the $a_n=0$) are given from equation 36 and 57 by

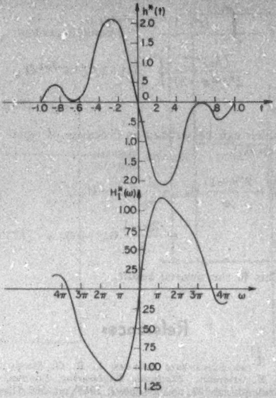

Fig. 7. H* and h* for sine function approximation of imaginary low-pass filter

$$b_n=2\int_0^1\frac{\cos\omega_c t-1}{\pi t}\sin\pi n t\ dt$$
$$=\frac{1}{\pi}[S_i(\pi n+\omega_c)-2S_i(\pi n)+S_i(\pi n-\omega_c)] \tag{58}$$

and the relative mean square error by

$$E_{rel}=1-\frac{\pi}{\omega_c}\sum_{n=1}^{N}b_n^2 \tag{59}$$

In this case, E_{rel} is near its smallest value at $\omega_c=3\pi$ when $N=4$ (four nonzero terms in h^*) where $E_{rel}=0.119$. The relatively large E_{rel} is probably caused by the discontinuity in H at $\omega=0$ in addition those at $\omega=\pm\omega_c$. Fig. 7 gives the b_n and shows $h^*(t)$ and $HI^*(j\omega)$ for $\omega_c=3\pi$ and $N=4$.

Both of the realizations in Figs. 3 and 4 have parallel signal paths, one of which is direct and a second which is through a delay line. Gain matching in the two paths must be exact or cancellation of $h_1(t)$ and $h_2(t-2T)$ will not occur for $t>2T$. In the case of the Legendre realization any difference between $h_1(t)$ and $h_2(t-2T)$ grows as t^N which cause a large error in the realized frequency response at zero frequency; in the case of sines or cosines realization the difference between $h_1(t)$ and $h_2(t-2T)$ oscillates with small amplitude at frequencies $\omega=\pi n$ which causes undesired resonances, in the realized frequency response. A practical expedient for reducing the criticalness in gain matching is to shift the singularities of H^* slightly to the left in complex p plane (by replacing $j\omega$ in $H^*(j\omega)$ by $j\omega+\sigma_0$). This causes $h^*(t)$ to become multiplied by $\epsilon^{-\sigma_0 t}$, a damping factor which is effective in reducing the error for large t. The shift σ_0 should be made as small as possible consistent with the obtainable accuracy in gain matching as the shift causes H^* to depart from the desired real or imaginary characteristics.

Conclusions

In this paper the synthesis of real and imaginary transferfunctions has been described. Realization is only possible within a time lag T, and requires a delay element filter with a finite memory of $2T$. The approximation problem has been solved in both the frequency domain and time domain by the introduction of two sets of orthogonal approximating functions, one based on Legendre polynomials in the time domain and the other on sines and cosines in the time domain. It appears that the latter approximating functions have the following realization advantages: 1. realization is simple in form, consisting of $(1-\epsilon^{-j\omega 2T})$ and H_3 in cascade and 2. at most, only one pole is required at $p=0$.

Appendix

Development of Recursion Formula for Legendre Function $\Theta_n(j\omega)$

From equation 19

$$\Theta_n(j\omega)=\int_{-\infty}^{\infty}\epsilon^{-j\omega t}\Theta_n dt$$
$$=\frac{1}{2^n n!}\int_{-1}^{1}\frac{d^n(t^2-1)^n}{dt^n}\epsilon^{-j\omega t}dt \tag{60}$$

Integration by parts of equation 60 gives (making the derivative of $\epsilon^{-j\omega t}$ appear in the new integrand)

$$\Theta_n(j\omega)=\frac{1}{2^n n!}\left\{\frac{d^{n-1}(t^2-1)^n}{dt^{n-1}}\epsilon^{-j\omega t}\right\}\Bigg|_{-1}^{1}+$$
$$j\omega\int_{-1}^{1}\frac{d^{n-1}(t^2-1)^n}{dt^{n-1}}\epsilon^{-j\omega t}dt \tag{61}$$

but

$$\frac{d^{n-1}(t^2-1)^n}{dt^{n-1}}=0\text{ for }t=\pm 1$$

Hence

$$\Theta_n=j\omega\int_{-1}^{1}\frac{d^{n-1}(t^2-1)^n}{dt^{n-1}}\epsilon^{-j\omega t}dt \tag{62}$$

Repeating the integration by parts a total of n times yields

$$\Theta_n=\frac{(j\omega)^n}{2^n n!}\int_{-1}^{1}(t^2-1)^n\epsilon^{-j\omega t}dt \tag{63}$$

Integration by parts of equation 63 gives (making the integral of $\epsilon^{-j\omega t}$ appear in the new integrand)

$$\Theta_n=\frac{(j\omega)^n}{2^n n!}\left\{(t^2-1)^n\frac{\epsilon^{-j\omega t}}{(-j\omega)}\right\}\Bigg|_{-1}^{1}+$$

$$\frac{(j\omega)^{n-1}}{2^{n-1}(n-1)!}\int_{-1}^{1}(t^2-1)^{n-1}\,t\epsilon^{-j\omega t}\,dt$$

$$=\frac{(j\omega)^{n-1}}{2^{n-1}(n-1)!}\int_{-1}^{1}(t^2-1)^{n-1}t\epsilon^{-j\omega t}\,dt,\qquad n>0 \quad (64)$$

Finally, a similar integration by parts of equation 64 gives

$$\Theta_n=\frac{(j\omega)^{n-1}}{2^{n-1}(n-1)!}\left\{(t^2-1)^{n-1}\,t\,\frac{\epsilon^{-j\omega t}}{(-j\omega)}\right\}\Bigg|_{-1}^{1}+$$

$$\frac{2(n-1)}{j\omega}\int_{-1}^{1}(t^2-1)^{n-2}\,t^2\epsilon^{-j\omega t}\,dt+$$

$$\frac{1}{j\omega}\int_{-1}^{1}(t^2-1)^{n-1}\,\epsilon^{-j\omega t}\,dt$$

$$=\frac{(j\omega)^{n-2}}{2^{n-2}(n-2)!}\int_{-1}^{1}(t^2-1)^{n-2}\,t^2\epsilon^{-j\omega t}\,dt+$$

$$\frac{(j\omega)^{n-2}}{2^{n-1}(n-1)!}\int_{-1}^{1}(t^2-1)^{n-1}\,\epsilon^{-j\omega t}\,dt,\qquad n>1 \quad (65)$$

Adding and subtracting

$$\frac{(j\omega)^{n-2}}{2^{n-2}(n-2)!}\int_{-1}^{1}(t^2-1)^{n-2}(t^2-1)\epsilon^{-j\omega t}\,dt,$$

$$\Theta_n=\frac{(j\omega)^{n-2}}{2^{n-2}(n-2)!}\int_{-1}^{1}(t^2-1)^{n-2}(t^2-1)\times$$

$$\epsilon^{-j\omega t}\,dt+\frac{j\omega^{n-2}}{2^{n-1}(n-1)!}\times$$

$$\int_{-1}^{1}(t^2-1)^{n-1}\,\epsilon^{-j\omega t}dt+$$

$$\frac{(j\omega)^{n-2}}{2^{n-2}(n-2)!}\int_{-1}^{1}(t^2-1)^{n-2}\,\epsilon^{-j\omega t}\,dt \quad (66)$$

which can be written as (because of equation 63)

$$\Theta_n=\frac{2(n-1)}{j\omega}\,\Theta_{n-1}+\frac{1}{j\omega}\,\Theta_{n-1}+\Theta_{n-2}$$

$$=\frac{2n-1}{j\omega}\,\Theta_{n-1}+\Theta_{n-2} \quad (67)$$

This is the desired result.

Design of an Eddy-Current Brake for a Sodium-Cooled Nuclear Power Reactor

R. S. BAKER
MEMBER AIEE

THE sodium-cooled nuclear power reactor, known as the sodium reactor experiment (SRE), is operated by Atomics International, a division of North American Aviation, Inc., for the Atomic Energy Commission. The reactor is located in the Santa Susana Mountains near Los Angeles, Calif. The design features of this reactor have been outlined by Siegel.[1]

During the early operation of this reactor, it was determined that some form of sodium-flow throttling device was necessary to prevent excessive thermal stresses from occurring in the reactor core and sodium piping after a shutdown, or "scram."

When the reactor is shut down, the production of heat within it reduces to a small fraction of its former value. This small amount of heat (due to afterglow) that is still being produced is sufficient to cause circulation of sodium into and out of the reactor by thermal convection. The result is that sodium, at a relatively low temperature, is brought into contact with piping which is still at a high temperature, thereby leading to excessive thermal stresses. These stresses can be minimized by controlling the sodium flow in proportion to the heat generation, resulting in constant temperature gradients.

Method Used to Control Flow after Shutdown

For the purpose of throttling the sodium flow throughout the reactor piping to maintain a constant reactor temperature gradient for afterglow power conditions, two eddy-current brakes were installed in the SRE. One is used on the primary piping system, the other on the secondary system. Each is constructed as shown in Fig. 1.

Both brakes are controlled by thermo-

Paper 60-150, recommended by the AIEE Nucleonics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted June 27, 1958; made available for printing December 8, 1959.

couples that measure sodium temperatures in primary and secondary systems. Performance has been satisfactory. The braking pressures obtained at different sodium flow rates agree with calculated figures.

Design Calculations

DETERMINATION OF REQUIRED FLUX DENSITY

To begin the design of the d-c electromagnet which constitutes the brake, a basic configuration was assumed; see Fig. 1. Dimensions of the braking section and thermal barriers are shown in Fig. 2, where the symbols represent quantities that will be used later in the design calculations. Fig. 3 shows dimensions of the braking section and pole face in planes parallel to the flow direction. Fig. 4 shows the yoke without coils and braking section.

The calculation of magnet design to produce a given braking pressure is based on Rudenberg's equation for the eddy-current drag on a copper disk.[2,3] Written in terms of the quantities used in designing the eddy-current brakes, this equation becomes

$$P=\frac{8.5\times10^{-16}\,QB^2_G}{r_1d_1}\times\left[\frac{\dfrac{d_3}{d_4}+\dfrac{d_4}{d_3}}{\left(\dfrac{39.2\times10^{-9}Q}{r_1d_2}\right)^2+\left(\dfrac{d_3}{d_4}+\dfrac{d_4}{d_3}\right)^2}\right] \qquad (1)$$

In test runs conducted at the SRE, it was determined that under scram conditions the sodium flow rate in the main primary circuit, through the reactor, should drop to about 12 gallons per minute. It was also determined that the eddy-current brake should cause a dragging pressure of 0.3 psi (pounds per square inch) at this flow rate. The flux density necessary to produce this drag pressure was calculated from equation 1, for a sodium temperature of 1,000 degrees Fahrenheit.

$P=0.3$ psi
$d_1=2$ inches
$d_2=4$ inches
$d_3=7^3/_4$ inches
$d_4=10$ inches (this value was determined by adding an estimated amount of 2.25 inches for pole face chamber to d_3.)
$Q=12$ gallons per minute
$r_1=10.5\times10^{-6}$ ohm-inches

Solving for B_G yields $B_G=35{,}800$ lines per square inch.

CALCULATION OF MAGNETOMOTIVE FORCE REQUIRED

The next step in the design was the calculation of the coil ampere-turns required to set up this flux density. Two coils were used, one on each side of the air gap, and placed as close as possible to the gap. Each coil was proportioned to have as nearly as possible the maximum ratio of inductance to resistance. This requires that each coil be square in cross section, with a mean diameter which is 3.02 times the length of one side;[4,5] see Fig. 1. Because of space limitations, it was not possible to construct the magnet yoke to meet this requirement precisely; however, the actual performance has not been measurably affected.

Fig 3. Section A-A of Fig. 1(A)

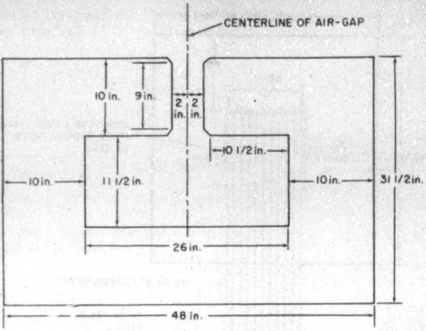

Fig. 4. View of yoke without coils and braking section

The effects of fringing and leakage were taken into account by empirical and analytical methods (see reference 6, and equation 14 of reference 7). The first of these, the fringing effect, causes an increase in the magnetomotive force as denoted by the fringing factor f_1 in the equation

$$AT_G = 0.313\ B_G d_2 f_{21} \tag{2}$$

From page 14 of reference 6, $f_1 = 1.5$; thus $AT_G = 0.313 \times 35{,}800 \times 4 \times 1.5 =$ 67,100 ampere-turns.

The second effect, the leakage factor f_2 was used in calculating the magnet yoke dimension d_6 in the equation

$$d_4 \times d_6 = \frac{f_2 B_G A_G}{B_m} \tag{3}$$

$$f_2 = 1 + \frac{3.4d_2(d_4+d_6)}{d_4 d_6} \times \left[\frac{d_8}{d_2+d_8} + \frac{0.45d_4}{d_2+0.67d_4+2d_8}\left(1+\frac{d_2+2d_8}{d_4}\right)\right] \tag{4}$$

(from reference 7).

The values of the quantities in the right-hand member of equation 4 are listed below. It will be noted that a value of 10 inches was assumed for d_6, which resulted in a square cross section of the yoke. The procedure was to calculate f_2, then solve for B_M in equation 3. If the value of B_M thus determined had been greater than the saturation flux density of 115,000 lines per square inch, it would have been necessary to assume a larger value for d_6. As shown by the calculations that follow, the value of 10 inches is satisfactory. In inches,

$d_2 = 4$
$d_4 = 10$
$d_6 = 10$
$d_8 = 0.5$

Then, $f_2 = 2.86$ and upon substituting this value in equation 3 and solving for B_M, it was found that $B_M = 102{,}000$ lines per square inch, which is a satisfactory operating flux density for the steel yoke. The reluctance drop in the steel from one side of the air gap, through the yoke around to the other side, was found to be 8,880 ampere turns.[8] This amount was added to the air-gap ampere-turns calculated in equation 2, to determine the wire size necessary for the coils.

Coil Design

The next step in designing the brake was to assume a coil current I of 10 amperes, direct current. Then, under the assumption that the coil is square in cross section, $d_4 = d_5 = 10$ inches.

The mean length of turn d_7 was calculated by the equation

$$d_7 = 2(d_4+d_5) + 2(d_6+d_5) = 2(d_4+2d_5+d_6)$$

$$d_7 = 80 \text{ inches}$$

The cross-section area of the coil conductor for a winding temperature of 60 C (degrees centigrade), or 140 degrees Fahrenheit, was calculated from the equation

$$A = \frac{kd_7NI}{1.16E} \tag{5}$$

(from reference 9).

where

$$k = \frac{100}{98} + 0.004(60-20) = 1.18 \text{ for copper of } 98\% \text{ conductivity at 60 C}$$

$$NI = \frac{67{,}100+8{,}880}{2} = 37{,}990 \quad \text{ampere-turns per coil}$$

$$E = 120 \text{ volts}$$

$$A = \frac{1.18 \times 80\ 37{,}990}{1.16 \times 120} = 25{,}200 \text{ circular mils}$$

No. 6 American Wire Gage double glass insulated wire was used for winding the coils, each of which was wound with approximately 3,400 turns. The cross section of each coil is approximately 10 by 10 inches; therefore the initial choice of magnet dimensions was correct.

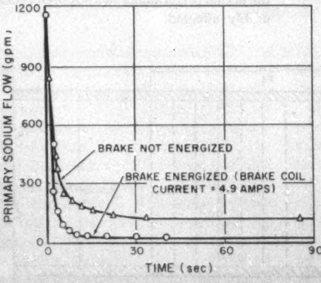

Fig. 5. Flow of sodium in SRE main primary piping circuit reactor to heat exchanger versus time, after reactor shutdown

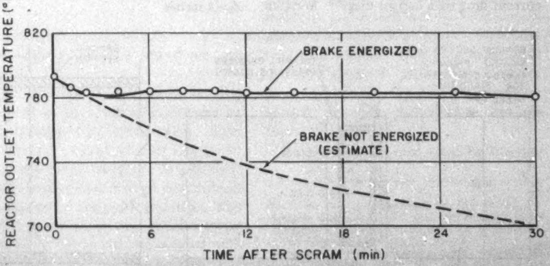

Fig. 6. Temperature of sodium at SRE reactor outlet to primary system versus time, after reactor shutdown

POWER LOSS IN COILS

The resistance of each coil at the operating temperature was calculated from

$$r_2=\frac{kd_7N}{1.16A} \qquad (6)$$

(from reference 9)

where

$$r_2=\frac{1.18\times 80\times 3{,}400}{1.16\times 22{,}700}=12.2 \text{ ohms}$$

Power loss in each coil = 10×120 = 1,200 watts.

Brake Performance

The effects of the eddy-current brake on the primary system are shown in Figs. 5 and 6. These curves illustrate the manner in which sodium flow in the primary system and sodium temperature at the reactor outlet vary with time for the condition where the brake is not energized, and the condition where the brake is energized, at the time of reactor shutdown.

It is possible to make the dragging pressure a maximum by variation of the dimensions of the brake, e.g., d_3, by taking $\partial P/\partial d_3$ from equation 1, setting $\partial P/\partial d_3=0$, and solving for d_3.

Nomenclature

P = dragging pressure in the sodium, psi
Q = sodium flow through the braking section, gallons per minute
d_1,d_2,d_3,d_4 = dimensions of braking section, shown in Figs. 1, 2, and 3, inches
B_G = flux density in sodium, lines per square inch
r_1 = resistivity of sodium, ohm-inches
f_1 = fringing factor (dimensionless)
f_2 = leakage factor (dimensionless)
AT_G = ampere-turns for air gap
B_m = flux density in steel yoke, lines per square inch
d_5 = coil dimensions shown in Fig. 1, inches
d_6 = yoke dimension shown in Fig. 1, inches
d_7 = mean length of coil turn, inches
d_8 = space between edge of coil and pole face, inches
A = cross-section area of coil conductor, circular mils
k = ratio of resistivity of copper conductor, used in coil winding to that of standard annealed copper at 20 C. For copper of $C\%$ conductivity at T C

$$k=\frac{100}{C}+0.004(T-20)$$

N = number of turns per coil
I = coil current, amperes
E = coil voltage
r_2 = resistance of each coil at operating temperature, ohms
A_G = area of pole face, square inches
$A_G=d_4\times d_6$

Difference Equations and Their Applications

LOUIS A. PIPES
MEMBER AIEE

Synopsis: This paper is intended to introduce the methods and literature of difference equations to engineers who are unaquainted with them or their wide applicability and power.

The nature of the calculus of finite difference is presented and the basic operators used in this calculus are defined. The general theory of linear difference equations with constant coefficients is discussed in detail and applied to the solution of typical electrical and mechanical problems. The paper is concluded with a short discussion of the use of difference equations for the approximate solution of ordinary and partial differential equations. A short summary of additional applications of difference equations is given with reference to the current literature.

DURING the last 15 years there has been a great deal of activity in the application of difference equations in the solution of many problems that arise in statistics, science, and engineering.

The development of high-speed digital computing machinery has motivated the use of difference equations as approximations to ordinary and partial differential equations.[1–3] The use of difference equations for solving partial differential equations was discussed in 1928 in a celebrated paper by Courant, Friedrichs, and Lewy.[4] However, the methods presented in this paper were not put into practical use until about 1943 as a result of the stimulus of war-time technology and with the assistance of the first digital automatic computers. Problems involving time-dependent fluid flows, neutron diffusion and transport, radiation flow, thermonuclear reactions, and problems involving the solution of several simultaneous partial differential equations are being solved by the use of difference equations throughout the country.

Besides the use of difference equations as approximations to ordinary and partial differential equations, they afford a powerful method for the analysis of electrical, mechanical, thermal, and other systems in which there is a recurrence of identical sections.

The study of the behavior of electric-wave filters, multistage amplifiers, magnetic amplifiers, insulator strings, continuous beams of equal span, crankshafts of multicylinder engines, acoustical filters, etc., is greatly facilitated by the use of difference equations. The usual methods for solving such systems are generally very lengthy when the number of elements involved is large. The use of difference equations greatly reduces the complexity and labor involved in the solution of problems of this type.

Nature of the Calculus of Finite Differences

As is well known, the most important concept of mathematical analysis is that

Paper 60-203, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted September 15, 1958; made available for printing December 22, 1959.

LOUIS A. PIPES is with the University of California, Los Angeles, Calif.

of a function. If to a given value of x a certain value of y corresponds, it is said that y is a function of the independent variable x and one writes symbolically $y(x)$. Two types of functions occur in the applications of mathematical analysis to physical problems; first there are functions in which the variable x may take every possible value in a given interval, that is, the variable x is continuous. Functions of this type are studied in the ordinary Differential and Integral Calculus.

A second type of function exists in which the variable x takes only the given values $x_1, x_2, x_3, \ldots x_n$. In this case, the variable x is discontinuous. The methods of the ordinary calculus are not in general applicable to such functions. The calculus of finite differences deals especially with functions of the second type, but it may be applied to functions of the first type as well. The origin of the calculus of finite differences is usually ascribed to Brooks Taylor who published his, "Methodus Incrementorum" in 1717. He pointed out that the relations between the terms of arithmetic and geometric progressions, which were known for a long time, represented the simplest examples of difference equations.

There are many analogies between the differential and integral calculus and the calculus of finite differences. For example, in the calculus of finite differences, the first difference, which is denoted by $\Delta(h)F(x)$ is defined by,

$$\Delta(h)F(x)=F(x+h)-F(x) \qquad (1)$$

In the differential calculus, the first derivative of a function $F(x)$ is defined by the equation,

$$DF(x)=\operatorname*{Limit}_{h\to 0}\frac{[F(x+h)-F(x)]}{h}$$

$$=\operatorname*{Limit}_{h\to 0}\frac{[\Delta(h)F(x)]}{h} \qquad (2)$$

It can be shown that the nth derivative of $F(x)$ may be expressed in the form,

$$D^nF(x)=\operatorname*{Limit}_{h\to 0}\frac{[\Delta(h)F(x)]}{h} \qquad (3)$$

The operator $\Delta(h)$ is called the forward difference operator. When there cannot be any misunderstanding about the increment h, the difference operator $\Delta(h)$ is mere written as Δ.

BASIC OPERATORS USED IN THE CALCULUS OF FINITE DIFFERENCES

The following fundamental operators are used widely in the Calculus of Finite Differences.

1. The Displacement Operator E

$$EF(x)=F(x+h) \qquad (4)$$

2. The Forward Difference Operator Δ.

$$\Delta F(x)=F(x+h)-F(x) \qquad (5)$$

3. The Backward Difference Operator ∇.

$$\nabla F(x)=F(x)-F(x-h) \qquad (6)$$

4. The Central Difference Operator δ.

$$\delta F(x)=F(x+h/2)-F(x-h/2) \qquad (7)$$

5. The Averaging Operator μ.

$$\mu F(x)=\frac{1}{2}[F(x+h/2)+F(x-h/2)] \qquad (8)$$

6. The Symbolic Representation of Taylor's Expansion.

$$e^{hD}F(x)=F(x+h),\ e=\text{base of natural logarithms},\ D=\frac{d}{dx} \qquad (9)$$

EQUIVALENT OPERATORS

If the fundamental basic defitions given previously are used, the following equivalent operators may be easily deduced.

$$E=e^{hD} \qquad (10)$$

$$\Delta=(E-1) \qquad (11)$$

$$\nabla=(1-E^{-1}) \qquad (12)$$

$$\delta=E^{1/2}-E^{-1/2} \qquad (13)$$

$$\mu=\frac{1}{2}\delta=\frac{1}{2}(E^{1/2}+E^{-1/2}) \qquad (14)$$

It can be shown[5-8] that except for a few restrictions, these operators can be manipulated according to the laws of ordinary algebra, and many relations between the basic operators may be obtained.

For example, one may write,

$$D=\frac{\ln E}{h}=\ln(1+\Delta)/h \qquad (15)$$

by the use of equations 10 and 11. Similarly by the use of equations 10 and 12, one has

$$\nabla=(1-E^{-1})=(1-e^{-hD}) \qquad (16)$$

It is easy to show that the operators δ and μ may be expressed in the forms

$$\delta=2\sinh(hD/2) \qquad (17)$$

$$\mu=\cosh(hD/2) \qquad (18)$$

An interesting and useful exposition of the symbolic calculus of operators will be found in a paper by Bickley.[9] By the use of these operators, and the relations between them, several finite difference formulas for interpolation, differentiation, integration, scanning, etc., may be obtained. These formulas are of great importance in numerical analysis.

For example, if the logarithm in equation 15 is expanded in powers of Δ, one obtains,

$$D=\frac{\ln(1+\Delta)}{h}=\frac{1}{h}(\Delta-\Delta^2/2+\Delta^3/3-\Delta^4/4+\ldots) \qquad (19)$$

This expression may be used to compute the derivative of a function in terms of its forward differences.

THE SCANNING OPERATOR, $S(h)$

In the theory of scanning, if one is given a function $F(z)$, it is required to obtain the functions $\phi(x)$ defined by,

$$\phi(x)=\int_{(q-h/)2.}^{(x+h/2)}F(z)dz \qquad (20)$$

If equation 20 is differentiated with respect to x, the result is,

$$D\phi(x)=F(x+h/2)-F(x-h/2)=\delta F(x) \qquad (21)$$

Hence,

$$\phi(x)=\frac{\delta}{D}F(x)=S(h)F(x) \qquad (22)$$

where $S(h)$ is the scanning operator defined by,

$$S(h)=\frac{\delta}{D}=\frac{2\sinh(hD/2)}{D}=\frac{h\sinh(hD/2)}{(hD/2)} \qquad (23)$$

If $\phi(x)$ is known, and it is desired to determine $F(x)$, one may write,

$$F(x)=S^{-1}(h)\phi(x) \qquad (24)$$

In equation 24, $S^{-1}(h)$ is the inverse scanning operator.

Linear Difference Equations with Constant Coefficients

The most important difference equations that arise in applications to electrical circuits, dynamics, structural problems, etc., are linear difference equations with constant coefficients.

These equations are of the type,

$$(a_nE^n+a_{n-1}E^{n-1}+\ldots+a_1E+a_0)y(x)=V(x) \qquad (25)$$

In the usual applications of difference equations, $h=1$, so that the operator E is defined by,

$$E^ky(x)=y(x+k),\ k=0, 1, 2, 3, \ldots \qquad (26)$$

Difference equations are classified in the same manner as differential equations. Equation 25 is called a linear difference equation of order n with constant coefficients, provided that the coefficients a_k are constants. If $V(x)=0$, then the equation is said to be homogeneous; if not, it is said to be nonhomogeneous. Let,

$$P(E)=(a_nE^n+a_{n-1}E^{n-1}+\ldots+a_1E+a_0) \qquad (27)$$

The general solution of equation 25 may be written in the form,

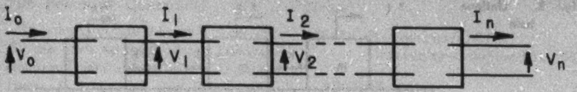

Fig. 1. Cascade connection of circuits

$$y=(y_c(x)+y_p(x)) \qquad (28)$$

If equation 28 is substituted into equation 27 the result is,

$$P(E)(y_c+y_p)=0 \qquad (29)$$

Now let,

$$P(E)y_c(x)=0 \qquad (30)$$

and

$$P(E)y_p(x)=V(x) \qquad (31)$$

By analogy to the solution of linear differential equations with constant coefficients, y_c is called the complementary function, and y_p is called the particular integral of the difference equation, equation 25.

DETERMINATION OF THE COMPLEMENTARY FUNCTION

To determine the complementary function $y_c(x)$, assume a tentative solution of the following form:

$$y_c(x)=Aq^x \qquad (32)$$

where A is an arbitrary constant and q is a number to be determined so that equation 32 is a solution of equation 30. It is noticed that if the operator E^k is applied to equation 32, the result is,

$$E^k y_c(x)=E^k Aq^x=q^k Aq^x=q^k y_c(x) \qquad (33)$$

It is therefore evident that if equation 32 is substituted into equation 30 the result may be written in the following form,

$$P(E)y_c(x)=P(q)y_c(x)=0 \qquad (34)$$

If the trivial solution $y_c(x)$ is excluded, then one must have,

$$P(q)=0 \qquad (35)$$

This is the characteristic equation of the difference equation, equation 25. The characteristic equation is an algebraic equation of the nth degree in q. The roots of this equation determine the possible values of q that allow equation 32 to be a solution of equation 30.

If the roots of equation 35 are the distinct numbers $q_1, q_2, \ldots q_n$, then the general solution of equation 30 may be written in the form,

$$y_c(x)=A_1 q^x{}_1+A_2 q_2{}^x+\ldots+A_n q_n{}^x \qquad (36)$$

The quantities A_k in equation 36 are arbitrary constants to be determined when the boundary conditions of the difference equation are given. The general solution of equation 36 is valid provided that the roots, q_k of the characteristic equation 35 are real or complex numbers provided that they are distinct.

If the characteristic equation 35 has a multiple root q_1 of the rth order, it can be shown[7] that the part of the general solution that corresponds to this rth fold repeated root is,

$$y_1(x)=(A_1+A_2x+\ldots+A_r x^{r-1})q_1{}^x \qquad (37)$$

where the A_k's are arbitrary constants.

THE PARTICULAR INTEGRAL

The difference equations most frequently encountered in practice are linear and homogeneous with constant coefficients. The various methods for obtaining the particular integrals of linear equations with constant coefficients have their counterpart in the theory of linear differential equations.[5,7,8] The special method to be used depends on the nature of the function $V(x)$. To illustrate the general procedure, let the function $V(x)$ be of the exponential form $V(x)=K\exp(mx)$. Let.

$$P(E)=(a_nE^n+a_{n-1}E^{n-1}+\ldots+a_1E+a_0) \qquad (38)$$

The difference equation for the particular integral is now,

$$P(E)y_p(x)=Ke^{mx} \qquad (39)$$

In this case, to obtain the particular integral assume a solution of the form,

$$y_p(x)=Ce^{mx} \qquad (40)$$

where C is to be determined. Now since,

$$E^k Ce^{mx}=Ce^{m(x+k)}=Ae^{mk}e^{mx} \qquad (41)$$

It follows that,

$$P(E)Ce^{mx}=Ce^{mx}P(e^m) \qquad (42)$$

Hence if equation 40 is substituted into equation 39, the following result is obtained:

$$Ce^{mx}P(e^m)=Ke^{mx} \qquad (43)$$

If $P(e^m)\neq 0$, then C is given by

$$C=K/P(e^m) \qquad (44)$$

the particular integral in this case is then,

$$y_p(x)=Ke^{mx}/P(e^m) \qquad (44A)$$

In general, the particular integral which is the solution of the equation

$$P(E)y_p(x)=V(x) \qquad (45)$$

may be obtained by an operational manipulation of equation 45 and can be expressed symbolically in the form,

$$y_p=P^{-1}(E)V(x) \qquad (46)$$

If $V(x)$ is a rational and integral function of x it is possible to expand $P^{-1}(E)$ in a series of ascending powers of Δ by the substitution $E=(1+\Delta)$, and operate with this series on $V(x)$. If $V(x)$ is a rational and integral function of x, the result of this operation will give a finite number of terms.

In some cases it is convenient to expand the operator $P^{-1}(E)$ into partial fractions. If this is done, the required particular integral may be obtained in terms of indefinite sums.[7]

Applications of Difference Equations to the Analysis of a Uniform Electric Network

An interesting and typical technical problem that illustrates the use of difference equations, is to determine the current and potential distribution of the electric circuit shown in Fig. 1, in the periodic steady alternating state.

The circuit of Fig. 1 is a cascade connection of n-boxes. Each box contains the Pi network of impedances Z and admittances $Y/2$ as shown in Fig. 2.

Each box of the network of Fig. 1 contains the Pi network of Fig. 2. This consists of a symmetrical arrangement of two shunt admittances $Y/2$ and a series impedance Z.

If the sending-end potential V_0 and the sending-end current are specified, it is required to determine the potential and current distribution of the uniform network. If Kirchhoff's first and second laws are applied to the network of Fig. 2, the following simultaneous difference equations are obtained:

$$I_{k-1}=I_k+\frac{1}{2}Y(V_k+V_{k-1}) \qquad (47)$$

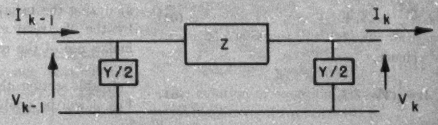

Fig. 2. Fundamental circuit

$$V_{k-1}=V_k+Z\left(I_{k-1}-\frac{Y}{2}V_{k-1}\right) \qquad (48)$$

In order to solve the simultaneous system of difference equations 47 and 48, it is necessary to separate the variables.

If equation 48 is solved for I_{k-1}, the result is

$$I_{k-1}=\frac{1}{Z}(V_{k-1}-V_k)+\frac{Y}{2}V_{k-1} \qquad (49)$$

If this equation is used to eliminate I_{k-1} and I_k in equation 47, the result is

$$V_{k+1}-(2+ZY)V_k+V_{k-1}=0 \qquad (50)$$

Equation 50 is a homogeneous difference equation of the second order of the type discussed in the previous section. Its solution is of the form,

$$V_k=Aq^k \qquad (51)$$

where A is an arbitrary constant and q satisfies the characteristic equation,

$$q^2-(2+ZY)q+1=0 \qquad (52)$$

The two roots of this equation satisfy the following equations:

$$q_1\cdot q_2=1 \qquad (53)$$

$$q_1+q_2=(2+ZY) \qquad (54)$$

Now let,

$$q_1=e^a, \quad q_2=e^{-a} \qquad (55)$$

where e is the base of the natural logarithms. Then,

$$(q_1+q_2)=(2+ZY)=2\cosh(a) \qquad (56)$$

THE PROPAGATION CONSTANT OF THE NETWORK

$$a=\cosh^{-1}(1+ZY/2)=\text{propagation constant} \qquad (57)$$

$$V_k=A_1e^{ak}+A_2e^{-ak} \qquad (58)$$

$$I_k=\frac{1}{Z}(V_k-V_{k+1})+\frac{Y}{2}V_k=\frac{1}{Z_0}\times[-A_1e^{ak}+A_2e^{-ak}] \qquad (59)$$

The quantity Z_0 is the characteristic impedance of the network and it is given by,

$$Z_0=\frac{2}{Y}\tanh(a/2) \qquad (60)$$

THE DETERMINATION OF THE ARBITRARY CONSTANTS

The two arbitrary constants A_1 and A_2 may be obtained from the following boundary conditions,

$$V_0=A_1+A_2 \qquad (61)$$

$$I_0=\frac{1}{Z_0}(-A_1+A_2) \qquad (62)$$

Hence,

$$A_1=\frac{1}{2}(V_0-Z_0I_0) \qquad (63)$$

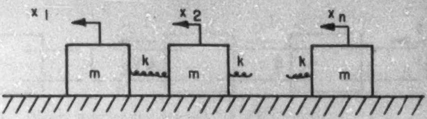

Fig. 3. Uniform train

$$A_2=(V_0+Z_0I_0)/2 \qquad (64)$$

If these values of A_1 and A_2 are substituted into equations 58 and 59 the results may be expressed in the following form,

$$V_k=V_0\cosh(ak)-Z_0I_0\sinh(ak) \qquad (65)$$

$$I_k=-V_0\frac{\sinh(ak)}{Z_0}+I_0\cosh(ak) \qquad (66)$$

where $k=0, 1, 2, \dots n$. To shorten the writing it is convenient to introduce the following matrix $[T]$. This matrix is known in the literature as the transmission or the chain-matrix of the network. This matrix is defined by the following equation,

$$[T]=\begin{bmatrix}\cosh(a) & Z_0\sinh(a)\\ \dfrac{\sinh(a)}{Z_0} & \cosh(a)\end{bmatrix}=\text{transmission matrix} \qquad (67)$$

If the following column matrix is introduced,

$$(y)_k=\begin{bmatrix}V_k\\ I_k\end{bmatrix} \qquad (68)$$

then equations 65 and 66 may be written in the compact matrix form,

$$(y)_k=[T]^{-k}(y)_0 \qquad (69)$$

From this it follows that one can write,

$$(y)_0=[T]^n(y)_n, \quad (y)_n=[T]^{-n}(y)_0 \qquad (70)$$

Longitudinal Oscillations of a Long Uniform Train

As another typical example of the use of difference equations in the solution of dynamical problems let it be required to determine the resonant frequencies and modes of oscillation of a chain of n cars that are coupled together by identical springs that satisfy Hooke's law. The system under consideration is depicted by Fig. 3.

Fig. 3 represents an idealized train of n cars of equal mass m couled to each other by identical springs of spring constant k. The effects of friction will be neglected in the analysis. The simplest method of analyzing the behavior of this system is by the electrical analog method which makes use of the results of the previous section.[9]

In this section, the dynamic system of Fig. 3 will be analyzed by the use of a chain of differential equations and difference equations.

If Newton's second law of motion is applied to the rth car in the chain of cars of Fig. 3, the following differential equation is obtained:

$$mD^2x_r+k(x_r-x_{r-1})+k(x_r-x_{r+1})=0, \quad r=2, 3, \dots (n-1) \qquad (71)$$

where $D^2=d^2/dt^2$. The set of differential equations 71 hold for the values of r indicated, but not for $r=1$ or $r=n$, (the two ends of the train).

In order to study the nature of the possible oscillations of the system, assume that the displacements x_r are executing simple harmonic oscillations of the form,

$$x_r=y_r\sin(wt+\phi), \quad r=1, 2, 3, \dots n \qquad (72)$$

where y_r are amplitudes of oscillation of the several cars, w is an angular frequency to be determined, and ϕ is an arbitrary constant.

If equation 72 is substituted into equation 71 and the result divided by $\sin(wt+\theta)$, one obtains,

$$y_{r+1}-2\theta y_r+y_{r-1}=0 \qquad (73)$$

where the quantity θ is given by,

$$\theta=(1-w^2m/2k) \qquad (74)$$

To solve the difference equation 73, assume a solution of the form,

$$y_r=Aq^r \qquad (75)$$

If this solution is substituted into equation 73, the following characteristic equation is obtained:

$$q_r-2\theta q+1=0 \qquad (76)$$

Let the two roots of this equation be q_1 and q_2 and let

$$q_1=e^a, \quad q_2=e^{-a} \qquad (77)$$

From equation 76 one has

$$(q_1+q_2)=(e^a+e^{-a})=2\cosh(a)=2\theta \qquad (78)$$

Hence, the quantity a is given by

$$a=\cosh^{-1}(\theta)=\cosh^{-1}(1-w^2m/2k) \qquad (79)$$

The solution of the difference equation 73 may therefore be written in the following convenient form:

$$y_r=B_1\cosh(ar)+B_2\sinh(ar), \quad r=2, 3, 4, \dots (n-1) \qquad (80)$$

where B_1 and B_2 are arbitrary constants.

Vol
Pt.
196

THE BOUNDARY CONDITIONS

In order to obtain the constants B_1 and B_2, use must be made of the boundary conditions at the front and rear of the train. It is realized that there are no cars corresponding to $r=0$ and to $r=(n+1)$. In order to extend the solution of equation 79 to take into account $r=0$ and $r=(n+1)$, let it be assumed that there are phantom cars that correspond to these indices. Since the front and rear of the train is able to move freely, there cannot be any strain in the phantom springs connecting the cr $r=0$ to the car $r=1$ or in the spring that is supposed to connect the car $r=n$ to the car $r=(n+1)$. This condition may be expressed mathematically by requiring that,

$$y_0=y_1 \text{ and } y_n=y_{n+1} \qquad (81)$$

Equation 80 can be used as if it were valid for $r=0$ and $r=(n+1)$.

The boundary conditions of equation 81 when expressed by equation 80, lead to the following two equations:

$$B_1=B_1 \cosh (a)+B_2 \sinh (a) \qquad (82)$$

$$B_1 \cosh (an)+B_2 \sinh (an)=B_1 \cosh [a(n+1)]+B_2 \sinh [a(n+1)] \qquad (83)$$

B_2 can be expressed in terms of B_1 by equation 82 in the form,

$$B_2=-\tanh (a/2)B_1 \qquad (84)$$

If this expression for B_2 is substituted into equation 83 and some algebraic reductions are made, the result is

$$B_1 \tanh (a/2) \sinh (an)=0 \qquad (85)$$

For a nontrivial solution, one must have $B_1 \pm 0$. Hence the possible values of the parameter a must satisfy the following transcendental equation:

$$\tanh (a/2) \sinh (an)=0 \qquad (86)$$

This equation is satisfied provided that,

$$\sinh (an)=0, \qquad (87)$$

This gives the following values for a,

$$a=a_s=j\pi s/n, \quad s=0, 1, 2, 3, \ldots (n-1), \quad j=(-1)^{1/2} \qquad (88)$$

If s is given the value $s=n$, equaton 86 leads to an indeterminate form and it is not satisfied.

THE RESONANT OR NATURAL FREQUENCIES OF THE TRAIN $=w_s$

To determine the possible natural angular frequencies of the system, one may use equation 78 written in the following form:

$$\cosh (a)=\cosh (a_s)=\theta=(1-w_s^2m/2k)=\cosh (j\pi s/n) \qquad (89)$$

Hence,

$$w_s^2m/2k=1-\cosh (j\pi s/n)=1-\cos (\pi s/n)=2 \sin^2 (\pi s/2n) \qquad (90)$$

Therefore,

$$w_s=2(k/m)^{1/2} \sin (\pi s/2n), \quad s=0, 1, 2, 3, \ldots (n-1) \qquad (91)$$

These are the n natural angular frequencies of the principal modes of oscillation of the train. The frequency $w_0=0$, corresponds to a rigid body translation of the entire train.

THE NATURAL MODES OF THE OSCILLATION OF THE TRAIN $=y_{rs}$

To determine the natural modes of the oscillation of the system write equation 80 in the form,

$$y_r=B_1 \cosh (ar)+B_2 \sinh (ar) \qquad (92)$$
$$=B_1 [\cosh (ar)-\tanh (a/2) \sinh (ar)], \quad r=1, 2, 3, \ldots n$$

To each value of $a=a_s=j\pi s/n$, there corresponds an amplitude function,

$$y_{rs}=B_s\phi(r, s) \qquad (93)$$

where

$$\phi(r, s)=[\cos (\pi rs/n)-\tan (\pi s/2n) \sin (\pi rs/n)] \qquad (94)$$

$r=1, 2, 3, \ldots n$ (cars)

$s=0, 1, 2, 3, \ldots (n-1)$ (modes)

The general solution of the chain of differential equations 71 with the appropriate boundary conditions can now be obtained by substituting equation 93 into equation 72 and summing over all the possible modes s.

The general solution of the chain of difference-differential equations 71 is, therefore,

$$x_r=\sum_{s=0}^{s=(n-1)} B_r\left[\cos\left(\frac{\pi rs}{n}\right)-\tan\left(\frac{\pi s}{2n}\right)\times \sin\left(\frac{\pi rs}{n}\right)\right] \sin (w_st+\theta_s) \qquad (95)$$

The index r refers to the car number and the index s pertains to the mode. The quantities B_r and θ_s are the $2n$ arbitrary constants of the general solution. These constants may be obtained if the initial displacements $x_r(0)$ and the initial velocities $\dot{x}_r(0)$ of each car is given.

Difference Equations Method for Solving Ordinary and Partial Differential Equations

In many problems of practical importance it is frequently not possible to solve the resulting ordinary or partial differential equations by known methods. However, it is sometimes possible to solve certain difference equations whose solutions approximate those of the original differential equations. In such cases one first approximates the differential equation by a difference equation and then solves the resulting difference equation. In this section the general procedure by which this is done is explained by means of typical examples.

From the definition of the derivative operator D and the operators Δ, ∇, and δ, it is easily seen that the following operators are approximations for the derivative operator D,

$$D \doteq \Delta/h \qquad (96)$$

$$D \doteq \nabla/h \qquad (97)$$

$$D \doteq \delta/h \qquad (98)$$

provided that the tabular interval h is sufficiently small. As $h \to 0$, the right members of these equations tend to D.

To illustrate the use of these finite difference approximations of the operator D, let it be required to obtain the finite difference approximation of the solution for the simple ordinary differential equation,

$$D^2y=x \qquad (99)$$

Let the initial conditions of equation 99 by $y(0)=0$ and $Dy(0)=1$. By the use of equation 98 and the operational equivalent, equation 13, the second derivative of the left member of equation 99 may be approximated by the following expression;

$$D^2y=(\delta/h)^2y=(E^{1/2}-E^{-1/2})^2y/h^2$$
$$=(E-2+E^{-1})y(x)/h^2 \qquad (100)$$

where h is small.

Hence the differential equation 99 may be replaced by the following approximate difference equation:

$$[y(x+h)-2y(x)+y(x-h)]/h^2=x \qquad (101)$$

The initial conditions can be written in the form,

$$y(0)=0, \quad [y(h)-y(0)]/h=1 \qquad (102)$$

Now let the difference equation 100 be required to be satisfied at the successive points $x=0, h, 2h, 3h, \ldots kh$. In such case the difference equation 100 may be written in the following form,

$$y_{k+1}-2y_k+y_{k-1}=kh^2, \quad k=1, 2, 3, \ldots \qquad (103)$$

where

$$y_k=y(kh) \qquad (104)$$

The initial conditions then take the form,

$$y_0=0, \quad y_1-y_0=h \qquad (105)$$

The solution of equation 103 with the initial conditions of equation 105 is

$$y_k = k(h-h^3)/6 + h^3k^3/6 \qquad (106)$$

The corresponds to the solution of equation 99 of the form,

$$y(x_k) = x_k + \frac{x^3}{6^k}k - \frac{h^2}{6}x_k \qquad (107)$$

The exact solution is,

$$y(x) = x + \frac{x^3}{6} \qquad (108)$$

In this case if h is so small that h^2 can be neglected, equation 107 tends to equation 108.

PARTIAL DIFFERENTIAL EQUATIONS

One of the most powerful methods for solving partial differential equations numerically when analytic methods fail because of the complexity of the differential equations or the boundary conditions is to use the method of finite differences.

The procedure is similar to the one used for the approximate solution of the ordinary differential equation 99. The differential equation is first approximated by a difference equation and then this resulting difference equation is solved subject to the appropriate boundary and initial conditions of the problem.

The partial differential equations that arise in the solution of physical problems are usually of the following form:

$$AU_{xx} + 2HU_{xy} + BU_{yy} + 2GU_{xz} + 2FU_{yz} + CU_{zz} = I \qquad (109)$$

In this equation the quantitites A, B, C, F, G, H, and I may be constants (including zero) or functons of (x,y,z). The dependent variable is $U(x,y,z)$ and the independent variables are (x,y,z). The notation U_{xx} denotes the second partial derivative of U with respect to x, etc. For example, if $A=B=C=1$ and $H=G=F=0$, then equation 99 reduces to the Poisson equation,

$$U_{xx} + U_{yy} + U_{zz} = I(x, y, z) \qquad (110)$$

If U is a function of x and y only, then equation 99 reduces to a 2-dimensional partial differential equation. This equation then takes the form:

$$AU_{xx} + 2HU_{xy} + BU_{yy} = I(x, y) \qquad (111)$$

In the standard literature on partial differential equations, equation 110 is classified into the following forms, depending on the nature of the coefficients A, B, and H.

1. Hyperbolic Equation.[10]

If $H^2 - AB > 0$, equation 111 is said to be hyperbolic.

2. Parabolic.[10]

If $H^2 - AB = 0$, equation 111 is said to be parabolic.

3. Elliptic.[10]

If $H^2 - AB < 0$, equation 111 is said to be elliptic.

THE POISSON EQUATION IN TWO DIMENSIONS

The 2-dimensional Poisson differential equation will be taken as an example of the method of finite differences to solve a partial differential equation. In this case the Poisson equation 110 takes the following form:

$$(D_x^2 + D_y^2)U(x, y) = I(x, y) \qquad (112)$$

In this case one may use the same approximation that was employed in equation 100 and write,

$$D^2_x = (E_x - 2 + E_x^{-1})/h^2 \qquad (113)$$

$$D_y^2 = (E_y - 2 + E_y^{-1})/h^2 \qquad (114)$$

where the displacement operators E_x and E_y are defined by the following equations:

$$E_xU(x, y) = U(x+h, y), \quad E_yU(x, y) = U(x, y+h) \qquad (115)$$

By the use of the operators in equations 113 and 114 the partial differential equation 112 may be written in the following approximate form,

$$U(x+h, y) - 4U(x, y) + U(x-h, y) + U(x, y+h) + U(x, y-h) = h^2I(x, y) \qquad (116)$$

A more convenient manner of writing equatin 116 is to express it in terms of the displacement operators E_x and E_y in the form:

$$(E_x + E_y + E_x^{-1} + E_y^{-1} - 4)U(x, y) = h^2I(x, y) \qquad (117)$$

A very ingenious method for the solution of the difference equation 117 in the interior of a rectangular domain has been given by P. C. Rosenbloom, in the paper, "Difference Equation Method for Solving the Dirichlet Problem."[11]

The classical example of the solution of a parabolic partial differential equation that represents the one-dimensional flow of heat in a conducting wire or the diffusion of a liquid or gas along a porous tube leads to the solution of the equation,

$$c^2U_{xx} = U_t \qquad (118)$$

with the initial conditions $U = f(x)$ at $t = 0$ and the two boundary conditions of the general type:

$$U + aU_x = b(t), \text{ at } x = x_1 \text{ and } x = x_2 \qquad (119)$$

This equation was studied by Courant, Friedrichs, and Lewy (see reference 4). It was discovered by these investigators that in order for the resulting difference equation 118 to have a solution that converges, it is necessary for the tabular intervals of the space and time variables h_x and h_t to be chosen in such a manner that the following inequality is satisfied:

$$c^2h_t/h_x^2 < 1/2 \qquad (120)$$

The relation 120 indicates that an unlimited decrease in the tabular interval h_x will not lead to improved accuracy of the solution unless it is accompanied by a suitable decrease in the tabular interval h_t.

Summary of Additional Applications

In this brief discussion of the applications of difference equations it is not possible to describe all the fields of applied mathematics in which they have been found useful. In conclusion, it may be mentioned that difference equations have been used in the following important types of problems:

1. The study of intermittent control systems.[12]
2. The analysis of systems with hereditary characteristics.[13]
3. The solution of certain problems in Probability.[14]

Difference equations have also been used in the solution of mathematical models of economic systems and in mathematical models used in the biological sciences.

Conclusions

It is hoped that this short exposition of the use of difference equations will serve to introduce the reader to the methods and the literature of difference calculus and will motivate engineers who are unaquainted with this subject to learn more about it and to apply it in the solution of technical problems.

◆

Discussion

W. E. Meserve, and **H. C. Torng** (Cornell University, Ithaca, N. Y.): The discussers would like to congratulate Professor Pipes on his lucid presentation on the art of the calculus of finite differences; especially that on linear difference equations with constant coefficients.

It is our opinion that in treating certain technical problems, for example the study of sampled-data control systems, the engineer often has to deal with nonlinear difference equations or linear difference equations with variable coefficients. It seems that it is to this area that efforts should be directed.

In a recent paper,[1] an approach is presented to extend the principle of first approximation to the field of nonlinear difference equations.

The discussers would also like to point out that one of the analogies between the differential and integral calculus and the calculus of finite differences, the concept of orthogonality, has been successfully used to study certain nonlinear sampled-data control systems. In terms of a set of orthogonal functions in the continuous domain, a periodic function can be expanded into a series of an infinite number of terms. An exact solution for certain nonlinear differential equations is therefore very difficult if not impossible, to obtain; while, in terms of a set of orthogonal functions in the discrete sense a periodic sequence can be replaced by a series with a finite number of terms. This property facilities greatly the task of identifying the exact solution of certain types of nonlinear difference equations.[2,3]

Louis A. Pipes: The author wishes to thank Mr. Meserve and Mr. Torng for their kind remarks on the lucidity of his paper. When this expository paper was being written, the author was not aware of the existence of the excellent work of Mr. Torng and Mr. Meserve on the applications of the methods of finite differences to the solution of nonlinear difference equations. These gentlemen are to be commended on the use of the concept of orthogonality of certain classes of functions to the study of an important class of nonlinear sampled-data control systems. The author is most grateful to Mr. Meserve and Mr. Torng for calling his attention to this very recent work and for including references to this work in their discussion.

A Magnetic-Tape-to-Paper-Tape Converter

M. RINGER
NONMEMBER AIEE

L. MINTZER
NONMEMBER AIEE

WITHIN THE LAST DECADE digital computation has evolved from the scientific computer with simple input-output devices to the present-day electronic data processors with their myriad of peripheral devices. This development is continuing with the addition of facilities to provide intercommunication between the central processor and remote points. Such a device has been developed by Honeywell for use with the DATAmatic 1000 System.

DATAmatic 1000 Data Processing System

The DATAmatic 1000 is a large-scale general-purpose electronic data processing system. It is composed of integrated business equipment employing high-speed computer principles designed to expedite all phases of record keeping and accounting. The processing units are co-ordinated to perform as a complete, highly efficient electronic office with the ability to handle a great variety and large volume of business operations quickly. Included is the handling of all steps in such operations as accounting, billing, payroll, production control, sales analysis, maintenance of name and address lists, inventory control, engineering computation, and numerous other office procedures.

The model 1500 Magnetic-Tape-to-Paper-Tape Converter (MTPT), Fig. 1, has been added to the DATAmatic 1000 family of peripheral devices as the first step in linking the DATAmatic 1000 to remote points via standard communication channels. The MTPT converts information stored on standard DATAmatic 1000 magnetic tapes to standard 5, 6-, 7-, and 8-level punched paper tapes at a rate limited only by the electromechanical speeds of present tape-punching mechanisms.

Magnetic Tape

The magnetic tape used in the DATAmatic 1000 System is 3 inches wide and has 31 information channels which run longitudinally along the tape. A tape block contains two 52-bit (binary digit) words in each channel. Blocks designated "first half of tape" are interlaced with those of "second half of tape." In this way, since intermittent motion with interblock stops is a common condition, the dead space required for acceleration and deceleration is actually used as

Paper 59-1190, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted June 17, 1959; made available for printing December 18, 1959.

M. Ringer and L. Mintzer are with the Minneapolis-Honeywell Regulator Company, Newton Highlands, Mass.

The authors wish to acknowledge the work of Dr. J. J. Eachus, Mr. S. D. Harper, Dr. W. L. Gordon, and Mr. W. M. Carey, who are chiefly responsible for the conception and design of the MTPT, and for their comments and criticisms which have considerably influenced the preparation of this material.

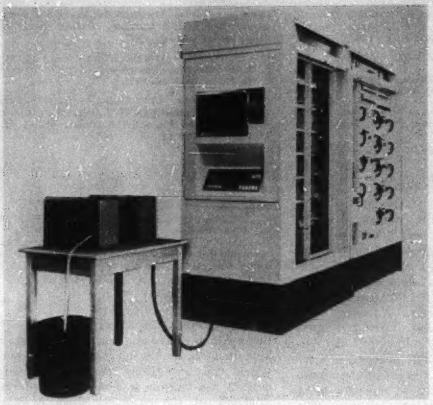

Fig. 1. Magnetic-tape-to-paper-tape converter

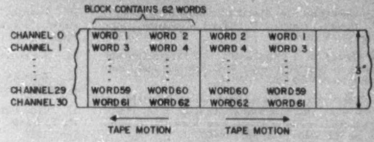

Fig. 2. Tape organization

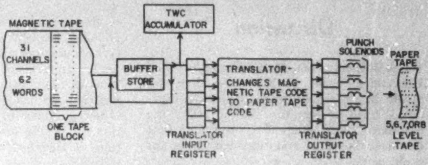

Fig. 3. Basic flow of information

active storage space for the other half of tape. Thus, high tape-storage efficiency obtained. One 2700-foot reel of DATAmatic 1000 tape stores the equivalent of 465,000 fully punched cards.

The tape moves at the rate of 100 inches or 100 blocks a second. A block is only 1/2 inch long but the foregoing rate prevails because of the interlacing feature. Acceleration and deceleration times are approximately 6 milliseconds. Thus it takes 18 milliseconds to start tape motion, read a block of information, and stop before the start of the next logical block.

A unique feature of the DATAmatic 1000 tape system is the ability to read tape moving in either direction. This considerably reduces access time, a desirable feature in any large file system.

Each of the 62 DATAmatic words in a magnetic tape block (Fig 2) consists of 48 bits of data plus four bits used for transfer checking. These four are called Transfer Weight Count (TWC) bits. In the MTPT the TWC bits are generated by making a mod 9 addition of the 48 data bits, bearing in mind their relative position in the word and weighting them accordingly. The mod 9 addition is discussed under the heating of "Logic." Consider the following example:

```
52 51 50 49 48 47 46 45................
                        9 8 7 6 5 4 3 2 1
TWC bits     8  4  2  1 ...............
                        1 8 4 2 1 8 4 2 1
```

Bit positions 1, 2, 3, and 4 have weights of 1, 2, 4, and 8 respectively. Similarly, bit positions 5, 6, 7, and 8 have weights of 1, 2, 4, and 8 respectively, etc. Whenever information is transferred from one part of the DATAmatic 1000 system to another, the TWC bits are recomputed and compared with those transferred with the word to check the validity of the information transferred.

MTPT Converter Used With DATAmatic 1000 System

The MTPT can be termed a hybrid unit in its use of components and circuits. It contains the magnetic core storage and logic circuits and the vacuum-tube control circuits that are standard with earlier converters; however, 75% of the converter contain newly developed transistorized circuits whose reliability has been established after many thousands of hours of error-free operation. These circuits, furthermore, are of such a form that they are intimately associated with Boolean expressions; hence one can derive from the logic equations all information necessary for their physical realization.

The MTPT is considered an output converter since it transfers information from magnetic tape to some terminal device such as, in this case, the paper-tape punch. Two earlier converters are the low-speed output converter which feeds a line printer at 150 lines per minute or a card punch at 80 cards per minute and the high-speed output converter which feeds a 900-line-per-minute printer.

All these converters provide the necessary buffer storage to accommodate the different instantaneous information rates of the magnetic tape and the particular terminal device. The converters, in addition, search for information on magnetic tape, select, edit, and translate from DATAmatic 1000 code to the codes required by the wide variety of output devices. Checking is an integral part of this process to assure error-free operation.

All these converters work with magnetic file (tape) units that operate via high-speed buffers with the central processor (CP). The converters are, however, "off line" devices, i.e., they function independently of the CP and hence require a magnetic file unit that has been released by the CP for such purposes.

The rate of processing information by the MTPT is 240 characters per second. Thus, it is obvious that for even the fastest paper tape punch, the MTPT is punch-speed limited and consequently only one channel of information buffer storage is required.

This paper will discuss the general system characteristics of the MTPT and the transistor circuits of the all solid-state portion of the equipment. In this portion, the variables of the logic equations are so intimately related to the components necessary to realize the logic that wiring information, component inventory etc., can be generated from the logic expressions alone. This will be described later.

BUFFERING

Fig. 3 illustrates the basic flow of information from magnetic tape to paper tape. The difference in the speed with which magnetic tape is read and the speed with which information is converted necessitates the use of a buffer stage. Information is read from the magnetic tape one channel at a time and stored in a buffer. It is possible to circulate this information in the buffer for the con-

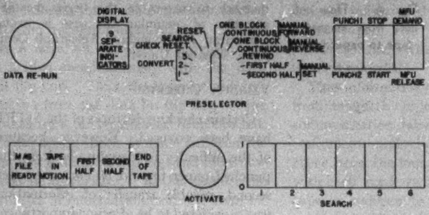

Fig. 4 (left). Control panel

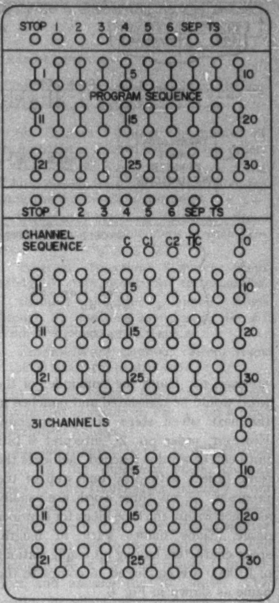

Fig. 5 (right). Program selection plug board

venience of conversion and for the purpose of TWC testing. The converter extracts information from the buffer one bit at a time. While conversion is taking place, the tape is mechanically repositioned in preparation for the next channel reading. The selection of the next channel is also accomplished during this period. Hence it is possible to utilize the time of conversion such that the rate at which the MTPT produces information is in no way limited by tape motion. The rate at which information is read into the buffers is controlled by the magnetic file unit. Once the information is in the buffer, the master clock of the MTPT takes over control of the rate at which the transistorized circuits perform. Finally, the punch determines the rate at which information is produced.

The buffer stage consists of two sections. One section, called "data store," is a 2-word store while the other section stores only one word and is called the "control word store." The control word serves two purposes. First, it indicates the position along the magnetic tape at which a particular conversion run is to commence. This is employed during the "search" mode of operation. Second, at the operator's convenience, it serves as an alternative to a plug board for the selection of programs.

DATA RETRIEVAL

The operator has the following facilities at his disposal for retrieving information and converting it into the desired form:

1. A rotary switch (Fig. 4) having the ability to select from 1 of 11 possible modes of operation.
2. Six toggle switches for establishing the search code.
3. Several self-explanatory push-buttons, lights, and toggle switches.
4. A program selection plug board (Fig. 5) which has the dual function of sequencing the 31 channels read into the buffer and sequencing the 6 available programs.
5. Program Plug Board. This plug board is divided into six major sections labeled Program 1–6. Each portion consists of 60 double hubs numbered 1–60 and performs the same function as can be handled by a sequence switch. These hubs are used in conjunction with the hubs positioned along the top and bottom of the panel. There are two sets of these hubs numbered from 1–22. The numbers represent the 22 conversion rules available in the converter which are listed in the Appendix. An impulse from a program hub to any of the conversion rule hubs will trigger the circuitry of the converter to execute the proper rule. The wiring between the program and conversion rule hubs determines the specific conversion rule to be executed during any given stage of the stepper. These 22 conversion rules can be plugged into 6 sections, each representing one program, using any desired valid format. It is therefore possible for a program to consist of 60 or less orders, made up of any combination of the 22 available orders. Generally, each program will be associated with a different format. For example, one program may convert the address of a message, one or more programs the content of the message itself, and yet another may be associated with the information concerning the source of the message.

With the aid of the foregoing facilities, the selection of data takes place in the following manner:

1. A block of information is selected, using part of the control word as a key. A comparison is made between the six search switch positions and the six high-order bits of the control word. A successful search results in the magnetic tape coming to a stop at the desired position.
2. Any one of the 31 channels in a block is selected via the program selection plug board.
3. Either of the two words in a channel can be selected by circulating the words in the buffer store. This is achieved by the use of conversion rule 19 which is "discard until end of word is reached."
4. The selection of bits within a word is accomplished by inserting the appropriate order in the desired position in a particular program.
5. Any one of the six available programs is selected by the program selection plug board, the control word or both.

TRANSLATION

A perusal of the Appendix will show that the order structure of the system is such that translation from the DATAmatic word to the desired tape code achieves the following results.

1. Alphanumeric, hexadecimal, and numeric interpretation.
2. Direct transcription.
3. Transcription of the TWC bits.
4. Generation of new information such as carriage return, dollar sign, decimal point, etc.
5. The omission of data.

The manner in which information is extracted from the store, translated, and punched on paper tape is best illustated by an example. Assume that the data store contains information, that the desired program has been selected, and that the first instruction of the program is "interpret 6 bits."

First, consider Fig. 6 which illustrates a 2-word channel on magnetic tape, in the data store and on punched paper tape. Order no. 1 transfers the first six bits from the data store into the translator input register. This is done one bit at a time, i.e., serially. When the six bits have loaded the input register, the translator fires and translation into a 5-level code (6-, 7-, or 8-level) is achieved in a single step. This results in the 5-level code for the letter *S* appearing in the translator output register causing the punch solenoids to be activated and the 5-level code *S* is punched on the paper tape. Order no. 1 could be repeated eight times in

Fig. 6. Flow of data from magnetic tape to paper tape

program no. 1 and the remainder of the word would be translated and punched in the next seven steps of the program. However, order no. 2 "interpret 6 bits until end of word is reached" achieves the same object with only one step of the program. A full three words are usually assigned within the tape block for a proper name. Since names vary in length, space characters having bit configurations of 010000 are employed to complete the name as shown in Fig. 6.

The information bits are fed from the store serially into the translator input register and serially circulated in the store. The translator and punch are fed in parallel one character at a time.

With the completion of the first word, the next order in the program takes over and either interprets, transcribes, generates, or omits any number of bits desired.

A 52-step counter keeps track of the bits and their relative position, while a 60-step counter cycles through the program steps and yet another 30-step counter steps from program to program.

When a program has completed the orders required of it or when all but one of the program hubs have been used, then the last step will always be either "terminate program and consult the program sequence stepper" or "terminate program and consult the control word." The program stepper or control word will then direct the converter to the next program.

If desired, rule no. 9 which is "punch TWC bits" may be inserted at the end of each word. Any other form of check may be included in the 48 bits on magnetic tape and suitably interpreted and punched on paper tape. Any desired mode of information check may thus be included on the paper tape and so ensure the opportunity of validity checking at the receiving end.

Modes of Operation

The mechanical modes of operation indicated on the control panel shown in Fig. 4 are self explanatory. The three convert modes, however, merit some explanation. On teleprinters all letters of the alphabet are in lower case and all other symbols are in upper case. For each convert order, the MTPT determines whether upper or lower case is required. It further automatically inserts the required case symbol prior to punching the character which is being interpreted. At the beginning of a message, the MTPT inserts the required case symbol but thereafter remembers the previous case and only a case change effects the insertion of a required symbol.

The three modes of conversion are variations of the foregoing and are as follows:

1. The case memory is affected only by emission of an upper or lower case symbol (American Telephone and Telegraph Company).
2. The case memory is affected also by emission of a space thus causing the converter to act as if the remembered case is lower (Western Union).
3. If the remembered case was upper, then the emission of a space causes the case memory to revert to the begin message situation of assuming the case is wrong (American Telephone and Telegraph Company, Western Union).

Validity Checking

Certain checking features of the MTPT have been covered. However, because of the difficulty in visually checking the punched paper tape at 60 characters per second, reliable transfer of information was considered to be of prime importance, and hence many checking features have been incorporated in the device. The following paragraphs consider these features in detail.

TWC Checks. The data, having been loaded into the register, are circulated prior to processing for the purpose of TWC checking. If the test should reveal an error, the primary clock is interrupted, effectively preventing any further processing. The appropriate lamp is illuminated indicating the condition to the operator who then has the option of either recirculating the data and repeating the TWC check or processing the word in spite of the error. These two courses are effected by the operation of the data rerun and check reset positions of the selector switch. A successful TWC check permits the processing of the word. During processing, the TWC accumulator is appropriately augmented and a TWC check is made after processing each word. The latter test reflects any error that may occur in the register during processing.

The control word is TWC checked as it is loaded into the register, as is the data word and a similar indication is provided. If the control word is used during the processing of a block of information, it is TWC checked after that block has been processed. Again this gives assurance that no error has been generated in the control word register during processing.

Duplicate Data Bit Flip-Flop— Translator Output Register. As information is extracted from the data store, a data bit flip-flop is appropriately loaded and

Table I. Punch Check Sequence

Step No.	1		2	3		4		5
Action	Fire translator		Check that at least one of each pair is a "1"	Fire the solenoids and use the echo to reset the "1" side if the "0" side is a "0"		Reset the "0" side		Check that all flip flops are "0"
	"0" *F-F*	"1" *F-F*		"0" *F-F*	"1" *F-F*	"0" *F-F*	"1" *F-F*	
	1	0	If so, proceed to step 3. If not, stop clock and indicate	1	0	0	0	If check fails stop clock and indicate; otherwise proceed to next cycle
	0	1		0	0	0	0	
	0	1		0	0	0	0	
	1	0		1	0	0	0	
	1	0		1	0	0	0	

this information is subsequently loaded into the translator input register. A duplicate data bit flip-flop is provided and is loaded simultaneously with the data bit flip-flop. Once the transfer of information from the data bit flip-flop to the translator input register has been effected, a comparison check is made between the duplicate data bit flip-flop and the translator input register. In this manner the transfer of information from the data bit flip-flop to the input of the translator is checked.

Translator Output Register—Punch. Assuming the translator input register to be fully loaded, the next step is to fire the translator, the outputs of which appropriately set the translator output register. This register consists of two flip-flops per level, one representing a "zero" and the other a "one." Thus one and only one flip-flop of each level should be set at any one time. The first portion of the output register check is to establish that at least one flip-flop of each pair is set. This having been established, the solenoids of the punch are fired. The echos of the punch solenoids are then utilized to reset their associated "one" flip-flop of the output register if the zero member of that pair is a zero. Subsequently, the "zero" flip-flop of each pair is set to zero. The final check is then to establish that all flip-flops are zero. The foregoing process is shown in Table I. A 5-level output is assumed. Should the test fail, then the process error indication is activated and again the operator has the option of repeating or proceeding in spite of the error.

Program Checks. A check is provided which establishes that not more than one of the 22 available orders is activated at any one given time. Should this check fail, the program error indication is energized, the clock interrupted and the operator then takes appropriate action.

Another means of checking that the program is correctly assembled is provided. An order such as "Interpret 6 bits" may be inserted in error when less than six bits remain in that word. A check is provided which detects this type of program error and again energizes the program error indication.

Magnetic Tape Checks. Any error detected in the magnetic tape control circuitry stops the tape mechanism and energizes the magnetic file unit (MFU) error indicator. On reaching the physical end of tape, the MFU signals this condition by energizing the "tape physical end" indicator.

Paper Tape Run-Out Alarm. The paper tape carriage unit is adjusted so that a signal indicates the impending end of paper tape. The operator can then switch to the second punch and have the first reloaded.

Thus information is checked thoroughly from magnetic tape to punch coil. If communication takes place with distant equipment employing the identical TWC check, then the four TWC bits associated with each word are included on the paper tape in addition to the information. A "punch TWC bits" order exists for this purpose. By suitable programming any desired form of check bits can be included on the paper tape.

MAGNETIC SWITCHES

Liberal use is made of magnetic cores for realizing logic in areas where operations of a sequencing nature are desired. Also, the translator of the MTPT, i.e., the portion responsible for the translation from DATAmatic code to Teletype code, is a magnetic switch.

TRANSISTORIZED CIRCUITRY

The basic building block, i.e., the flip-flop, is illustrated in Fig. 7, it being contained within the broken-line rectangle. Significant features of this flip-flop are:

1. The use of a silicon diode in the base to provide an added 0.6-volt threshold in discriminating against noise.
2. The so-called K diodes which provide a second input to the flip-flop with the only component addition being a diode.

This second input is achieved by tying into the crossover gate. Note that this entry responds to a ground (0) signal whereas the base input responds to a negative (1) signal. Grounding K_1K_2 converts the flip-flop into a pair of amplifiers. In addition, the equations

$$\bar{A}=C \tag{1}$$

$$\bar{B}=A \tag{2}$$

are achieved by grounding one K. The K terminals appear on the connector and so make for considerable versatility merely by a connection on the connector.

BINARY COUNTER

This circuit is employed in achieving the following counters:

1. Six Counter. Counts the number of bits up to six associated with any one order.
2. Data Bit Counter. Keeps track of the 52 bits of each word and differentiates between the two words of a channel.
3. Command Selection Counter. Steps through the 60 possible steps of each program.
4. Program Selection Counter. Steps through 30 steps, sequencing the programs.
5. Channel Selection Counter. Steps through 31 positions representing the 31 channels from magnetic tape.
6. Control Word Counter. Keeps track of the 52 bits of the control word.

In all, 32 binary flip-flops are used. The circuit is shown in Fig. 7 and a brief description follows.

Assume A and C to be "1" and B to be "0". In the quiescent state, current flows in the transformer primary from transistor B via x, transformer, y, and register to -6 volts. Assume a negative pulse is applied to the input of C. The leading edge of the pulse causes C to conduct and assume the "0" state. This results in effectively applying a short circuit across the points x and y, i.e., across the primary of the transformer. The fall of current in the primary and the resulting transformer action causes transistor A to conduct. A becomes a "0" and by flip-flop action B a "1". The trailing edge of the pulse causes C to revert to the "1" state and the short circuit across x and y to be removed. This results in a rise of current through the primary of the transformer in the direction of y to x since the states of A and B are reversed. The back electromotive force caused by this rise in current is in the same direction as the back electromotive force due to the previous fall in current.

The electromotive force across the

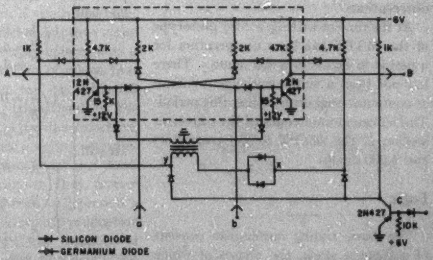

Fig. 7. Binary counter schematic diagram

secondary winding has the same polarity in both cases. Therefore, the leading edge of the input pulse switches the flip-flop and the trailing edge merely reiterates this state. The binary flip-flop, therefore, changes state once with each negative pulse.

PUNCH SOLENOID ENERGIZING CIRCUIT

This circuit, like the flip-flop package, achieves versatility of application by a suitable choice of connector wiring; see Fig. 8. Its basic function is to provide the drive for any circuit requiring current of the order of a quarter of an ampere to one ampere.

The input to this circuit is a standard logical function. The power transistor will be come active if either a "1" or a "0" is applied to the input of the circuit. The desired condition is established by a suitable choice of connector wiring.

CLOCK

Fig. 9 illustrates the basic circuitry of the master clock. The basic frequency of the clock is 50 kc. The square-wave output of each side is differentiated to give the *P* and *Q* pulses as illustrated in Fig. 10.

The timing elements of both the clock and differentiators are inductive. A paper[1] by W. M. Carey describes this type of circuit in detail. The function of the 51-ohm resistor is to bias the transistors slightly into the active region and so ensure self-starting. The function of the 1-kilohm resistor in series with the inductance is to ensure rapid recovery time.

Reliability and Margins of Operation

Included in the design specifications is the requirement that all circuitry be designed so that during a 25% variation of the supply voltages (−6, −13, and 6 volts) either separately or together, the MTPT is to operate reliably. The maintenance technician is required to vary the supply voltages accordingly during regular marginal tests and to maintain a record of his observations.

At the time of writing, a 20% prototype of the MTPT has been in operation for a period in excess of 8,000 hours. There has not been a single component failure or computational error during this period. The semiconductor count of the converter section of the MTPT is 850 transistors and 4,000 diodes.

Logic

The basic timing mechanism consists of a 2-phase clock, the phases of which are represented by *P* and *Q* pulses; see Fig. 10. The nominal frequency of the clock is 25 kc, resulting in a nominal separation of 20 microseconds between the *P* and *Q* pulses.

Logic is performed by two distinct types of circuitry: 1. flip-flops, amplifier, and diode gates, and 2. magnetic switches. The first type achieves a gate buffer form of logic and the magnetic switch realizes its "and" and "or" logic essentially by a suitable choice of wiring.

The subsequent discussion is concerned with the gate-buffer type of logic. Consider the equation

$$\bar{A} = CD + EFG \tag{3}$$

In the presentation of the logic, the following ground rule is established: The function to be generated is that effect which a number of inputs would have on an inverter. Furthermore, any one of the inputs is effective only when it is true and is represented on the right-hand side of the equality sign in the true state. Since an inverter realizes the complement of its inputs, the form in which it is presented is the complement of an affirmation.

In establishing the ground rules, it was decided that the collector of a conducting inverter would have the state of "0" and a nonconducting inverter the state of "1."

A flip-flop essentially consists of two inverters and two gates and is represented by the broken square enclosure in the following equations.

$$\bar{A} = B + CD \tag{4}$$
$$\bar{B} = A + E \tag{5}$$

The addition of inputs to the flip-flop is shown by a double input gate *CD* and a single input gate *E*.

The equations which follow describe the TWC accumulator as used in the MTPT:

2nd half

$$\bar{A}_3 = B_3C_3 + P\,B_1C_1 \qquad \bar{D}_3 = A_3 \tag{6}$$
$$\bar{B}_3 = A_3C_3 + P\,A_1C_1 \qquad \bar{E}_3 = B_3 \tag{7}$$
$$\bar{C}_3 = A_3B_3 + P\,A_1B_1 \qquad \bar{F}_3 = C_3 \tag{8}$$
$$\bar{A}_4 = B_4C_4 + P\,B_2C_2 \qquad \bar{D}_4 = A_4 \tag{9}$$
$$\bar{B}_4 = A_4C_4 + P\,A_2C_2 \qquad \bar{E}_4 = B_4 \tag{10}$$
$$\bar{C}_4 = A_4B_4 + P\,A_2B_2 \qquad \bar{F}_4 = C_4 \tag{11}$$

1st half

$$\bar{A}_1 = B_1C_1 + X_0F_3 + X_1F_3 + X_2F_3 + X_3E_3 + \text{Reset Function} \tag{12}$$
$$\bar{B}_1 = A_1C_1 + X_0D_3 + X_1F_3 + X_2D_3 + X_3F_3 \tag{13}$$
$$\bar{C}_1 = A_1B_1 + X_0E_3 + X_1D_3 + X_2E_3 + X_3D_3 \tag{14}$$
$$\bar{A}_2 = B_2C_2 + X_0C_3D_4 + X_0F_3F_4 + X_1A_3F_4 + X_1D_3D_4 + X_2C_3F_4 + X_2F_3E_4 + X_3A_3D_4 + X_3D_3E_4 + \text{Reset Function} \tag{15}$$
$$\bar{B}_2 = A_2C_2 + X_0C_3E_4 + X_0F_3D_4 + X_1A_3D_4 + X_1D_3E_4 + X_2C_3D_4 + X_2F_3F_4 + X_3A_3E_4 + X_3D_3F_4 \tag{16}$$
$$\bar{C}_2 = A_2B_2 + X_0C_3F_4 + X_0F_3E_4 + X_1A_3E_4 + X_1D_3F_4 + X_2C_3E_4 + X_2F_3D_4 + X_3A_3F_4 + X_3D_3D_4 \tag{17}$$

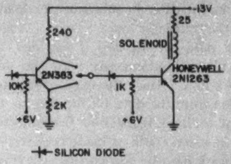

Fig. 8. Punch solenoid schematic diagram

The TWC accumulator consists of two pairs of registers, each pair having two tristable devices. A tristable device is recognized as those portions of the foregoing equations contained within the broken line squares. It comprises three amplifiers and three double-input gates.

Each of the four tristable devices is capable of assuming the three stable states indicated as follows, and no other stable states. All possible combinations of the stable states of the three inverters are thus exhausted.

A	*B*	*C*	*A*	*B*	*C*	*A*	*B*	*C*
0	1	1	1	0	1	1	1	0

The ternary digits are interpreted as follows:

0 1 1 as 0
1 0 1 as 1
1 1 0 as 2

A pair of tri-stable devices can thus assume the following nine distinct states:

A	B	State
0	0	0
0	1	1
0	2	2
1	0	3
1	1	4
1	2	5
2	0	6
2	1	7
2	2	8

The two halves of the TWC accumula-

Vol.
Pt. 1

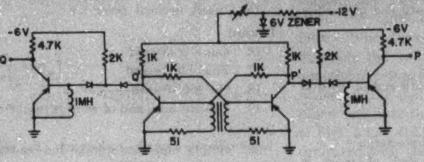

Fig. 9. Master clock schematic diagram

Waveforms at P, Q, P', and Q' are shown in Fig. 10

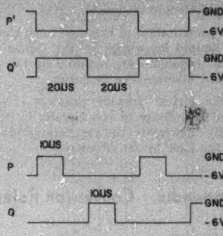

Fig. 10. Clock timing diagram

tor, each capable of nine distinct states, count modulo 9 as follows. Assume the accumulator to be in the "0" state. At the time of a Q pulse, a number is added to the first half. The succeeding P pulse results in this state being copied into the second half. The following Q pulse establishes a state in the first half which is the sum of the state of the second half and the new number of be added. This process continues as the weights of each of the 48 bits are added to the accumulator. Finally the state of the TWC accumulator is compared with the TWC bits of the word.

The functions $X0$, $X1$, $X2$, and $X3$ are dependent upon the Q pulse; bit position for weight; and knowledge as to whether the bit is a "1" or a "0". An $X2$ being a "one," for example, indicates that a bit having a weight of 4 is being added.

Consider Fig. 11 as representing the two registers of the accumulator and assume them both to be in the reset state. Now add 2 to the first half and transfer this state to the second half. The state of the first half at the next step will be the addition of the new number, say 8, and the state of the second half, which is 2. The new state of the first half is shown in Fig. 11.

The following chart indicates the new state of the first half subsequent to the addition of one of the X's to the second half:

State of Second Half	New State of First Half			
	X0	X1	X2	X3
00	01	02	11	22
01	02	10	12	00
02	10	11	20	01
10	11	12	21	02
11	12	20	22	10
12	20	21	00	11
20	21	22	01	12
21	22	00	02	20
22	00	01	10	21

Generation of Wiring Information

In the previous paragraphs it was observed that an exact correspondence exists between the logical equations and the hardware. It will now be shown how wiring information as well as maintenance and inventory records are generated directly from the equations. Distinct letters of the alphabet are allocated to represent different parts of the hardware. The letters A and B, associated as they are in the following equations, represent a flip-flop. Each of the letters D, E, F, K, R, V, and U represents a particular type of amplifier. The letters A, B, and C, associated as in the TWC accumulator, represent a tristable device. Figures added to the letters distinguish one of a kind from another of the same kind:

$$\begin{cases} \bar{A}_1 = B_1 + C_3 & (18) \\ \bar{B}_1 = A_1 + D_1A_4 & (19) \end{cases}$$

$$\bar{E} = A_1X_0 \qquad (20)$$

It is now possible to interpret the left-hand side of the equality sign in every equation in terms of the hardware. The right-hand side of the equations represents the inputs to amplifiers, flip-flops, etc., and are gates, the number of inputs being the number of letters per gate. The connection to a gate is indicated by the letter which states that it is directly connected to the output of the inverter represented by the letter. Thus in the foregoing equations, representing inputs to a flip-flop, the gate $D1A4$ has its inputs directly connected to the output of inverter D_1 and to the A_4 inverter of the A_4B_4 flip-flop. The output of the gate is directly connected to the b input of the A_1B_1 flip-flop. In addition, there exists standard flip-flop packages, amplifier packages, gate packages, etc. The input and output pin numbers of the packages are known.

It then becomes a fairly simple matter allocate a particular flip-flop to one of the three available positions in a package. Gates are allocated in a similar fashion. The foregoing information can thus make the listing of the interpin connections a simple matter. Therefore, it follows that sufficient information can be extracted from the equations, transferred to the input medium of a data handling machine, and effectively produce a wiring list automatically. This, in fact, has been done. The reader will recognize that certain aspects of the wiring may well present a difficult problem in automatic production of listings. However, the number of such problems was sufficiently small that a large percentage of the wiring information was automatically produced.

Conclusion

The gradual replacement of the human operator by the more efficient and speedy machine aids at the various stages of information transfer has received the attention of the development engineer since the beginning of communication systems. It is conceivable that an entire telegraphic system could take advantage of electronic computer techniques. Communication between an electronic computer and a distant point or in fact another computer remote from it, is a real need that is being met in varying degrees. Security, cost of communication link, and urgency are the factors that have determined the varying degrees with which a particular situation has been met.

The MTPT owes its development to the necessity to satisfy a need in this direction. The particular need was that in which a large quantity of information was to be retrieved from the magnetic tape file of a DATAmatic 10000 system and transmitted to a number of remote points. The action of retrieval and production of a fully edited paper tape was to be completely automatic. The function of the operator is restricted to that of activating a few switches and that of a monitor.

In developing the MTPT the following engineering objectives were maintained:

1. Use of machine aids wherever possible, in the production of wiring information.

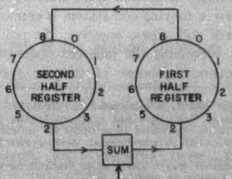

Fig. 11. Accumulator registers

2. Reliable and designable circuits.

3. A presentation of the logic such that a very limited knowledge of the logical designers techniques are required by the circuit and maintenance engineer.

4. The logical designer requires a very limited knowledge of the circuits in order to fully appreciate the restrictions placed upon the logic by the circuits.

An Analysis of a Polarized Electromagnetic Drive System and of Vibrator Drive Systems

R. STEWART NUNN
NONMEMBER AIEE

Synopsis: Conventional electromagnetic contact-drive systems suffer from the disadvantage that resonant oscillation cannot be obtained, and this is shown in the analysis included. A scheme which overcomes this defect by the use of a permanent magnet and a tuned drive circuit is described. The drive power efficiency is shown to be greatly increased or alternatively for a given power input greater amplitudes of oscillation are obtained.

MECHANICAL OSCILLATION may be obtained electromagnetically either from an a-c or a d-c supply and, it has been shown in a previous paper by the author,[1] when the power input exceeds a certain minimum the drive force obtained when using a moving-armature is greater than that obtained when a moving-coil system is employed. There still arises, however, the problem of overcoming the inherent nonresonant frequency response of the d-c system. The problem is not difficult to overcome in a-c systems, provided a supply having the appropriate frequency is available, but in d-c systems resonant conditions cannot be obtained under normal circumstances, as will be seen subsequently.

By the use of a permanent magnet in the magnetic circuit of the actuating coil, and a tuned circuit also, energy that would normally be expended in opposing the motion is utilized in assisting it. Thus the power required to maintain a given oscillation is reduced. Alternatively, for a given power input larger amplitudes of oscillation are obtained.

The drive power has to supply the iron and copper losses of the actuating coil as well as the loss resulting from the internal molecular friction of the oscillating member and that resulting from windage. Also ohmic losses caused by charge and discharge of the shunt capacitor have to be accounted for in the conventional system (discussed later). The elimination of this and the reduction of the iron and copper losses at low oscillating frequencies will therefore enable systems to be operated at high frequency with improved efficiencies. The need for improved efficiency becomes greater as oscillation frequency requirements increase, and also when the dissipation of power in the contacts is appreciable in high power contact-drive systems.

Contact-Drive Systems

In electromagnetic contact-drive systems, such as that shown in Fig. 1, oscillation is obtained by means of an actuating coil energized from a d-c supply through contacts. One of these contacts is attached to the oscillating member which is attracted by the flux from the actuating coil when energized, so as to open the contacts. When this has occurred the potential energy continues to be stored in the compliance of the oscillating member throughout the period of its attractive excursion and thereby establishes its return, and while the energy is progressively converted into kinetic energy the contacts reclose. Repetition of events thus occurs, and during the dwell period of the contacts (which is achieved by mounting them resiliently) energy is imparted to the system, enabling continuous oscillation to be obtained from a constant voltage source.

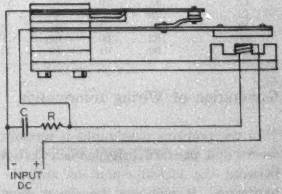

Fig. 1. D-c system to obtain continuous oscillation

Paper 60-201, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted May 7, 1959; made available for printing January 26, 1960.

R. STEWART NUNN is with the Ministry of Aviation, London, England.

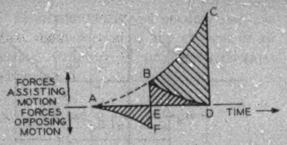

Fig. 2. Force-time diagram—conventional system

Unfortunately the derivation of the energy transferred to the mechanical system is not simply the total mechanical work done. During the first half of the closed period of the contacts it will be observed that the oscillating member is moving away from the force derived from the coil, and during the second half period it is moving towards the pole piece. Thus the net transference of energy to the system is the difference between the amounts of work done in each of these periods. That there is a balance of energy will be realized when the behavior of the coil inductance is taken into account. Not only does the coil flux establish the actuating force of the system, its time rate of change also resolves the gradual increase of force during the cycle, so that greater forces are manifested during the second half of the contact closed period than are manifested during the first. The force-time diagram in Fig. 2 will therefore indicate the unequal areas of half-contact-closed periods, area *BCD* representing the balance of energy necessary for oscillation.

If, therefore, the work done in opposing the motion of the oscillating member is reduced or eliminated there will be a greater transference of energy to the system, and improved drive-power efficiences will result.

This may be achieved by arranging the direction of the winding of the coil such that the flux emanating from it is opposed by the flux established by the permanent magnet, and therefore rendered inactive when the motion is against the coil force. When the motion is in the opposite direction the coil flux will be in the opposite direction (and therefore rendered active) if the coil shunt capacitance is tuned such that the waveforms as shown in Figs. 3 and 4(A) are obtained. Thus, compared with the conventional system a greater amplitude of oscillation is obtained, and this, moreover, is increased still further because of the fact that the energy that would normally be expended in opposing the motion is re-established [see Fig. 9(B)] such that it effectively boosts the active flux. It can be arranged that no energy such as that represented by area *AEF* (equal to area *DEB*) is expended, leaving the total coil energy (area *ACD*) available.

Fig. 3. Oscillograms of voltage waveform of tuned circuit

By referring to Figs. 4(A), (B), and (C) the sequence of events may be followed. If the coil resistance and iron losses are neglected, then when the drive contact is closed the induced voltage will be equal and opposite to the applied voltage. The rate of change of flux will be constant since the applied voltage is contant, so that the flux wave will be linear.

During the open period of the contacts the current (which is supplied by the coil shunt capacitance given by C^{dv}/dt) and the flux which is in phase with it will be zero at the reversed voltage peak *P*. When the voltage is zero the rate of change of flux will be zero since the voltage across the coil is given by $N^{d\phi}/dt \times 10^{-8}$. The flux will therefore reach a peak at these points, so that the waveform of flux will be an alternating one depending for its precise shape on the contact closure period. Thus an alternating wave of flux may be established from a d-c input by tuning the waveform of voltage, to that as shown in Figs. 3 and 4(A).

The alternating wave of flux is shown in Fig. 4(B) and it is seen that when the contacts close the flux derived from the coil is negative. It will also be observed that the oscillating member is moving away from the pole-piece, so that if the coil winding is in the direction such that the flux from it is opposed by the flux from the permanent magnet during the period *A* to *B*, the coil force opposing the motion may be reduced or eliminated. During the succeeding two quarter cycles, *B* to *C* and *C* to *D*, the flux derived from the coil is positive, so that it assists the motion (which is now towards the pole-piece) together with the reimbursed flux provided by the magnet. During the final quarter period *D* to *E* the flux is negative, but the oscillating member is moving away from the pole-piece, so that once again the permanent magnet neutralizes the coil-flux and it is not expended in opposing the motion.

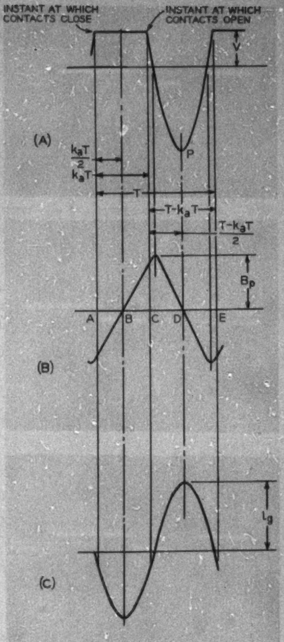

Fig. 4. Voltage, flux, and deflection diagrams

A—Voltage waveform
B—Flux waveform
C—Deflection

The effect of the permanent magnet therefore in an electromagnetic drive system using a tuned circuit, is to reverse energy derived from the coil that would be expended in opposing the motion to energy that is applied in assisting it. With the requisite strength of permanent magnet all the energy transferred to the mechanical system may be utilized to produce motion.

Analysis of the Motion Obtained

Consider first the conventional system in which the *C*, *R* leg in Fig. 1 is simply a spark suppression unit, and no permanent magnet is employed. The voltage waveform is as shown in the oscillograms Fig. 5. The flux waveform may then be taken to be as shown in Fig. 6(A); the

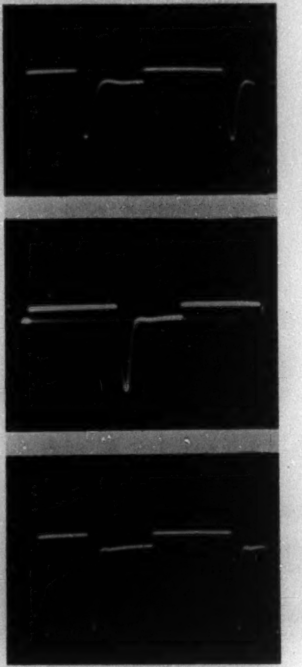

Fig. 5. **Oscillograms of voltage waveforms (various drive coils, conventional system)**

waveform of force will be as shown in Fig. 6(B), since the force F is given by

$$\frac{B^2A}{8\pi}\text{ dynes}$$

where

B = flux density in the air gap, gauss

A = cross-sectional area of the air gap, centimeter^2

Since the compliant and inertial forces set up by the drive contact on closure have little or no effect on the motion of the oscillating member, the waveform of force can be resolved into a series of harmonic waves, and accordingly the motion may be determined.

One has by Fourier's theorem

$$F=f(t)=a_0+\sum_{n=1}^{\infty}a_n\cos(nwt)+\sum_{n=1}^{\infty}\times b_n\sin(nwt)$$

and

$$F=\left\{\frac{2Bpt}{2\pi k_d}\right\}^2\frac{A}{8\pi}$$

where

$2B_p$ = the peak value of flux density attained

k_d = the closure period of the drive contact given by the ratio of

$$\frac{\text{time contact is closed per cycle}}{\text{time for the cycle}}$$

Since one wishes to examine the conditions for resonance by considering the phase displacement between force and deflection, reference will be made to peak values. The amplitude of oscillation occurs at the midpoint of the open and closed periods of the drive contact so that from Fig. 6(A) one obtains for $f(t)$

$$F=\left\{\frac{2Bp}{2\pi k_d}\right\}^2\{t+\pi k_d\}^2\frac{A}{8\pi}$$

The constant term

$$\frac{1}{2\pi}\int_0^{2\pi}f(t)dt$$

$$=\frac{Bp^2A}{16\pi^4k_d^2}\int_{-\pi k_d}^{\pi k_d}(t+\pi k_d)^2\,dt$$

$$=\frac{4Bp^2A}{3}\;k_d$$

The sine coefficients $\frac{1}{\pi}\int_{-\pi k_d}^{\pi k_d}f(t)\sin nt\,dt$

$$=\frac{Bp^2A}{8\pi^4k_d^2}\left\{\int_{-\pi k_d}^{k_d}(t+\pi k_d)^2\sin nt\,dt\right\}$$

$$=\frac{Bp^2A}{8\pi^4k_d^2}\left\{(2t+2\pi k_d)\frac{\sin nt}{n^2}-(t^2+2t\pi k_d+\pi k_d^2)\frac{\cos nt}{n}+\frac{2\cos nt}{n^3}\right\}_{-\pi k_d}^{\pi k_d}$$

$$=\frac{Bp^2A}{2\pi^3k_d}\left\{\frac{\sin[n\pi k_d]}{n^2}-\frac{\pi k_d\cos[n\pi k_d]}{n}\right\}$$

The cosine coefficients

$$\frac{1}{\pi}\int_{-\pi k_d}^{\pi k_d}f(t)\cos nt\,dt$$

$$=\frac{Bp^2A}{8\pi^4k_d^2}\left\{\int_{-\pi k_d}^{\pi k_d}(t+\pi k_d)^2\cos nt\,dt\right\}$$

$$=\frac{Bp^2A}{8\pi^4k_d^2}\left\{(t^2+2t\pi k_d+\pi^2k_d^2)\frac{\sin nt}{n}+(2t+2\pi k_d)\frac{\cos nt}{n^2}-\frac{2\sin nt}{n^3}\right\}_{-\pi k_d}^{\pi k_d}$$

$$=\frac{Bp^2A}{2\pi^3k_d}\left\{\frac{\pi k_d\sin[n\pi k_d]}{n}+\frac{\cos[n\pi k_d]}{n^2}-\frac{\sin[n\pi k_d]}{\pi k_d n^3}\right\}$$

As this is a rapidly converging series only the fundamental need be considered. Therefore the fundamental component of force producing oscillation will be

$$\frac{Bp^2A}{2\pi^3k_d}\left[\left\{\sin[\pi k_d]-\pi k_d\cos[\pi k_d]\right\}\sin nt+\left\{\left(\pi k_d-\frac{1}{\pi k_d}\right)\sin[\pi k_d]+\cos[\pi k_d]\right\}\cos\omega t\right]$$

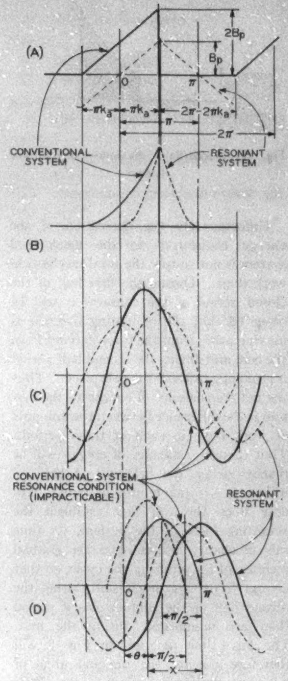

Fig. 6. Flux and force diagrams

A—Waveform of flux
B—Waveform of force
C—Fundamental harmonic components of force
D—Phase displacements between force and deflection

In order to be able to apply this to the determination of the motion obtained it is necessary to take into account the mass of the oscillating member as well as the mass of the armature. In the method first suggested by Lord Rayleigh and quoted by Timoschenko and Lessels[2] the kinetic energy of the oscillating member is determined by summation of the kinetic energy of every element of the member, from which a mass acting at the point of application of the drive force that is equivalent to the mass of the oscillating member is obtained. The mass of the member is normally small compared with the mass of the armature so that it makes little or no difference to the potential energy of deflection, but as stated by Timoschenko and Lessels the method is accurate even in cases where the mass of the oscillating member is equal to the mass of the armature.

From the theory of bending one has that the deflection of any element of an elastic structure of uniform section is given by

$$y=\frac{P}{EI}\left\{\frac{\text{le}\,x^2}{2}-\frac{x^3}{6}\right\}$$

where

x = any point along the length of the oscillating member measured from its root
le = total length from root
P = force acting
E = modulus of elasticity of the material
I = area moment of inertia of section

The deflection at the extremity of the elastic member is given by

$$\frac{P\,\text{le}^3}{3\,EI}$$

so that if V is the velocity of the armature at the point of application of the drive force (in this case at the extremity of the oscillating member) then the linear velocity of any element will be

$$\frac{P}{EI}\left\{\frac{\text{le}\,x^2}{2}-\frac{x^3}{6}\right\}\frac{V}{\dfrac{P\,\text{le}^3}{3EI}}$$

If q is the mass per unit length of the member its kinetic energy will be given by

$$\int_0^{\text{le}}\left\{\frac{3\,\text{le}\,x^2-x^3}{2\,\text{le}^3}\right\}^2\frac{V^2}{2}\,q\,dx$$

$$=\frac{33}{140}\,\text{le}\,q\,\frac{V^2}{2}$$

But le q is the total mass of the oscillating member, so that only 33/140 of it need be considered to be acting in addition to the mass of the armature. Let this mass equivalent and the mass of the armature equal M, then

$$M\frac{d^2y}{dt^2}+r\frac{dy}{dt}+Sy=\sqrt{H_s^2+H_c^2}\cos[wt-\theta]$$

where

r = viscous damping
S = stiffness of oscillating member
H_s = sine component of the fundamental harmonic of drive force
H_c = cosine component

The solution may be written

$$\frac{\sqrt{H_s^2+H_c^2}}{\sqrt{(S-\omega^2M)^2+r^2\omega^2}}\{\cos[\omega t-\theta-\psi]\}$$

to represent the motion after transient conditions have subsided

$$\psi=\tan^{-1}\frac{r}{\dfrac{S}{\omega}-\omega M}$$

and

$$\theta=\tan^{-1}\frac{H_s}{H_c}$$

Resonant conditions are obtained when the frequency of oscillation is equal to the undamped natural frequency, i.e.

$$\sqrt{\frac{S}{M}}=\omega \text{ and } \psi \text{ becomes 90 degrees}$$

As will be seen from Fig. 6(D) $\{\theta+\psi\}$ must always equal 180 degrees so that under conditions of resonance θ becomes 90 degrees also, so that H_c becomes zero, or

$$0=\{\pi^2k_d^2-1\}\sin[\pi k_d]+\pi k_d\cos[\pi k_d]$$

The solution is obtained when k_d is 0 and when k_d is 0.88 (approximately).

It is thus seen that under normal conditions resonant oscillation cannot be obtained in a conventional system. The relationship of phase angle with contact closure period is shown in Fig. 7.

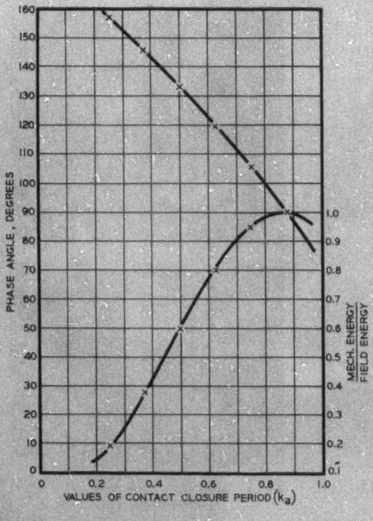

Fig. 7. Relationship of mechanical energy versus field energy and phase angle with various values of contact closure period

The system described in this paper can be analyzed in a similar manner. The waveform of force is shown in Fig. 6(B), the sine coefficient being

$$\frac{Bp^2A}{\pi^4}\left[\left\{\frac{1}{k_d}+\frac{1}{(1-k_d)}\right\}\pi\sin[\pi k_d]+\left\{\frac{1}{k_d^2}-\frac{1}{(1-k_d)^2}\right\}\cos[\pi k_d]-\frac{1}{k_d^2}-\frac{1}{(1-k_d)^2}\right]$$

and the cosine coefficient being

$$\frac{Bp^2A}{\pi^4}\left[\left\{\frac{1}{(1-k_d)^2}-\frac{1}{k_d^2}\right\}\sin[\pi k_d]+\left\{\frac{1}{k_d}+\frac{1}{(1-k_d)}\right\}\pi\cos[\pi k_d]\right]$$

When k_d is 1/2 the cosine coefficient is zero, so that resonant oscillation is obtained. If, however, the force is considered in its entirety, when k_d is 1/2 we almost have the classic case of a sinusoidal oscillation from a sinusoidal force. It will be observed that amplitudes greater than those obtained at resonance can be achieved, and moreover can be obtained at all practical values of contact closure periods whereas they can never be achieved at any value of closure period in the conventional system.

From the equation of motion of a sinusoidal system we obtain the amplitude of oscillation

$$=\frac{\text{Peak Harmonic Force}}{\sqrt{(S-\omega^2M)^2+\omega^2r^2}}$$

and w can be varied so as to obtain amplitudes greater than those obtained at resonance, so that

$$[(S-\omega^2M)^2+\omega^2r^2]$$

must be a minimum. This is when

$$\omega=\sqrt{\frac{S}{M}-\frac{r^2}{2M^2}}$$

Substituting this in the equation for amplitude of oscillation we obtain a maximum value attainable by the use of the resonant system:

$$=\frac{\text{Peak Harmonic Force}}{\sqrt{\left\{S-M\left(\frac{S}{M}-\frac{r^2}{2M^2}\right)\right\}^2+r^2\left\{\frac{S}{M}-\frac{r^2}{2M^2}\right\}}}$$

$$=\frac{\text{Peak Harmonic Force}}{2\pi\, r \text{ x True Natural Frequency}}$$

Energy Considerations

From Figs. (6A) and (B)

Actuating force throughout cycle=

$$\frac{A}{8\pi}\left\{\frac{2Bp}{2\pi k_d}\right\}^2\{t+\pi k_d\}^2$$

or

$$\frac{A}{8\pi}\left\{\frac{2Bp}{\frac{k_d}{f}}\right\}^2\left\{t+\frac{k_d}{2_f}\right\}^2$$

$$=\frac{Bp^2f^2A}{2\ \pi k_d^2}\left\{t+\frac{k_d}{2_f}\right\}^2$$

Assume sinusoidal oscillation is obtained, then

$$\text{deflection}=-\text{lg}_c\cos[\omega t]$$

Then the energy transferred to the mechanical system per cycle

$$=\frac{Bp^2f^2A}{2\pi\ k_d^2}\int_{-k_d/2f}^{k_d/2f}\left\{t+\frac{k_d}{2f}\right\}^2\text{lg}_c\,\omega\sin\omega t\,dt$$

$$=\frac{Bp^2A\ \text{lg}_c}{2\pi}\left\{\frac{\sin\ [\pi k_d]}{\pi k_d}-\cos\ [\pi k_d]\right\}$$

and this will be a maximum when

$$(\pi^2k_d^2-1)\sin[\pi k_d]+\pi k_d\cos[\pi k_d]=0$$

or when k_d is 0.88, i.e., the value of contact closure period necessary for resonance.

In the case of the resonant scheme, the energy transferred to the mechanical system.

$$=\frac{2Bp^2A\omega\,\text{lg}\,f^2}{\pi^2k_d^2}\int_0^{k_d/2f}t^2\sin\omega t\,dt+$$

$$\frac{Bp^2A\omega\,\text{lg}}{2\pi(1-k_d)^2}\int_{k_d/2f}^{1/2f}(1-2ft)^2\sin\omega t\,dt$$

$$=\frac{Bp^2A\ \text{lg}}{\pi^2}\Bigg[\left\{\frac{1}{k_d}+\frac{1}{(1-k_d)}\right\}\sin\ [\pi k_d]+$$

$$\left\{\frac{1}{\pi k_d^2}-\frac{1}{\pi(1-k_d)^2}\right\}\cos\ [\pi k_d]-$$

$$\frac{1}{\pi k_d^2}-\frac{1}{\pi(1-k_d)^2}\Bigg]$$

and when k_d is 1/2, this becomes

$$0.147\ Bp^2A\ \text{lg}$$

The energy transferred to the magnetic field

$$=\frac{2Bp^2f^2At^2}{\pi k_d^2}\{\text{lg}+\text{lg}\cos\omega t\}$$

and when k_d is 1/2 this is a maximum when $t=1/4f$, so that maximum field energy

$$=0.1595\ Bp^2\ A\ \text{lg}$$

and

$$\frac{\text{energy transferred to the mechanical system}}{\text{energy transferred to the magnetic field}}=92.3\%$$

In the case of the conventional system, the energy transferred to the magnetic field is given by

$$\frac{Bp^2\ A\ \text{lg}_cf^2}{2\pi\ k_d^2}\left\{t+\frac{k_d}{2f}\right\}^2\{1+\cos\ [\omega t]\}$$

and when k_d is 1/2 this is a maximum when it is approximately $0.2/f$ so that the maximum field energy

$$=0.1695\ Bp^2\ A\ \text{lg}_c$$

The energy transferred to the mechanical system when k_d is 1/2 equals

$$0.1015\ Bp^2A\ \text{lg}_c$$

so that

$$\frac{\text{energy transferred to the mechanical (conventional) system}}{\text{energy transferred to the field of the conventional system}}=59.8\%$$

The relationship between the energy transferred to the mechanical (conventional) system for all values of contact closure periods and the maximum energy transferred to the magnetic field of the conventional system is shown in Fig. 7.

Considering only the energy provided by the actuating coil in the resonant system when k_d is 1/2 the energy transferred to the magnetic field is given by

$$\frac{2\ Bp^2Af^2t^2}{\pi}\{\text{lg}+\text{lg}\cos\omega t\}$$

the maximum value of which

$$=0.04\ Bp^2\ A\ \text{lg}$$

so that

$$\frac{\text{energy of the field of the resonant system}}{\text{energy of the field of the conventional system}}=\frac{0.04\ \text{lg}}{0.1695\ \text{lg}_c}$$

The value of lg/lg_c can be evaluated from the coefficients of the fundamental harmonic of force, viz.,

$$\frac{\text{lg}}{\text{lg}_c}=\frac{1.46}{\sqrt{1+\left\{\frac{\pi}{2}-\frac{2}{\pi}\right\}^2}}=1.1$$

and since the energy of the field ∝ {current}²

$$\frac{\text{current in the resonant system}}{\text{current in the conventional system}}=\sqrt{\frac{0.04(1.1)}{0.1695}}=0.51$$

The flux may also be resolved into harmonic components in order to evaluate the iron losses of the systems.

From Fig. 6(A)

$$\text{Flux}=\frac{Bp}{\pi k_d}\{t+\pi k_d\}$$

the sine coefficient being

$$\frac{Bp}{\pi^2k_d}\int_{-\pi k_d}^{\pi k_d}(t+\pi k_d)\sin nt\,dt$$

from which the fundamental

$$=\frac{2Bp}{\pi^2k_d}\{\sin\ [\pi k_d]-\pi k_d\cos\ [\pi k_d]\}$$

Similarly the cosine coefficient

$$=\frac{Bp}{\pi^2k_d}\int_{-\pi k_d}^{\pi k_d}(t+\pi k_d)\cos nt\,dt$$

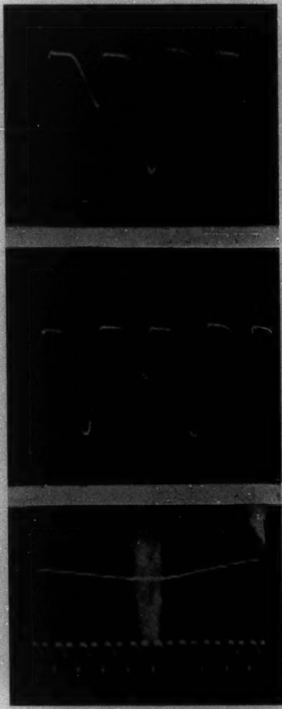

Fig. 8. Oscillograms of voltage waveforms (abnormal conditions)

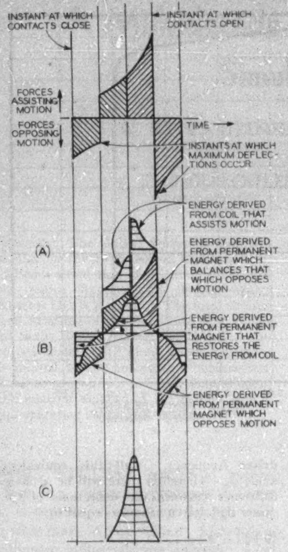

Fig. 9. Flux-time diagrams of

A—Permanent magnet
B—Combined coil and permanent magnet
C—Resultant

the fundamental being

$$\frac{Bp}{\pi^2 k_d}\{2\ \pi k_d \sin\ [\pi k_d]\}$$

When k_d is 1/2 one obtains for the peak harmonic flux a value of

$$\sqrt{\left(\frac{4Bp}{\pi^2}\right)^2+\left(\frac{2Bp}{\pi}\right)^2}=0.755\ Bp$$

In the case of the resonant scheme the flux is given by

$$\frac{Bpt}{\pi k_d}$$

so that the sine coefficient

$$=\frac{Bp}{\pi^2 k_d}\int_{-\pi k_d}^{\pi k_d} t \sin nt\ dt$$

the fundamental being

$$=\frac{Bp}{\pi^2 k_d}\{2 \sin\ [\pi k_d]-2\ \pi k_d \cos\ [\pi k_d]\}$$

When k_d is 1/2 this becomes

$$\frac{4Bp}{\pi^2}=0.406\ Bp$$

Considering the case when Bp is 2 kilogauss we have a peak value of flux of 1,510 gauss in the case of the conventional system and a peak value of 812 gauss in the case of the resonant scheme. The watts loss per pound at 500 cps (cycles per second) is found (in manufacturer's data for a particular grade of iron) to be 0.5 in the case of the conventional system and 0.18 in the case of the resonant scheme. At a frequency of 200 cps the values are found to be 0.14 and 0.06 respectively.

Additional losses occur in the conventional system because of the surge of current flowing through the coil resistance that is necessary to charge the shunt capacitor to the voltage of the supply, when the contacts close; see Fig. 5. With the tuning of the voltage waveform in the proposed resonant scheme this does not occur since the oscillatory voltage attains the same voltage as that of the supply when the contacts close.

Conclusions

It will be evident that the tuning of the voltage waveform as proposed without the use of a permanent magnet will have unsatisfactory results. The effect can be examined as in the following.

Consider the half-cycle: $-kd/2f$ to $kd/2f$; the flux is given by

$$\frac{2Bpf}{k_d}\,t$$

and the force

$$=\frac{4Bp^2f^2t^2}{k_d^2}\,\frac{A}{8\pi}$$

The mechanical energy derived during the half-cycle will be

$$=\frac{4Bp^2f^2 \lg\omega A}{k_d^2\pi}\int_{-k_d/2f}^{k_d/2f} t^2 \sin \omega t\ dt$$

$$=\frac{Bp^2f^2\omega \lg A}{2k_d^2\pi}\left[-\frac{t^2 \cos \omega t}{\omega}+\frac{2\,t \sin \omega t}{\omega^2}+\frac{2 \cos \omega t}{\omega^3}\right]_{-k_d/2}^{k_d/2}$$

and this will be found to be zero whatever vaue of contact closure period is employed.

It is therefore observed that only a small degree of asymmetry of the flux wave will enable oscillation to be obtained but the system will be very sensitive resulting in instability. This is indicated by the abnormal voltage waveforms shown in the oscillograms Fig. 8.

The use of a permanent magnet and tuned waveform as described effects a phase shift of the drive force, so that compared with the conventional system greater amplitudes of oscillation may be obtained (in some cases it will be doubled) for the same power input, or alternatively for the same amplitude the power input may be reduced (in some cases halved). Furthermore amplitudes exceeding those obtained at resonance can be achieved for all practical values of contact closure period whereas this can never be achieved in the conventional system.

The strength of the permanent magnet need have no critical value only in so far as that necessary to conserve all the counter-motion components of force. All the energy derived from the coil will be utilized in producing motion at this value, beyond which, very little further energy is derived, the energy expended by the permanent magnet in assisting the motion is counterbalanced by approximately the same amount opposing the motion. This is illustrated in Figs. 9(A) and 9(B), which serve to show how the coil flux is reimbursed. The maximum energy derived is shown in Fig. 9(C). It will therefore be observed that the strength of the permanent magnet can be increased further without upsetting the operation, and so realize greater starting forces. In some cases it may be preferable to increase the total coil input by the adoption of two coils connected in series, still using permanent magnets and tuned waveform. Two such arrangements are shown in Figs. 10 and 11. The coils are wound differentially so that when one is attracting the armature the other is restrained by the opposing permanent magnet flux. This double acting (pull-pull) arrangement also has the advantage that any external force (such as high values of

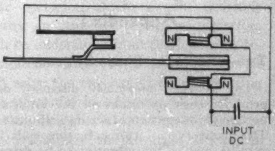

Fig. 10. Double acting drive system (Cantilever)

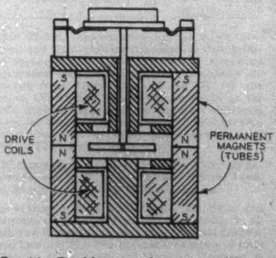

Fig. 11. Double acting drive system (Plunger)

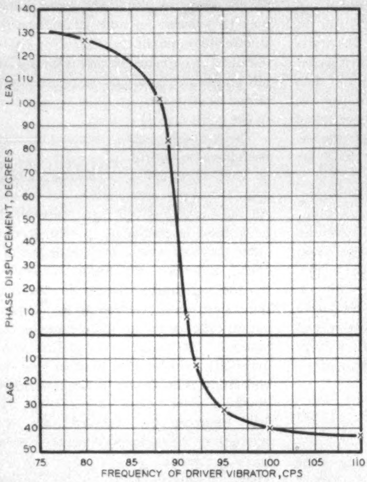

Fig. 12 (left). Phase displacement between the deflections obtained when one vibrator is used to drive another. Determined by calculation

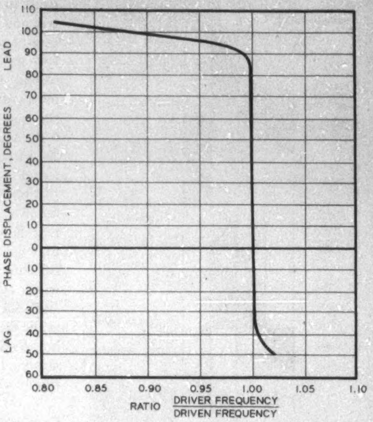

Fig. 13 (right). Phase displacement between the deflections obtained when one vibrator is used to drive another. Determined experimentally

acceleration) has a symmetrical disturbing influence on the system. Large starting forces will be required under such circumstances.

By tuning the waveform as described the oscillatory voltage spans the whole of the open period of the contacts so that the reversed voltage peak will be smaller than that obtained in the conventional system, thus insulating and radio interference problems are simplified.

Appendix I

Two- and Three-Phase Systems

The systems[1] previously discussed depend for their operation on the interconnection of the contacts of separate vibrators. The connection of two actuating coils in parallel enables the vibrators to be driven by the drive contact of one of them, but it gives rise to a two-phase oscillation and an explanation of this may be obtained by further consideration of the equation of motion y

$$=\frac{\sqrt{H_s^2+H_c^2}}{\sqrt{(S-\omega^2M)^2+r^2w^2}}\cos\,[wt-\theta-\psi]$$

where

$$\psi=\tan^{-1}\frac{r}{\frac{S}{\omega}-\omega M}$$

and

$$\theta=\tan^{-1}\frac{H_s}{H_c}$$

It is seen from this that if the mechanical characteristics of the two oscillating members are not identical, the frequency of oscillation will be governed by the characteristics of the driver vibrator and that since θ is the same for both vibrators when they are operated by their own drive contacts with equal contact closure periods the equivalent angle ψ for the driven vibrator must vary from that of the driver to satisfy the condition of operation at the driver frequency. Call this equivalent angle ψ_1. Therefore there will be a phase difference between the deflections of the driver and driven vibrators equal to

$$\{\theta+\psi\}-\{\theta+\psi_1\}$$

$$=180-\{\theta+\psi_1\}$$

A complete range of values can be evaluated as has been undertaken in Fig. 12 for a ratio of contact closure period of 0.5. Fig. 13 illustrates a similar relationship but determined experimentally. Thus, it will be observed that the graph has a very steep portion indicating that only a small difference in the mechanical characteristics of the driver and driven oscillating members is required to cause the phase displacement to be 90-degree lead. Furthermore complete transition from lagging to leading phase displacement can be achieved with small change in operating frequency.

Synopsis: The United States Government exhibit for the 1958 Geneva Conference included a simulation of the main portion of the entire Experimental Boiling Water Reactor (EBWR) plant. The total simulation consisted of two operating panels similar to the EBWR control panels and an animated model of the plant. This discussion is limited to the computer technique utilized to accomplish a linear simulation of the neutron kinetics of the reactor over a full operating range of 8 decades.

ol. 79
t. 1
960

THE NUCLEAR reactor is unique among industrial processes because it is capable of operating through such a wide range of flux values. Although a common industrial-type process might be capable of operating only through a range of 100 to 1, a nuclear reactor can easily operate through a range of 100,000,000 to 1, or 8 decades. This fact is responsible for the great difficulty that exists in adequately simulating the reactor throughout its entire operating range by means of analog computing equipment.

There are several possible methods available for solving the neutron kinetic equations of the reactor. For many applications, adequate results may be obtained by solving the linear form of the kinetic equations with a simple linear simulation.[1-7] This method of solution is limited to a maximum range of $2^1/_2$ to 3 decades by the characteristics of the analog equipment involved. Although this operating range is entirely adequate for many problems, the operation of EBWR covers a range of 8 decades which could not be performed by a simple linear simulation.

One possible method of solving the kinetic equations involves dividing the equations by the factor $1/n$, the inverse of the neutron flux signal, and solving for $(1/n)\,dn/dt$, the inverse period. This result is then integrated to obtain the natural logarithm of the output.[8] This method, which can successfully cover a range of 6 to 8 decades, is ideal for conducting short transient studies, such as start-up accidents, where the computer is run only for a short period of time and where a linear output signal is not required.

Several basic limitations, however, are present in this method. First, it is often necessary to obtain a linear flux signal. This becomes extremely difficult if a range of 8 decades is to be covered. Second, the analog computer circuit requires the use of an open-loop integrator. This is undesirable for a real time training simulator that may be run for many hours. A further limitation results because the computer circuit requires that a multichannel multiplier be placed in a high gain amplifier loop. When relatively short values of neutron mean lifetime are used, the loop gain becomes great enough to make a servomultiplier loop somewhat unstable. An electronic-type multiplier would perform satisfactorily but the circuit would require a 3-channel multiplier for even a 2-group approximation.

One additional method makes use of two linear simulators, each covering specified portions of the reactor output range. While one of the simulators is in the operating mode, the other is in the reset mode where it is constantly receiving its initial conditions from the operating simulator. When the first simulator reaches the end of its operating range, a switch-over is made and the two simulators interchange their modes of operation. The second simulator assumes the computing mode while the first simulator goes into the reset condition.

This switching may be repeated as often as necessary to permit the two simulators to cover the full range of the nuclear reactor output which may be 8 decades or more. The principle limitation of this method is the rather complex logic circuit and relay system required to perform the switching operation. However, for the simulation of the EBWR power plant, it was necessary to provide a linear output signal throughout the entire range of 8 decades. The problems associated with providing a linear signal from the logarithmic simulator, made this 2-channel simulator method the most desirable. Before considering the details of the 2-channel simulator, it will be helpful to describe briefly the operation of a simple linear simulator.

Linear Simulator

The dynamic response of many nuclear reactors can be described by the following set of differential equations which relate neutron flux and total reactivity.

$$\frac{dn}{dt}=\frac{\delta K n}{\ell^*}-\frac{\beta n}{\ell^*}+\sum_{i=1}^{n}\lambda_i C_i+S \tag{1}$$

$$\frac{dC_i}{dt}=-\lambda_i C_i+\frac{\beta_i n}{\ell^*} \tag{2}$$

where

n = thermal neutron density, neutrons/cm (per centimeter)^3
δK = reactivity $=(k_{eff}-1)/k_{eff}$
ℓ^* = mean effective lifetime of neutron in finite reactor, seconds
λ_i = decay constant, sec^{-1}
C_i = delayed neutron concentration of ith group
β_i = fraction of prompt neutrons delayed by ith group
$\beta=\Sigma\beta_i$
S = neutron source

Since the derivation and interpretation of these familiar equations has been covered in great detail elsewhere, no attempt will be made to explain them in this paper. It is sufficient for us to be able to construct an analog computer circuit that will properly obey these nuclear kinetic equations. This is done in Fig. 1 which shows a computer circuit for solving a 2-delay group approximation. The operation of the circuit, which is drawn in standard computer notation, can be understood from the following description. The two integrators on the left solve the two equations representing the effect of delayed neutrons.

Assuming that a signal proportional to $-n$ is available, the output of each of the integrators will be $(\ell^*\lambda_1/\beta_1)\,C_1$ and $(\ell^*\lambda_2/\beta_2)C_2$ respectively. The appropriate values of λ for the two groups are indicated by the coefficient potentiometer on the

diagram. These delayed neutron signals are modified by the appropriate gain factors β_1/ℓ^* and β_2/ℓ^* to give signals proportional to $\lambda_1 C_1$ and $\lambda_2 C_2$. These signals, together with signals proportional to $-\beta n/\ell^*\ \delta K n$, and a source term S are then fed to an integrator which solves equation 1 and gives an output signal $-n$. Since this was the initial assumption, the circuit will correctly solve the desired equations. The sign change at the left of the circuit is necessary to provide both positive and negative signals to the servo-multiplier so that the product of δK and n may be obtained for both positive and negative values of reactivity.

The computer circuit shown in Fig. 1 requires an operational amplifier for each of the two delay groups shown because the appropriate delay equations are solved actively rather than by the more common passive method. This has been done so that when this circuit is extended to a dual channel simulator, the appropriate initial condition may be transferred between computers. If the passive method were used, it would be extremely difficult to charge one lag circuit from the corresponding one in the second computer.

Since the active method of simulation requires the use of an amplifier for each group of delayed neutrons, it was decided to use a 2-group approximation rather than the six groups that are actually present.

For the EBWR simulation the following constants were used:

$$\begin{array}{ll} \lambda_1 = 0.275\ \text{sec}^{-1} & \beta_1 = 0.0053 \\ \lambda_2 = 0.0263\ \text{sec}^{-1} & \underline{\beta_2 = 0.0020} \\ \ell^* = 6\times 10^{-6} & \beta = 0.0073 \end{array}$$

It was felt that this 2-group approximation gives a sufficiently accurate result to justify the reduction in computing equipment made possible by its use.

Description of Multidecade Simulator

The multidecade simulator incorporates two complete single-channel linear computers such as the one described in Fig. 1. One of the two computers is always in the operating or computing mode, while the other is in the reset mode, receiving its initial conditions from the operating computer. The technique by which this is accomplished is shown in Fig. 2. Here only the final integrator and sign changer of each computer is shown but similar circuitry is used for the two delayed neutron integrators.

Each integrator has two relays asso-

ciated with it, the *A* and the *B* relay. When the *A* relay is energized all input resistors are connected to the integrator and the circuit computes in the usual manner. When the *A* relay is de-energized, however, the summing junction of the integrator is transferred to a resistance network consisting of two input resistors, selected by the *B* relay, and a feedback resistor. A signal applied to the input lead of this network charges the feedback capacitor to a voltage proportional to the input signal and the ratio of the feedback to the input resistance. There are time lags associated with this charging process of 0.01 and 1.0 second for the final and delayed neutron integrators respectively which have essentially a negligible effect upon the performance of the computers.

Referring to Fig. 2, it can be seen that when relay *1A* is de-energized, computer 1 receives its initial conditions from computer 2. Likewise, when relay *2A* is de-energized, computer 2 receives its initial conditions from computer 1. Close inspection of the figure will reveal that the computer signals are arranged to be of opposite polarity. This is necessary because a signal reversal occurs in each computer amplifier. Therefore, $-n_1$ must be used as the initial condition signal for n_2 and, in a corresponding manner, n_2 must be used as the initial condition signal for $-n_1$.

In order that the two computers will be capable of simulating both increasing and decreasing flux signals, it is necessary for the computer that is in the reset mode to follow at an output voltage of either 1/10, or 10 times the output of the operating computer. When one computer reaches the top of its operating range, the other computer must be ready to operate with an output voltage that is lower by a factor of 10. In a similar fashion, when one computer reaches the bottom of its operating range, the other computer must be ready to operate with an output voltage that is higher by a factor of 10. These two conditions are provided by the action of the *B* relays.

When the *B* relay is energized, the ratio of the resistance network is 1/10, and the reset computer follows at a factor of 1/10 below the operating computer. When the *B* relay is de-energized, the ratio of resistance is 1/0.1, and the reset computer follows at a factor of 10 above the operating computer.

As a result of selecting these ratios, each of the computers is restricted to operate over a range of 1 decade. The remainder of the useful operating range of 3 decades is required to insure that the proper initial conditions are produced. If a choice had been made to restrict the simulation to cases where the power was only increasing, each computer could operate satisfactorily through a range of 2 decades. However, it was felt to be extremely important to be able to reduce as well as increase power level.

We have seen how the two linear computers are arranged to alternately compute and follow throughout the full range of the simulation. Since each computer will operate for 1 decade it is convenient to assign computer 1 to the odd-numbered decades and computer 2 to the even-numbered decades. It is then necessary to provide a means of control so that a usable output signal may be obtained from the two computers. First, an additional sign changer is required to provide neutron signals of the same polarity from both of the computers. This additional sign changer is placed in the output of computer 2 to give the output $+n_2$. When output signals of the same polarity are obtained they are then fed to the logic circuit and the output switching circuit.

The logic circuit determines the operation of the two computers. It has as its outputs the *A* and *B* relays that control the reset and compute modes and a bidirectional stepping switch which selects the decade that is being simulated.

Vol.
Pt. 1
1960

When the limit of 1 decade is reached the switch will be stepped up or down to reach the desired decade. A complete description of the logic circuit will be given in the next section.

The output signals are also supplied to the output switching circuit. Each of the various decades of the simulators operating range are represented by the same voltage range in the computers. In order to obtain a full 8-decade linear output signal, it is necessary to switch the output signal lead alternately to the computer that is operating. It is also necessary to insert the proper scale factor for the decade involved. When operating in decade 8 for example, the output is directly connected to computer 2. In decade 7, however, the output lead is connected to computer 1 through a gain factor of 1/10. Similarly in decade 6, the output is connected to computer 2 through a gain factor of 1/100. This output switching process converts this combined analog-digital output signal of the two computers into a continuous analog signal. Only the output switch for the power simulation is shown in Fig. 2; however, similar switching arrangements are used for the outputs to the linear N and log N recording channels.

A further study of Fig. 2 will show that the magnitude of the source term S is modified by the position of the stepping switch. This is necessary, since each decade of the simulation represents many different neutron levels by the same voltage ranges. Therefore, it is necessary to represent a constant neutron source term by a varying voltage. The strength of the source is reduced by a factor of 10 for each decade the simulator is operating above the source signal. Since the two computers produce signals of opposite polarity, a sign changer is required to produce source signals of opposite polarities. The source level is set equal to zero after the first 3 decades of operation.

In this section we have described how the two individual computers are operated together to produce a common output signal over a range of 8 decades as a function of the input reactivity signal δK. The next section will describe how the logic circuit selects the proper decade of operation.

Logic Circuit

The basic operation of the two computers that make up the multidecade simulator is controlled by the logic circuit shown in Fig. 3. As previously stated, in order that the simulator can be capable of both increasing or decreasing power level, the ranges during which each computer operates is restricted to 1 decade. A convenient voltage selection for the operating range is from 2 volts to 30 volts. The remainder of the useful computer output range is reserved for the reset mode where the proper initial conditions are inserted.

When a computer in the operating mode reaches a level of 30 volts, the stepping switch is advanced one position causing the alternate computer to begin operating at a level of 3 volts. This process can be repeated over and over again. When an operating computer reaches a level of 2 volts, the stepping switch is stepped down one position causing the alternate computer to begin operating at a level of 20 volts. This process may also be repeated throughout the range of the simulation.

The condition of the computer in the reset mode is controlled from the voltage level of the operating computer. When the voltage of the operating computer exceeds 10 volts, the reset computer is prepared to follow an up step and therefore is following a voltage that is 1/10 the output of the operating computer. When the voltage of the operating computer becomes less than 9 volts, the reset computer is then prepared to follow a down step and therefore follows at a voltage that is 10 times the output of the operating computer. If these basic rules of operation are obeyed by the logic circuit, the two computers will function correctly throughout their operating range. Since it is important to determine accurately the voltage level at which to change the computer's operating modes, several comparator circuits, commonly used in analog computer work, are incorporated in the logic unit. The comparator consists of a high gain operational amplifier connected with two or more input resistors but with no feedback resistor. The output voltage of the amplifier will then flip-flop its polarity as the sign of the input signal changes. A diode connected between the amplifier output and summing junction restricts the output voltage to one polarity. The circuit then gives an output voltage of either 0 or 100 volts as the input signal passes through the input reference voltage.

If the output of the amplifier is then connected to a relay coil, the relay will be energized by the specified input condition. For example, the lowest of the four comparators shown at the left of Fig. 3 is connected so that the relay *E* energizes when the input drops below 2 volts. The comparator directly above is connected so that relay *D* energizes when the input increases above 30 volts. Since the amplifiers have a very high gain, the exact point of switching is determined by the input resistors and input voltages and is relatively independent of relay characteristics.

The relay circuit shown in Fig. 3 performs just the operations that were stated at the beginning of this section. When n_1 is greater than 10 volts, relay *2B* is energized by the comparator circuit. The additional 1-volt signal carried over a normally open contact of *2B* prevents the relay from dropping out until n_1 is less than +9 volts. The second comparator circuit performs a similar function on relay *1B* as input n_2 changes value.

The input signal to the lower two comparators is broken over normally open contacts of *1C* and *2C*. These relays are arranged to repeat the position of the operate-reset relays, *1A* and *2A*. Their circuits, however, include a normally closed contact which prevents both *C* relays from being energized when both *1A* and *2A* are energized. This is important since, at the time of a switch-over, it is necessary to have both computers in the operate mode and correspondingly both *1A* and *2A* energized, for a brief instant to insure a continuous output signal.

By means of the *C* relay network, the lower two comparators are connected to the computer in the operate mode. The third comparator circuit is energized when the input exceeds 30 volts, and the fourth comparator circuit is energized when the input is less than 2 volts. If the conditions imposed by the network in series with the relay coils are met, then the up and down stepping coils respectively of the stepping switch can be energized. These conditions are simply that for an up step the output of the following computer must be less than 9 volts, and for a down step the output of the following computer must be greater than 10 volts. This insures that the *B* relays have had time to insert the proper initial conditions. Normally, closed contacts are placed in series with the open contacts in the stepping switch circuit to prevent both coils from being energized at once in the event of an equipment failure.

The remainder of the relay circuit shows how the *2A* and *1A* relays are energized at the even and odd decade positions of the stepping switch. The contacts in the holding path of the *1A* and *2A* relays insure that one relay cannot drop out until the other has been energized.

The operation of the relay logic circuit and the complete simulation can be best understood by referring to Fig. 4, the relay sequence chart. The upper half of the figure indicates typical analog voltages that might be present in the computers while the lower half shows the condition of the various relays corresponding to the analog voltages. A heavy line indicates that the relay is energized.

Starting at the left of the figure, assume that computer 1 is operating at a level of 10 volts and that computer 2 is following at a level of 1 volt. At this point relays *1A*, *1C*, and *2B* are energized; relays *1A* and *1C* energized indicating that computer 1 is operating, and *2B* energized indicating that computer 1 has an output of 10 volts or more. As a positive reactivity input is supplied to the simulator, the output begins to increase in an exponential fashion. When the output of computer 1 reaches 30 volts, the comparator circuit fed through *1C* energizes the *D* relay and causes the stepping switch to advance position. This causes *2A* to energize, *1A* to drop out, *1C* to drop out, *D* to drop out, and *2C* to energize. Computer 2 is now operating and computer 1 following at a voltage that is 10 times the output of computer 2.

When the output of computer 2 exceeds 10 volts *1B* is energized, causing the output of computer 1 to follow at 1/10 the amount of computer 2. When computer 1 drops to 1 volt, relay *2B* drops out. The simulator is now ready to step up in a similar manner except this time computer 2 is connected to the comparator circuit through relay *2C*. When computer 2 reaches 30 volts the process repeats and the stepping switch is advanced another position.

This now leaves computer 1 operating at an output of 3 volts. If it is now decided to reduce power by inserting a negative reactivity signal into the simulator, the output voltage will begin to fall. When the output of computer 1 falls below 2 volts relay *E* will energize, causing the stepping switch to step down and placing computer 2 in operate at an output of 20 volts. During this change of direction computer 2 has remained at a voltage of 10 times computer 1 since the output voltage of computer 1 never exceeded 10 volts.

When the output of computer 2 falls below 9 volts *1B* will drop out, causing the output of computer 1 to follow at 10 times the output of computer 2. Relay *2B* then energizes, since the output of computer 1 is greater than 10 volts. Computer 1 is now ready to begin operating when the level of computer 2 falls below 2 volts.

It can be seen from Fig. 4 that this up or down switching process can continue for as many decades as is desired within the range of the stepping switch. The EBWR simulator used 8 switch positions corresponding to 8 decades of operation, but this could have been increased, if necessary. When the top of the range is reached, it is simply necessary to open the circuit to the up coil of the stepping switch to prevent further switching. The presence of the source term prevents the output of the simulator from decreasing below the lower end of the operating range.

Conclusions

The dynamic responses of the simulator closely approximate the actual performance of EBWR. Transients do occur in output during computer switching. The transients are larger when the switching is in the down direction than in the up direction because of the time constant associated with charging the delay neutron integrators to the correct initial conditions. However, these transients did not detract from the performance of the simulator since the characteristics of the two computers were closely matched to minimize any output offset.

A Dual-Channel Reactor Protection System for Nuclear Power Plants

ALLEN S. BARTU
ASSOCIATE MEMBER AIEE

Synopsis: A dual-channel reactor protection system similar to the one that was developed for the Dresden Nuclear Power Station is described. This protection system utilizes commercially available components in coincidence circuits to achieve the system reliability that is required for power plant service.

THE FUNCTION of the reactor protection system is to prevent the reactor from operating in a manner that is dangerous to itself or its environment, without jeopardizing its output at any time when it is operating safely.

In a nuclear power plant, one is faced with the marriage of two opposing philosophies. Traditionally, reactor protection has been designed to shut the reactor down if there is any doubt about plant safety. Power plant protection, however, has traditionally been designed to keep the plant running until it is definitely established that a dangerous condition exists. Both operating philosophies are well founded and the reactor protection system for a nuclear power plant must satisfy the basic requirements that led to both of these opposing philosophies.

During the design of the Dresden Nuclear Power Station, a dual-channel reactor protection system was developed. The system described herein is essentially a generalization of that design and is believed to be applicable to many types of nuclear power plants.
